## Abstract

We perform numerical experiments to study the Lyapunov spectra of dynamical systems associated with the Navier–Stokes (NS) equation in two spatial dimensions truncated over the Fourier basis. Recently new equations, called GNS equations, have been introduced and conjectured to be equivalent to the NS equations at large Reynolds numbers. The Lyapunov spectra of the NS and of the corresponding GNS systems overlap, adding evidence in favor of the conjectured equivalence already studied and partially extended in previous papers. We make use of the Lyapunov spectra to study a fluctuation relation which had been proposed to extend the “fluctuation theorem” to strongly dissipative systems. Preliminary results towards the formulation of a local version of the fluctuation formula are also presented.

## 1 Introduction

The idea of viewing turbulent fluid motions as trajectories in the phase space of a chaotic dynamical system is a long standing one. In particular, treating

turbulence in terms of invariant probability distributions on the phase space of the dynamical system given by the Navier-Stokes (NS) equation for a fluid, and asserting that the distributions ought to have special properties, is an idea which dates back to the early 1960's: it has been formalized a little later, see[1].<sup>1</sup>

Mathematical and numerical studies have been performed, at first for the purpose of relating fluid dynamical parameters, such as the Reynolds number or the amplitude of external forcing, to the fractal dimension of the attractor<sup>2</sup>. In this way the onset of turbulence has been quite well understood, along with the discovery that the relevant physical phenomena are far more interesting and complex than previously anticipated, see[3,4,5,6,7].

However, understanding developed turbulence remains a most challenging problem and it is not clear how to use the basic ideas of Lorenz, Ruelle and Takens in this context. The approach to the analysis is very often based on numerical experiments in which simulations of reduced models of turbulence are considered. For instance the shell models of Yamada and Okhitani [8,9,10] have been studied in great detail with the aim of finding or checking connections between Lyapunov spectra and the turbulent cascade.

Another viewpoint [11,12] stems from the well known fact that macroscopic irreversibility of particle systems can be obtained from microscopic reversible dynamics, provided the ratios between the microscopic and the macroscopic

---

<sup>1</sup> Quoting [2], "It is widely accepted that the statistical properties of a turbulent flow can be described by a dynamical evolution on a strange attractor in a high-dimensional phase space. An important characterization of the ergodic properties of the attractor is given by the Lyapunov spectrum."

<sup>2</sup> It is important, when discussing fractality, to distinguish between *attractor* and *attracting set*. An attracting set is a *closed set* such that all points in its vicinity get as close as one wants to the set as time tends to infinity and, *furthermore*, such that none of its closed subsets have the same property. The notion of attractor, that none of its closed subsets have the same property. The notion of attractor is associated with a method of choice of initial data in the vicinity of an attracting set. Suppose that the data are randomly selected with a distribution  $\mu_0$  and, with  $\mu_0$ -probability 1, their asymptotic motion is described by a probability distribution  $\mu$  on the attracting set, in the sense that time averages can be obtained simply by integration with respect to  $\mu$ . Then, *any* subset of the attracting set with  $\mu$ -probability 1 *and* smallest Hausdorff dimension is called "attractor" for the random choices with distribution  $\mu_0$ , and  $\mu$  is called the *statistics of  $\mu_0$* . Quite commonly, the attracting set is not fractal, and it might even coincide with the whole phase space, while the attractor for (some)  $\mu_0$  is fractal and with dimension lower than that of the attracting set. We recall that the special statistics generated on an attracting set from data randomly chosen with a probability distribution  $\mu_0$  absolutely continuous with respect to the volume is called a "*SRB distribution*", which is usually unique: in this paper we shall, as usual, only consider the SRB statistics.

time and length scales are sufficiently large. In that case, in fact, the microscopic reversible equations of motion are “equivalent” to dissipative equations of motion at the macroscopic level.

Assuming that forced turbulence is described by the (irreversible) NS equation, a different (reversible) equation called the “Gaussian Navier Stokes”, or GNS, equation was proposed to describe the same physical phenomena [11,12]. In the GNS equation the usual viscosity constant is replaced by a fluctuating term, which makes the equation itself *time reversal invariant* and keeps the total energy exactly constant. Equivalence should occur when the constant energy of the GNS evolution equals the average energy in the NS evolution provided the Reynolds number is large: in a way which is similar to the equivalence between microcanonical and canonical ensembles in statistical mechanics[13], with the large volume limit replaced by the limit of large Reynolds number  $R$ . The conjecture states that the forward time statistics of the NS and of the GNS models of the same fluid are the same, for what concerns “local observables”, *i.e.* for the time averages of functions of the velocity field which depend only on a small number of its Fourier components physically corresponding to observables on the inertial scale.

The idea, if correct, could be used to analyze phenomena which would not be easily understood in terms of the NS equation. For instance, time reversal invariance and chaoticity of the GNS dynamics imply that the fluctuations of certain quantities verify a relation (cf. Ref.[14]), here referred to as “fluctuation relation” (FR), which might eventually be amenable to experimental verification as attempted in Refs. [15,16]. It should be remarked that the possibility of using several different representations of the statistical properties of a turbulent fluid flow, which result equivalent from a practical point of view, was considered already in previous works, see, e.g. Refs.[17,18,19], and is still under investigation [20].

Of course despite the expected equivalence, the NS and GNS representations of a turbulent fluid remain different, similarly to the microcanonical and the canonical ensembles descriptions of equilibrium statistical mechanics: although “equivalent in the thermodynamic limit” they differ in many respects (*e.g.* in the distribution of fluctuations of the total energy).

## 2 NS and GNS equations. Aims of our analysis.

Suppose that the side of the periodic cell is  $L$ , and that the forcing term  $\mathbf{f}$  is the product of a dimensional parameter  $F$  times a fixed function. We shall suppose the Fourier components  $F_{\mathbf{k}}$  to have modulus 1 and, usually, to vanish

for all but one value of  $\mathbf{k}$ .<sup>3</sup> Then, in the NS case with viscosity  $\nu$ , we define the *Reynolds number*  $R$  to be

$$R^2 = FL^3\nu^{-2}, \quad \text{or} \quad R = \nu^{-1}\sqrt{FL^3}. \quad (1)$$

and we shall consider the NS equations in dimensionless form. Here, the lengths are measured in units of  $L/2\pi$  and time in units of  $L^2/\nu$ , so that the change of variables  $\mathbf{u}(x, t) = V\mathbf{u}^g(\mathbf{x}/L, Ct)$  with  $V = FL^2/\nu, C = \nu/L^2$ , yields (re-defining simply by  $\mathbf{u}$  the dimensionless field  $\mathbf{u}^g$  for notational convenience) the *dimensionless NS equations*

$$\dot{\mathbf{u}} + R^2(\mathbf{u} \cdot \partial)\mathbf{u} = \Delta\mathbf{u} + \mathbf{f} - \partial p, \quad \partial \cdot \mathbf{u} = 0 \quad (2)$$

with  $\mathbf{u}$  periodic in the position coordinates with period  $2\pi$  and *divergenceless* (*i.e.*  $\mathbf{u}$  represents an incompressible flow). Correspondingly, the GNS equations will be defined by

$$\dot{\mathbf{u}} + R^2(\mathbf{u} \cdot \partial)\mathbf{u} = \alpha \Delta\mathbf{u} + \mathbf{f} - \partial p, \quad \partial \cdot \mathbf{u} = 0 \quad (3)$$

where  $R$  is a free parameter and  $\alpha$  is defined so that the solutions of the equation (3) conserve  $Q_0 = \int \mathbf{u}^2 d\mathbf{x}$ , *i.e.* twice the total kinetic energy.

In order to compare motions that the GNS equations generate with (suitably selected) motions of the NS fluid, the constant  $Q_0$  has to be chosen. For a given  $R$  and taking as reference the NS equation, we call  $\langle Q_0 \rangle$  the infinite time average of  $Q_0$  produced by the NS evolution. We shall compare, according to the analysis of [21,22], the solutions of the NS equation with those of the GNS equations with the conserved quantity  $Q_0$  set equal to  $\langle Q_0 \rangle$ .

We write  $\mathbf{u}(\mathbf{x}) = \sum_{\mathbf{k}} e^{i\mathbf{k} \cdot \mathbf{x}} u_{\mathbf{k}} \mathbf{k}^\perp / |\mathbf{k}|$ , where the scalar term  $u_{\mathbf{k}}$  obeys  $u_{\mathbf{k}} = -\overline{u_{-\mathbf{k}}}$ , and  $\mathbf{k}^\perp = (k_2, -k_1)$  if  $\mathbf{k} = (k_1, k_2)$ . Hence  $Q_0 = (2\pi)^2 \sum_{\mathbf{k}} |u_{\mathbf{k}}|^2$  (and the total vorticity is  $Q_1 = (2\pi)^2 \sum_{\mathbf{k}} |\mathbf{k}|^2 |u_{\mathbf{k}}|^2$ ). If we define the *effort*  $\mathbf{G}_1$  as

$$\begin{aligned} \mathbf{G}_1 &= (\Delta^{-1}(\mathbf{a} - \mathbf{f} - \partial p), (\mathbf{a} - \mathbf{f} - \partial p)) = \\ &= (2\pi)^2 \sum_{\mathbf{k}} \frac{(\dot{u}_{\mathbf{k}} + iR^2 \sum_{\mathbf{j}+\mathbf{h}=\mathbf{k}} \frac{(\mathbf{j}^\perp \cdot \mathbf{h})(\mathbf{h} \cdot \mathbf{k})}{|\mathbf{j}||\mathbf{h}||\mathbf{k}|} u_{\mathbf{j}} u_{\mathbf{h}} - f_{\mathbf{k}})^2}{\mathbf{k}^2} \end{aligned} \quad (4)$$

where  $(\cdot, \cdot)$  denotes the usual scalar product in  $L_2(d\mathbf{x})$ , and  $\mathbf{a} = d\mathbf{u}/dt = \partial_t \mathbf{u} + R^2(\mathbf{u} \cdot \partial)\mathbf{u}$  is the acceleration field, Eq.(3) can be obtained from Gauss' least effort principle by considering an Euler fluid subject to the constraint

---

<sup>3</sup> The cases of Fig.2 are the only exceptions considered here.

of constant  $Q_0$ , *i.e.* constant total energy. In this case the acceleration  $\mathbf{a}$  of the velocity field  $\mathbf{u}$  minimizes the effort  $\mathbf{G}_1$  among all possible accelerations compatible with the incompressibility and with the constraint. If we write Eq.(3) in terms of Fourier components we find

$$\dot{u}_{\mathbf{k}} = -iR^2 \sum_{\mathbf{j}+\mathbf{h}=\mathbf{k}} \frac{(\mathbf{j}^\perp \cdot \mathbf{h})(\mathbf{h} \cdot \mathbf{k})}{|\mathbf{j}||\mathbf{h}||\mathbf{k}|} u_{\mathbf{j}} u_{\mathbf{h}} - \alpha \mathbf{k}^2 u_{\mathbf{k}} + f_{\mathbf{k}} \quad (5)$$

where  $\alpha$  is given by

$$\alpha = \frac{\sum_{\mathbf{k}} f_{\mathbf{k}} \bar{u}_{\mathbf{k}}}{\sum_{\mathbf{k}} |\mathbf{k}|^2 |u_{\mathbf{k}}|^2} . \quad (6)$$

Of course the fact that the equations above can be obtained from a variational principle might be merely accidental, and in itself does not justify their use. However in Refs.[11,21,22,12] it has been argued that they should give a description of the fluid motions which in the large Reynolds number regime is as accurate as the NS equations themselves. More generally, one can consider an Euler fluid subject to a Gaussian constraint on  $Q_m$  with effort function  $\mathbf{G}_\ell$ ,  $\ell \leq m+1$ , given by

$$Q_m = (2\pi)^2 \sum_{\mathbf{k}} |\mathbf{k}|^{2m} |u_{\mathbf{k}}|^2, \\ \mathbf{G}_{\ell,m} = ((\Delta)^{-(\ell-m)}(\mathbf{a} - \mathbf{f} - \partial p), (\mathbf{a} - \mathbf{f} - \partial p)) . \quad (7)$$

This leads to equations like (3) with the Laplace operator replaced by  $\Delta^\ell$ , and with  $\alpha$  replaced by a new coefficient  $\beta_{\ell,m}$  that can be easily computed by imposing that  $Q_m$  remains exactly constant. We call the resulting equations “*G-hyperviscous*” equations while we call “*hyperviscous*” the corresponding equations in which  $\beta_{\ell,m}$  is replaced by a constant. The above case (5) corresponds to  $\ell = 1, m = 0$ . The special cases  $\ell = 0, m = 0$  and  $\ell = 1, m = 1$  have been considered in [11] and the general hierarchy of the hyperviscous equations has been considered and partially studied in [22]. The case  $\ell = 1, m = 1$ , for instance, yields:

$$\beta_{1,1} = \frac{\sum_{\mathbf{k}} |\mathbf{k}|^2 f_{\mathbf{k}} \bar{u}_{\mathbf{k}}}{\sum_{\mathbf{k}} |\mathbf{k}|^4 |u_{\mathbf{k}}|^2} . \quad (8)$$

A general feature of the G-hyperviscous equations is that they generate *reversible dynamics* in the sense that the velocity reversal operation  $Iu_{\mathbf{k}} = -u_{\mathbf{k}}$  anticommutes with the time evolution map  $S_t$  (the mapping of an initial datum  $\mathbf{u}$  into its value  $S_t \mathbf{u}$  at time  $t$ ) in the sense that

$$I \cdot S_t = S_{-t} \cdot I . \quad (9)$$

Note that here we call GNS equations the case  $\ell = 1, m = 0$  for consistency with [22] because we shall often refer to Ref.[22], although in [11] this name was used for the case  $\ell = 1, m = 1$ .

In this paper we study via computer simulations:

- (1) Relations between the Lyapunov spectra of corresponding NS and GNS models. Equivalence between the Lyapunov spectra is not part of the earlier proposals on equivalence because the Lyapunov exponents are not “local observables”: however it seems possible that they reflect properties of the individual modes of the velocity field [23] so that it is interesting to test whether equivalence extends to them. In the models that we consider the Lyapunov spectra appear to be essentially *identical* within the errors.
- (2) Fluctuation properties of the observable defined by the phase space contraction in the reversible GNS equation and its relation with the Lyapunov spectra following the proposal in [11]. The relation proposed in [11] is, however, based on several assumptions which we cannot check directly. Therefore we have measured quantities for which predictions are available as consequences of the mentioned assumptions, finding that the predictions match with the observations. This lends support to the idea that the property called “*axiom C*” as well as the assumptions on the structure of the attracting sets discussed in [11,24] may be actually verified in the models considered here.
- (3) The equivalence analysis can be extended to involve not only NS and GNS equations but also to several members of the hierarchy of hyperviscous and G-hyperviscous equations. We have made a few tests analogous to those made in the case of the NS and GNS equations, and some of the results are briefly presented below.
- (4) Local fluctuations. The theory of the fluctuations of  $\alpha$  considered in item (2) above concerns the global phase space contraction rate, which in our models is extensive. Extensivity makes it very difficult to measure the fluctuations of  $\alpha$  in systems with a large number of modes (*i.e.* many degrees of freedom). To overcome this difficulty, we define and study the “local phase space contraction” related to a portion of the volume occupied by the fluid, where fluctuations are strongly enhanced.

The investigation is important because in comparing fluctuations of phase space contraction between corresponding NS and GNS evolutions one must look at smaller subsystems. For instance, in the (truncated) NS equation there is no fluctuation of the *total* phase space contraction rate, because the friction coefficient is constant: the phase space contraction rate (*i.e.* the divergence of the equations of motion) is simply  $-2 \sum_{|\mathbf{k}| < N} \mathbf{k}^2$  if  $N$  is the cut off parameter.

Furthermore, in real experiments, one is forced to look at the fluctuations within small portions of fluid in order to obtain good statistics [15,16]. Our

results on this matter are only preliminary, but encouraging so that we report them in the Appendix.

We integrated Eq.(5) by means of a pseudospectral code truncating it to a small number  $K$  of Fourier modes,  $u_{\mathbf{k}}$ , of the velocity field. The computation of the entire Lyapunov spectrum is, generally, expensive (in terms of CPU time), and testing the validity of the FR (for the GNS equation) requires high statistics on the fluctuations of the phase space contraction rate  $\alpha$ . Thus we have been forced to adopt a “low resolution” approximation of the dynamics in Fourier space: i.e. to take  $\mathbf{k}, \mathbf{p}, \mathbf{q} \in [-(N-1), \dots, (N-1)]^2$ , where  $N$  is a small truncation value. In this way, the number of independent real components of the velocity field is  $2K$  with  $2K = 4N(N-1)$  not counting the components corresponding to  $\mathbf{k} = \mathbf{0}$  which, being constants of motion, have been fixed to be zero. We say that the equations are “truncated at  $K$  modes” calling “mode  $\mathbf{k}$ ” a (complex) Fourier component  $u_{\mathbf{k}}$  of the velocity field. In our cases  $2K$  ranges between 24 and 168: this corresponds to  $N-1$  between 2 and 6. Given our Reynolds numbers,  $K$  is much less than the value it should have (which we estimate to be about one order of magnitude higher) in order to interpret the results as relevant for developed turbulence (albeit in two dimensions), consistently with the theories of homogeneous turbulence. However, our present computer facilities make it impossible for us to reach much higher numbers of modes with the precision demanded by our analysis.

### 3 Extension of equivalence between the NS and GNS dynamics to Lyapunov spectra

The equivalence principle introduced in Refs.[11,21] yields quantitative relations between certain observables, which can be tested in numerical experiments. The principle states that NS and GNS equations should have same statistics for the “local observables”<sup>4</sup>, when the limit of large Reynolds number is taken and the average phase space contraction of the GNS evolution equals the (constant) phase space contraction rate of the NS evolution.

The phase space contraction rate associated with a differential equation is the divergence of the equations of motion: it can be straightforwardly computed from Eqs. (5),(6) to be  $\sigma = (-1 + 2 \sum_{|\mathbf{k}_i| < N} 1) \cdot \alpha$  in the case  $\ell = 0$  and  $m = 0$

---

<sup>4</sup> *i.e.* for the time averages of functions of the velocity field which depend only on a finite number of its Fourier components or, more generally and more physically, which depend only on Fourier components of modes with  $\mathbf{k}$  in the inertial range.

(which we call GED case), and

$$\sigma^{GNS} = 2 \left( \sum_i |k_i|^2 - \frac{Q_2}{Q_1} \right) \cdot \alpha + \frac{\sum_{|k_i| < N} \mathbf{k}^2 f_{k_i} \bar{u}_{k_i}}{Q_1} \quad (10)$$

in the GNS case, i.e. for  $\ell = 1, m = 0$  (see Eq.(7))<sup>5</sup>. Denoting by

$$\sigma^{NS} = 2 \sum_{|k_i| < N} |k_i|^2 = M \quad (11)$$

the (constant) phase space contraction rate of the NS evolution, and by

$$\begin{aligned} \langle \sigma^{GNS} \rangle &= \left\langle 2 \left( \sum_i |k_i|^2 - \frac{Q_2}{Q_1} \right) \cdot \alpha + \frac{\sum_{|k_i| < N} \mathbf{k}^2 f_i \bar{u}_{k_i}}{Q_1} \right\rangle = \\ &= M \cdot \langle \alpha \rangle + o(M) \end{aligned} \quad (12)$$

the average phase space contraction rate of the GNS evolution, the equivalence conjecture studied in [22] can be stated as follows.

**Equivalence Conjecture (EC).** *The stationary probability distributions on the phase space associated with the NS equations and the GNS equations are equivalent in the limit of large Reynolds number, provided the value of  $Q_0$  is chosen so that  $\sigma^{NS}$  and  $\langle \sigma^{GNS} \rangle$  coincide or, equivalently, provided the value of  $Q_0$  is chosen so that  $\langle \alpha \rangle$  equals 1.*<sup>6</sup>

The idea behind this conjecture is that if the fluctuations of  $\alpha$  occur on time scales which are short compared with the macroscopic observation time scales, and if  $\langle \alpha \rangle = 1$ , the macroscopic observables should be equally well computed from the NS and the GNS dynamics. The large  $R$  limit is, then, required to ensure that the fluctuations of  $\alpha$  do really occur on sufficiently short time scales. The results of [22] suggests that this is the case.

To obtain such results, the steady state of the NS evolution was first determined by following during a long time  $T$  the approach of the time average of  $Q_0$  to its asymptotic value  $\langle Q_0 \rangle$ . At time  $T$ , the evolution was continued with the GNS dynamics with initial condition taken to be the vorticity field produced by the NS dynamics at time  $T$ . It was then observed that  $\langle \sigma^{GNS} \rangle / \sigma^{NS} \approx \langle \alpha \rangle$ , and that  $\langle \alpha \rangle$  differ little from 1 already at small  $N$  (of order  $O(10^1)$  and even less) *as long as the initial (fixed) value  $Q_0^{GNS}$  of  $Q_0$  was close to its NS time*

<sup>5</sup> In experiments on real fluids this quantity must be associated with some physical observable (a very delicate matter, [15,16])

<sup>6</sup> i.e. equals the viscosity in our dimensionless units.

average  $\langle Q_0 \rangle$ . Furthermore the details of the initial condition for the GNS evolution did not affect *too much* the statistical results produced by the GNS dynamics. In other words, it appeared that only the parameter  $Q_0^{GNS}$  needs to be adjusted to obtain equivalent NS and GNS evolutions. Although the meaning of “*too much*” and “*close*” was not sharply quantified in [22], the results suggested the validity of an EC also in the following alternative sense:

**Equivalence Conjecture (EC').** *The stationary phase space probability distributions of the NS equations and of the GNS equations are equivalent in the limit of large Reynolds number, provided the energy  $Q_0$  is fixed in the GNS evolution to coincide with the average value  $\langle Q_0 \rangle$  of the NS evolution at the same (large)  $R$ .*

In this paper, we first investigate the possibility of extending the EC, EC' to the equivalence of the Lyapunov spectra. We evaluate the Lyapunov exponents of the NS equation by performing a long numerical simulation from time 0 up to time  $T$ , yielding the NS Lyapunov spectrum and the average value  $\langle Q_0 \rangle$ , with an error bar  $\delta Q_0$ . From time  $T$ , we continue the NS evolution until  $Q_0$ , which fluctuates, equals  $\langle Q_0 \rangle$ . This usually takes a short time  $t_s$ . Then, at time  $T + t_s$ , we switch to the GNS evolution and compute the corresponding GNS Lyapunov spectrum. The reason to adopt this procedure, rather than just taking a random initial field with  $Q_0^{GNS} = \langle Q_0 \rangle$  for the GNS evolution, is that *a priori* the attractor might be not unique, and different initial fields may be evolved by the GNS dynamics towards attractors different from the one found by following the NS evolution. In other words, the NS and the GNS statistical properties may not always result comparable because of possible hysteresis phenomena. Our procedure was originally designed to avoid this problem, although it turned out subsequently that our choice of parameters yields no hysteresis, as discussed in Ref.[25].

The Lyapunov spectra produced by the NS and GNS dynamics in this way appear *equivalent*, meaning that the Lyapunov spectra of the NS and GNS dynamics appear to become identical for large  $R$  and  $K$ . At finite  $R$  and  $K$ , instead, the sums of the Lyapunov exponents should be related by (cf. eqs.(11,12))

$$\sum_{i=1}^K \lambda_i^{GNS} = \sum_{i=1}^K \lambda_i^{NS} + o(M) , \quad \text{where} \quad \sum_{i=1}^K \lambda_i^{NS} = -M. \quad (13)$$

The typical situation is represented in Fig. 1 where the  $2K - 2$  nontrivial exponents are drawn. Note that two exponents are *a priori* known to vanish in the GNS case: one corresponding to the direction of motion and one to the direction of the conserved quantity; in the NS case one is *a priori* known to

$R^2$	$\delta Q_0/\langle Q_0 \rangle_{NS}$	$\Delta\alpha$	$\Delta Q_1$	$o(M)/M$

5000	0.010	0.008	0.058	0.033

Table 1

Equivalence of NS and GNS dynamics, i.e. with  $\ell = 1$  and  $m = 0$ , for different Reynolds numbers. The last column gives the relative difference of the computed sums of the NS and GNS Lyapunov exponents (cf. eq.(13)).

$R^2$	$\delta Q_0/\langle Q_0 \rangle_{NS}$	$\Delta\alpha$	$\Delta Q_1$	$o(M)/M$
408	0.002	0.039	0.001	0.060
800	0.002	0.038	0.001	0.067
2222	0.003	0.003	0.002	0.042

Table 2

Same as in Table 1 but for the ED and GED case with  $\ell = 0$  and  $m = 0$ .

vanish, corresponding to the direction of motion. However in all cases the NS evolution shows another exponent very close to zero in agreement with the equivalence conjecture and we have taken it to be zero in drawing the figures 1 and 2 below, see also footnote 11 below.

The Lyapunov exponents are obtained by the method of Ref.[26] over times  $T$  of the order of up to  $10^5$  Lyapunov time units.<sup>7</sup> Error bars do not appear, since they are not larger than the size of the symbols in the figures, as explained below in Section 5.

Consistently with the EC', and up to numerical errors, we observed that the viscosities and the average enstrophies of the NS and GNS evolutions with  $2K = 24$  result equal if the average energies are equal. The numerical errors we refer to can be attributed to our approximate knowledge of the average of  $Q_0$  (which is affected by an error bar  $\delta Q_0$ ); and to the finite values of  $R, N$ , and  $T$  (which, in turn, can only be reached through a sequence of time steps of finite size  $h$ ). The corresponding deviations from the conjectured equalities of the viscosities and of the average enstrophies are measured by the terms  $\Delta\alpha = (\langle\alpha\rangle - 1)$  and  $\Delta Q_1 = |\langle Q_1 \rangle_{NS} - \langle Q_1 \rangle_{GNS}|/\langle Q_1 \rangle_{NS}$  in Tables 1 and 2, where the subscripts *NS* and *GNS* indicate the two relevant kinds of dynamics.

---

<sup>7</sup> We define the Lyapunov time unit as  $1/\lambda_{max}$ , where  $\lambda_{max}$  is the largest Lyapunov exponent.

Fig. 1. Lyapunov spectra for the NS runs with normal viscosity ( $\ell = 1$ ) at  $R^2 = 2222$  (left) and  $R^2 = 5000$  (right), and corresponding GNS runs with constrained energy  $Q_0$ . The  $2K - 2$  nontrivial exponents are drawn by associating each value of the abscissa  $k = 1, 2, \dots, K - 1$  with the  $k$ -th largest exponent  $\lambda_k$  and the  $k$ -th smallest exponent  $\lambda'_k = \lambda_{2K-k-1}$ . The symbols “+” refer to the NS spectra, the “\*” to the GNS spectra, and the “x” to the sums  $(\lambda_k + \lambda'_k)/2$  for the NS case. There is no “pairing” of the exponents to a common average value, unlike the cases of isokinetic Gaussian systems [27]. Essentially identical results have been obtained by studying the ED and GED equations.

Further computations of the Lyapunov spectra were performed for  $2K = 168$ , starting from random initial data, evolving with the NS evolution, and then switching to a GNS evolution, as above. In this case, however, the fixed quantity  $Q_m$  of the GNS evolution was the energy  $Q_0$  in one instance, the enstrophy  $Q_1$  in another instance, and the palinstrophy  $Q_2$  in the last instance. The motivation of this computation was to check the validity of the conjecture, proposed and partially tested in [22], that “several” pairs of equations of the hierarchies of hyperviscous and G-hyperviscous equations, with  $\ell \leq m + 1$ , are equivalent to each other in the limit of large Reynolds numbers.

If the EC can be extended to such general cases and to cover the Lyapunov spectra, the spectra should overlap (for large  $R$ ). Considering the fact that the error bars  $\delta Q_0, \delta Q_1, \delta Q_2$  on  $\langle Q_0 \rangle, \langle Q_1 \rangle, \langle Q_2 \rangle$  in these cases were larger than in the cases with  $2K = 24$  (the largest being  $\delta Q_1 \approx 0.09 \langle Q_1 \rangle$ ), our results for  $\ell = 1$  and  $m = 0, 1, 2$ , seem to confirm this property. This is illustrated by Fig.2 which shows the equivalence, within our numerical accuracy, of the computed Lyapunov spectra of the NS and GNS systems. A similar equivalence was observed in several other cases which we do not describe here for brevity. This reinforces the previous results of [22], and provides a heuristic motivation for the validity of the conjectures EC, EC’.

In Fig.1 and Fig.2 two exponents for the GNS equation vanish exactly reflecting that  $Q_0$  is a constant of motion and neither expands nor contracts in the direction of the flow. There is a third exponent close to 0 which, however, seems to be numerically distinct from 0. In the NS cases only one exponent is certainly 0 (corresponding to the flow direction) but there are two other

Fig. 2. Lyapunov exponents for one NS run with normal viscosity (+) at  $N = 7$ ,  $R^2 = 10^6$ , and forcing on modes  $(4, -3)$ ,  $(3, -4)$ . The  $2K - 2$  nontrivial exponents are drawn as in Fig. 1. The middle line ( $\times$ ) is the graph of  $(\lambda_k + \lambda'_k)/2$ . The other symbols refer to the corresponding GNS runs with fixed energy (\*) *i.e.*  $m = 0, \ell = 1$ , fixed “enstrophy” ( $\square$ ) *i.e.*  $m = 1, \ell = 1$ , or fixed “palinstrophy” ( $\blacksquare$ ) *i.e.*  $m = 2, \ell = 1$ . The spectra are obtained from runs of different lengths with  $T \in [125, 250]$ , in units of  $1/\lambda_{max}$ ,  $\lambda_{max}$  being the largest Lyapunov exponent. The overlap of the four spectra (albeit approximate, because of the uncertainties  $\delta Q_0, \delta Q_1, \delta Q_2$ ) reflects the validity of the extension of the EC, EC' to the whole spectrum and to different members of the hierarchy of equations. The error bars, see Sec. 5, can be identified with the size of the symbols.

exponents which are numerically very close to 0, see also footnote<sup>11</sup> below.

#### 4 Time reversal symmetry, axiom C and the fluctuation theorem

A fluctuation theorem (FT), [28], for the fluctuations of the phase space contraction rate  $\sigma^{GNS}(\mathbf{u})$  in our GNS truncated systems can be derived under the assumption that the Chaotic Hypothesis (CH) is verified by the GNS dynamics at the considered Reynolds number, [14]. The CH can be formulated as follows:

**Chaotic Hypothesis (CH).** *A chaotic many-particle system or fluid in a stationary state can be regarded, for the purpose of computing macroscopic properties, as a smooth dynamical system with an attracting set on which the system is a smooth transitive Anosov system.*

This means that the attracting set can be considered, *for practical purposes*,

to be a connected “smooth surface”, on which the dynamics is hyperbolic and in fact verifies the Anosov property, see [12] for a mathematical definition. In other words, one supposes that the attracting set is a smooth surface possibly of dimension lower than that of phase space, thinking that its fractality is not important (here the difference between attracting set and attractor matters: the latter being very often fractal, cf. footnote 2 above). If the CH is valid for the GNS systems, the FT of [14] follows *provided the attractor is dense in phase space* and *provided the evolution is time reversible*. The FT imposes strong restrictions, which we illustrate below, on the form of the fluctuations of the contraction of the surface elements on the attracting set (cf. eq.(9)).

Let  $t \mapsto S_t \mathbf{u}$  be the time evolution for the initial velocity field  $\mathbf{u}$  generated by the equations of motion on phase space, and call  $T$  the *total* simulation time, which must be adequately longer than the characteristic time  $\theta$  of the fluctuations of  $\sigma^{GNS}$ . Assume that relaxation to a statistically stationary state takes place in a time  $t_0 \ll T$  with  $t_0 \gg \theta$  where  $\theta$  is a characteristic time for the evolution, *e.g.*  $\theta = 1/\lambda_{max}$ , and introduce the infinite time average of the phase space contraction rate  $\sigma^{GNS}$ :

$$\langle \sigma^{GNS} \rangle = \lim_{T \rightarrow \infty} \frac{1}{T} \int_0^T \sigma^{GNS}(S_t \mathbf{u}) dt = \int \mu(d\mathbf{u}) \sigma^{GNS}(S_t \mathbf{u}). \quad (14)$$

If  $T$  is large, we can subdivide the time interval  $[t_0, T]$ , into a number of subintervals of length  $(\tau + t_d)$ , with  $\tau \gg \theta$  and  $t_d$  a decorrelation time, separating the consecutive evolution segments of length  $\tau$ . Consider the dimensionless quantities

$$\overline{\sigma^{GNS, \tau}}(i) = \frac{1}{\tau \langle \sigma^{GNS} \rangle} \int_{t_0 + (i-1)(\tau + t_d)}^{t_0 + i(\tau + t_d)} \sigma^{GNS}(S_t \mathbf{u}) dt, \quad (15)$$

with  $i = 1, \dots, (T - t_0)/(\tau + t_d)$  and arrange them in a histogram which allows us to approximate the probability distribution  $\pi^\tau$  of the values of  $p = \overline{\sigma^{GNS, \tau}}$ . The total time  $T$  is empirically chosen large enough so that larger simulation times and different initial fields produce differences in the probability distributions that lie within the error bounds over a range of  $p$ 's which is sufficient to perform meaningful tests.

Within the range of values of  $p$  in which the number  $n$  of events per histogram bin is statistically meaningful,<sup>8</sup> and for sufficiently large  $\tau$ , it was observed

---

<sup>8</sup> Here, we chose the range with  $n \geq 10$  ( $n$  being the number of events in a bin), and we weighted the contribution of each bin to the fit as inversely proportional to the associated error bar. In this way, the cases with low statistical relevance (e.g.

(cf. [22]) that the quantity

$$F(p; \tau) = \frac{1}{\tau \langle \sigma^{GNS} \rangle} [\log (\pi^\tau(p)) - \log (\pi^\tau(-p))] \quad (16)$$

could be fitted by a function linear in  $p$  with slope  $c(\tau)$ , obtaining:

$$\frac{1}{\tau \langle \sigma^{GNS} \rangle} [\log (\pi^\tau(p)) - \log (\pi^\tau(-p))] = c(\tau)p , \quad (17)$$

within the error bars. If the conditions of the CH and of time reversibility are verified, one can check whether or not  $c(\tau)$  converges to a limit  $c_\infty$ , as  $\tau$  is increased. *If the attractor was really dense in phase space,*<sup>9</sup> *then the validity of the FT would imply that  $c_\infty$  exists and, precisely, that  $c_\infty = 1$ .* In such limiting case we refer to Eq.(17) by calling it the “fluctuation relation” (FR).

However, the attractors of systems with strong dissipation often *are not dense* in phase space. This is the case of the NS equations, in which the attracting sets have a large open complement. In such cases further assumptions are needed before the CH can be used to derive interesting predictions. We shall consider the possibility that there is proportionality between phase space contraction of volume elements *around* the attracting set and contraction of surface elements *on* the attracting set itself (which has dimension lower than that of phase space). This somewhat surprising possibility can be related to (and predicted from) other assumptions which involve geometric and dynamic hypotheses introduced in general in [24] and applied to the GNS equations in [11].

To understand the hypotheses, first note that smoothness of the attracting set and reversibility of the dynamics do not suffice to deduce Eq.(17). Indeed, the image under time reversal of the attracting set  $A$  will be a repelling set  $IA$  which, if the attractor is not dense in phase space, is disjoint from it, cf. Fig.3.

Nevertheless the following may happen and be stable under perturbations of the equations of motion. Consider the stable manifold of the points on the attracting set: part of this manifold will be on the attracting set (which we suppose to be a smooth surface) and another part will stick out, cf. (a) in Fig.3. Likewise the unstable manifold of the points on the repelling set will be partly on it and partly stick out, cf. (b) in Fig.3.

It is possible that the parts of the manifolds that stick out cross each other transversally along a manifold that connects the attracting and repelling sets, with  $n \approx 10$ ) have little influence on the computed  $c(\tau)$ ’s and, particularly, on its values extrapolated to large  $\tau$ .

<sup>9</sup> Hence the whole phase space would be an attracting set.

Fig. 3. Illustration of axiom-C systems. The bottom squares represent the attracting set  $A$ , while the top squares represent the repelling set  $IA$ . The leftmost figure with vertical segments represents a point  $x \in A$  with a piece of its stable manifold connecting  $A$  to  $IA$ . Similarly, the central figure represents a point  $x' \in IA$  with a piece of its unstable manifold. The rightmost figure represents the corresponding intersection of the stable manifold of  $x$  with the unstable manifold of  $Ix$ , which associates a point  $\tilde{I}x$  in  $IA$  with a point  $x$  in  $A$ .

determining on each of them a single intersection point, cf. the line in (c) in Fig.3. In this way, a correspondence  $\tilde{I}$  between attracting set and repelling set is constructed [24]. By construction the map  $\tilde{I}$  commutes with the time evolution maps  $S_t$ . The composition  $I^*$  of  $\tilde{I}$  with the time reversal map  $I$  of Eq.(9) leaves the attractor *invariant* and *anticommutes* with time evolution restricted to it, *i.e.*

$$S_t \cdot I^* = I^* \cdot S_{-t} \quad \text{on the attracting set.}$$

A system verifying the above geometric properties, introduced and discussed at some length in [24] and in [29,12], is said to verify *Axiom C*. For such systems, time reversal symmetry can be “spontaneously broken” as a control parameter ( $R$  in our case) varies, meaning that the attracting set  $A$  becomes smaller than the whole phase space, and distinct from the repelling set  $IA$ . However, upon breaking, it spawns a new (lower) symmetry  $I^*$  which acts on the attracting set and anticommutes with time evolution. In a sense, in such systems time reversal *cannot be broken* as it is always dynamically regenerated.

In Refs.[24,29] this scenario was presented as the simplest possible way in which time reversal symmetry could be spontaneously broken via the splitting of the phase space of a reversible system into an attracting set, a repelling set and a large region in between, as in Fig. 3. *Under this assumption*, the CH holds for the dynamical system obtained by restricting the dynamics to the attracting set. To such system the FT applies, and the fluctuations of the contraction rate of the area element of the attracting set obey the FR with an asymptotic slope  $c_\infty = 1$ .

A further difficulty is that, usually, it is not possible to measure the contraction rate of the surface of the attracting set because this set is practically

inaccessible dynamical object. However such a measurement is not necessary if one can relate the area contraction on the surface of the attracting set to the *total* phase space contraction rate which is easily accessible, at least in numerical experiments.

In Figs.1,2 the  $2K - 2$  nontrivial Lyapunov exponents are arranged in pairs, each consisting of the  $k$ -th largest exponent and the  $k$ -th smallest exponent (see [21] for a heuristic theoretical argument motivating this arrangement of our data). We imagine that the pairs with one positive and one negative exponent pertain to the restriction of the evolution to the attracting set.<sup>10</sup> The other pairs, consisting of two negative exponents, would then pertain to the directions of the stable manifold that stick out of the attracting set.

Adopting the above view, we see that in a time  $T$  and on the attracting set the phase space contracts by  $\sum^*(\Lambda_{k,T} + \Lambda_{2K-1-k,T})$  where  $\Lambda_{k,T}$  denotes the “local contraction” exponent of the surface of the attracting set over a time interval  $T$  around the phase point occupied by the system at the beginning of the interval. Here,  $\sum^*$  denotes the summation over the values of  $k$  corresponding to pairs of exponents with one positive and one negative exponent. The total contraction of phase space is  $\sum_{k=1}^K(\Lambda_{k,T} + \Lambda_{2K-1-k,T})$ . The two contractions are asymptotic to  $T \sum^*(\lambda_k + \lambda_{2K-1-k})$  and to  $T \sum_{k=1}^K(\lambda_k + \lambda_{2K-1-k})$ , respectively, if  $\lambda_k$  denotes the  $k$ -th nontrivial Lyapunov exponent. Hence, their ratio tends to

$$\begin{aligned} c &= \frac{\sum^*(\lambda_k + \lambda_{2K-1-k})}{\sum_{k=1}^K(\lambda_k + \lambda_{2K-1-k})} = \\ &= \lim_{T \rightarrow \infty} \frac{\sum^*(\Lambda_{k,T} + \Lambda_{2K-1-k,T})}{\sum_{k=1}^K(\Lambda_{k,T} + \Lambda_{2K-1-k,T})} = \lim_{T \rightarrow \infty} C(T) . \end{aligned} \quad (18)$$

If the ratio  $C(T)$  is constant over the typical time scales over which we observe the fluctuations of the phase space contraction, there is proportionality between the phase space contraction and the area contraction on the surface, and the proportionality constant is precisely  $c$  (which implies a weaker property than the one envisaged in[21]: the latter in fact seems too strong and not verified in the present case). We have tested whether this is the case, by taking as time scale  $1/\lambda_{max}$ , the inverse of the largest Lyapunov exponent. The result is that, after a short transient, the quantity  $C(T)$  is indeed practically

---

<sup>10</sup> By the axiom C, i.e. by the consequent existence of a time reversal symmetry on the attracting set, we know that on such set half of the exponents is positive and half is negative, once the vanishing exponent associated with the flow direction has been discarded together with the other vanishing exponent associated with the conserved quantity (energy, or enstrophy or any of the global quadratic quantities  $Q_m$ , depending on the model). Arranging the remaining  $2K - 2$  exponents in decreasing order:  $\lambda_1 \geq \lambda_2 \geq \dots \geq \lambda_{2K-2}$ , one can form the pairs  $(\lambda_k, \lambda'_k)$  of Figs. 1,2.

constant (with fluctuation amplitudes of a few percent of its average value) while the phase space contraction fluctuates with *much larger* amplitudes. This is also reflected, for instance, in the variances of the histograms of  $C(T)$  with short  $T$ 's for the cases we checked, which are more than one order of magnitude smaller than the variances of the corresponding histograms of the phase space contraction. Therefore the FR with slope 1 for the (not directly accessible) surface contraction on the attracting set will imply a FR for the *total* (measurable) phase space contraction with a slope  $c$  given by Eq.(18).

If in Eq.(16) we use the histograms for  $\pi^\tau$  obtained as outlined above, the result is well fitted by the linear law (17). This is the case starting from  $\tau$ 's comparable to  $1/\lambda_{max}$ , and remains valid throughout the range of  $\tau$ 's that we can consider. In this range, the values of  $c(\tau)$  can be computed through a least square fit and, as suggested by the CH, the results can be interpolated by a function like

$$c_\infty + A/\tau, \quad (19)$$

where  $c_\infty$  is the asymptotic slope and  $A$  is a constant: in fact, in Anosov systems the limit of  $\tau^{-1} \log \pi^\tau(p)$  is reached with errors of order  $\tau^{-1}$ , as  $\tau \rightarrow \infty$  [28,14]. In all cases we considered, such an interpolation fits well our data. Figures 4 – 5 illustrate that the above statements are valid even in the cases with small  $R^2$ . The reason for the smallness of the  $\tau$ 's that we can consider can be understood by looking at Fig.4 where, by comparing the graph on the left panel (smaller  $\tau$ ) with the one on the right panel (larger  $\tau$ ), we see that the range of  $p$ 's over which Eq.(16) can be assessed rapidly decreases with  $\tau$ . This is due to the decrease of the frequency of the negative fluctuations of  $\overline{\sigma^{GNS, \tau}}$ , which rapidly becomes practically zero as  $\tau$  grows.

Nevertheless, the interpolation by  $c_\infty + A/\tau$ , where the  $c_\infty$  and  $A$  are obtained from a least square fit, looks convincing within our range of  $\tau$ 's and we therefore investigate the consequences of assuming that it remains valid beyond this range. In this case, one can compare the values of  $c_\infty$  with those of  $c$  obtained from Eq.(18). The results are reported in tables 3 and 4. One realizes that, within the accuracy of our numerical results, discussed more in detail in the next section, there is agreement between the predictions of Ref.[21] for  $c$  and our values for  $c_\infty$ . Of course, this is only a consistency check of the axiom C hypothesis which, as mentioned above, can only be indirectly tested in our cases.

We also remark that the axiom C hypothesis leads to a simple expression for the dimension of the attracting set, according to which the ratio between the dimension of the attracting surface (on which the attractor is dense) and the dimension of the phase space ( $2K - 1$  in our cases because of the existence of the conserved quantity  $Q_0$ ) is the ratio  $D_P = (2K - 1 - 2n_-)/(2K - 1)$ , where

Fig. 4. Computed values of  $F(p; \tau)$ , Eq.(16), for a GNS system with fixed energy ( $\ell = 1$ ,  $m = 0$ ) and  $R^2 = 686$ . The straight lines interpolate the data, and the error bars represent the statistical errors. The left panel has  $\tau \approx 1.2$ , while the right panel has  $\tau \approx 2.5$ , in  $1/\lambda_{max}$  units. In order to obtain the fit in Fig.5 we repeated similar measurements for various values of  $\tau$ . Data refer to a 24-real modes truncation ( $2K = 24$ ). The data for  $p < 0$  can be inferred from the symmetry  $p \leftrightarrow -p$ . The kurtosis of  $\pi^\tau$  is defined by  $\langle (p-1)^4 \rangle / \langle (p-1)^2 \rangle^2$ , and equals 3 if  $\pi^\tau$  is Gaussian.

Fig. 5. The value  $c(\tau)$  for the GNS run with fixed energy ( $\ell = 1$ ,  $m = 0$ ),  $R^2 = 686$ . The times  $\tau$ , in the horizontal axis are given in  $1/\lambda_{max}$  units. Data refer to a 24-real modes truncation ( $2K = 24$ ) and to values of  $\tau$  to which already corresponds a linear graph of  $F(p; \tau)$ . The datum with smallest  $\tau$  has not been used in constructing of the fit (but it matches it, nevertheless).

$n_-$  is the number of pairs with two negative Lyapunov exponents. Obviously, the fractal dimension of the attractor cannot be larger than the dimension of the attracting surface. Therefore, under our assumptions on the nature of the attracting set, if the Kaplan–Yorke dimension is a measure of the fractal dimension of the attractor, its value divided by  $2K - 1$  should be  $\leq D_P$ . It is therefore of some interest to check whether this holds in our case or not.

$R^2$	$c$	$c_\infty$	KY	$D_P$
556	0.534	$0.535 \pm 0.008$	0.734	0.565 ( $n_- = 5$ )
638	0.436	$0.421 \pm 0.020$	0.610	0.478 ( $n_- = 6$ )
686	0.630	$0.624 \pm 0.013$	0.848	0.652 ( $n_- = 4$ )
800	0.639	$0.614 \pm 0.025$	0.830	0.652 ( $n_- = 4$ )
1250	0.639	$0.621 \pm 0.024$	0.845	0.652 ( $n_- = 4$ )
2222	0.834	$0.717 \pm 0.011$	0.914	0.826 ( $n_- = 2$ )
5000	0.842	$0.839 \pm 0.015$	0.939	0.826 ( $n_- = 2$ )

Table 3

Properties of the GNS dynamics with fixed energy ( $\ell = 1$ ,  $m = 0$ ). The value of  $c$  is obtained from Eq.(18) using the measured Lyapunov exponents. The value  $c_\infty$  is obtained by extrapolation of the data as in Fig. 5. The column labeled by KY, gives the Kaplan-Yorke dimension computed from our measured Lyapunov exponents. The column labeled by  $D_P$  is the ratio  $(2K - 1 - 2n_-)/(2K - 1)$  where  $n_-$  is the number of pairs with two negative Lyapunov exponents. Data refer to a 24-real modes truncation ( $2K - 1 = 23$ ). Our estimate of  $n_-$ , given in brackets in the column of  $D_P$ , affects the calculations of both  $c$  and  $D_P$ .

In most cases cases (*e.g.* in the cases of Fig.1) there are three exponents very close to 0 and they are affected by a large relative error (see comments in sect. 5 below). We interpret as 0 the two of smallest absolute value (as we know that two exponents necessarily vanish). Although the signs of the second and third smallest exponents are stable with the length of our simulations, some uncertainty remains, at times, on which of the two approximates a zero exponent, and which approximates a finite exponent. For this reason, the values  $n_-$  reported in brackets in Tables 3 and 4 are uncertain by 1, and this implies an uncertainty also on the calculations of  $c$  and  $D_P$  (cf. point 3 of Section 6 below).

Table 3 shows that in our system the axiom C prediction and the KY value do not seem really compatible. The comparison of the dimensions and its consequences has been suggested by F. Bonetto. The incompatibility between the axiom C and the KY methods for determining the fractal dimension of an attractor seems to be quite general and to apply to rather different kinds of chaotic motions.

The same questions addressed here have been investigated in the case of the GED equations, obtaining the results reported in Table 4.

It should be noted that the *a priori* pairing assumption which, together with axiom C, allowed us to interpret and organize our data, does not have firm theoretical grounds other than the discussion in [11]. Therefore the above

$R^2$	$c$	$c_\infty$	KY	$D_P$
408	0.911	$0.823 \pm 0.009$	0.943	0.913 ( $n_- = 1$ )
556	0.813	$0.812 \pm 0.006$	0.957	0.826 ( $n_- = 2$ )
800	0.910	$0.910 \pm 0.007$	0.983	0.913 ( $n_- = 1$ )

Table 4

Properties of the GED dynamics with fixed energy ( $\ell = 0$ ,  $m = 0$ ). The meaning of the columns is the same as in table 3 above. Data refer to a 24–real modes truncation ( $2K - 1 = 23$ ).

analysis is highly conjectural and finds its main justification in its capability to fit the data.

## 5 Technical coments on the simulations. Accuracy.

The calculations summarized by Figs.1, 4-5, and by Tables 1–4, all refer to cases with rather small  $R$  and  $N$  compared to the cases studied in Ref.[22]. Small  $R$  is needed to obtain values of  $c_\infty$  sufficiently small to be distinguished clearly from 1, while small  $N$  is needed to compute with reasonable accuracy the Lyapunov spectra. The actual values  $R$  and  $N$  that we chose constitute a compromise, but the result is that the frequency of the negative fluctuations, needed for a test of the fluctuation formula, is quite low, and very rapidly it becomes negligible for growing  $\tau$ 's, even in long simulations. Given our present computer facilities, our standard simulation was of order of  $10^8$  time steps, with sizes  $DT$  of order between  $10^{-6}$  and  $10^{-4}$ , corresponding to times  $T$  of order between  $10^3$  and  $10^5$  in  $1/\lambda_{max}$  time units.

Such  $T$ 's suffice for calculations of the average of quantities like the  $Q_m$ 's, and to build with some accuracy the histograms of the fluctuations of  $\sigma^{GNS,\tau}$  for relatively small  $\tau$ 's. The accuracy is reflected by the error bars placed on the computed quantities, like in Figs.4-5, which cover the range of  $\tau$ 's beyond which the negative fluctuations are too rare to have any statistical significance (cf. footnote 8). These bars represent the statistical errors, obtained from the error bar on the histogram for  $\pi^\tau$ , i.e.  $\pm\sqrt{n}$  on a bin, if  $n$  is the number of counts in that bin.

The times  $T$  are also sufficient for an accurate evaluation of the largest Lyapunov exponents. Indeed, out of 24, the largest (in absolute value) 20 exponents have an uncertainty ranging from 25% down to 0.06% of the computed value, for the largest one. The uncertainty on the remaining 4 (smallest) exponents at times exceeds 100% of the computed value. The uncertainty on one exponent has been evaluated as the amplitude of the largest fluctuation of the computed value of that exponent in the second half of a simulation of

length  $T$ . In all cases, the error bars do not exceed the symbols size, if drawn in figures such as Fig.1. Nevertheless, at times, it is not obvious which two, of the three smallest exponents, vanish and which does not. This makes  $n_-$  uncertain by one unit. In particular, in the GNS case with  $R^2 = 2222$  and in the GED case with  $R^2 = 408$ ,  $n_-$  could have been taken to be 3 and 2, respectively, rather than 2 and 1 as reported in Tables 3 and 4. In fact, the third and the second smallest exponents are both quite small and close in absolute value, but the third smallest is positive while the second smallest is negative. Therefore, considering zero the third smallest exponent, rather than the second, makes  $n_-$  grow by 1.

The slopes  $c(\tau)$ , from which the values  $c_\infty$  of Tables 3 and 4 have been extrapolated, were computed by fitting our data to Eq.(17) and by using our histograms of  $\overline{\sigma^{GNS,\tau}}$  for  $\pi^\tau$ . The limiting slopes  $c_\infty$  and its error bar reported in Tables 3 and 4 have been computed by a least square fit the function  $c_\infty + A/\tau$  to the  $c(\tau)$ 's.

## 6 Concluding remarks

**1.** The results on the equivalence between NS and GNS dynamics obtained in Ref.[22] have been strengthened through the analysis of the Lyapunov spectra of NS and GNS systems, albeit at very low spectral resolution. Similar results were obtained for spectral resolutions with up to 190 modes.

**2.** The results of Ref.[22] on the validity of the FR for the GNS dynamics have been strengthened. Unfortunately, the relatively high dissipation of the systems considered here did not allow us to study the fluctuations of  $\overline{\sigma^{GNS,\tau}}$ , with  $\tau \gg 1/\lambda_{max}^+$ , as desired, due to lack of appreciably frequent negative fluctuations at such  $\tau$ 's. Nevertheless, our data are well fitted by  $c_\infty + A/\tau$ , in the whole ranges of  $\tau$  we considered, in accord with the validity of the CH.

**3.** The Lyapunov spectra have been used to compute the values  $c$  of Eq.(18) reported in Tables 3 and 4. These values equal the corresponding quantities  $c_\infty$  in agreement with the axiom-C hypothesis, except for the GNS case with  $R^2 = 2222$  and for the GED case with  $R^2 = 408$ . The uncertainty on  $c$  looks more pronounced than the uncertainty on  $c_\infty$ , because of the uncertainty on the number of positive Lyapunov exponents arising from the fact that often one of them is too close to 0.<sup>11</sup> The effect of this uncertainty on  $c$  is of about

---

<sup>11</sup> Two exponents have to vanish: the one corresponding to the conserved quantity  $Q_m$ , and the one corresponding to the direction of the flow. However there are other exponents very close to zero, and one faces, therefore, the difficult task of distinguishing numerically the small (positive or negative) exponents from the vanishing

9%, since it affects by 1 the number of pairs appearing in the numerator of Eq.(18), and the contributions of the different pairs do not fluctuate much around their average value. In particular, in the GNS case with  $R^2 = 2222$  and in the GED case with  $R^2 = 408$ , taking  $n_+ = 3$  and  $n_- = 2$ , respectively, leads to a close agreement between  $c$  and  $c_\infty$  also in these two cases.

4. Our codes, considered as dynamical systems in their own, seem to verify the axiom C, within the time scales of our simulations. Whether this property can be inferred to hold for the dynamics of real fluids is not clear, because of the low spectral resolution we have used.

5. Global fluctuations of macroscopic systems can hardly be observed, although the experiments of Refs.[15,16] attempt at studying precisely this kind of fluctuations. However, as argued in the Appendix, the (observable) local fluctuations seem to obey laws similar to those of the global fluctuations discussed here.

6. The extrapolation hypothesis Eq.(19) leads to a slope  $c_\infty$  which has been fitted to a value  $< 1$ . If confirmed by further experiments, this implies that the stochastic fluctuation theorems which lead to  $c_\infty = 1$ , such as those recently proposed in [30], would require extra ideas to be adapted to the description of the fluctuations of our deterministic dynamical systems.

## Appendix: Remarks on local fluctuations and on spatio-temporal chaos.

Recently, local versions of the FT have been considered to overcome the problem that the large global fluctuations which are the object of the original FT cannot be observed in real macroscopic systems. One possible approach has been outlined in Ref.[31], where a fluctuation relation similar to (17) has been derived for the fluctuations of local quantities, in an infinite chain of weakly interacting chaotic maps, which is a paradigmatic system exhibiting spatio-temporal chaos. In particular, let  $V_0$  be a finite region of the chain centered at the origin,  $T_0 > 0$  be a time interval, and define  $\eta_+$  and  $p$  as

$$\eta_+ = \lim_{V_0, T_0 \rightarrow \infty} \frac{1}{|V_0|T_0} \sum_{j=0}^{T_0-1} \eta_{V_0}(S^j x) , \quad p = \frac{1}{\eta_+ |V|} \sum_{j=-T_0/2}^{T_0/2} \eta_{V_0}(S^j x) , \quad (20)$$

where  $V = V_0 \times T_0$ , and  $\eta_{V_0}(x)$  is a properly chosen quantity which in [31] is called the *entropy production rate in  $V_0$*  and is identified with the phase space ones.

contraction rate in  $V_0$ . The following relation was obtained for the steady state probability distribution of  $p$ :

$$\pi_V(p) = e^{\zeta(p)|V|+O(|\partial V|)} , \quad \text{with } \frac{\zeta(p) - \zeta(-p)}{p\eta_+} = 1 \quad \text{and } |p| < p^* , \quad (21)$$

where  $|\partial V|$  is the size of the boundary of  $V$ ,  $p^* \geq 1$  and  $\zeta$  is analytic in  $p$ . This is perfectly analogous to the original FT, except for the boundary term  $|\partial V|$  whose influence should diminish with growing  $V$ .

The question of the validity of relations analogous to Eqs.(20,21) in 2-dimensional fluids is beyond the scope of the present paper. Nevertheless, it seems worthwhile to report our encouraging preliminary results on the validity of a local fluctuation relation for the NS dynamics. In fact, these results make plausible a linear relation with slopes smaller than 1, and indicate that in the NS case, in which dissipation occurs uniformly throughout the system, the local fluctuations may obey laws very similar to those obeyed by the global fluctuations considered in the previous sections. The interest lies in the possibility that, in agreement with the EC, the local fluctuations can be observed also in the NS dynamics, despite their irreversibility.

The first study of a local fluctuation relation to obtain the value of  $c_\infty$  is in [32], and the problem has raised many discussions since.

Let us consider the NS equation on a periodic cell of side  $2\pi$ , and let  $V_0 = [-L/2, L/2] \times [-L/2, L/2]$  be a box with side  $L \leq 2\pi$ . We define the power dissipated in  $V_0$  by the forcing field  $\mathbf{f}$  at time  $t$  as:

$$\hat{p}_L(t) = \int \mathbf{f}(x) \cdot \mathbf{u}(\mathbf{x}, t) \chi_{V_0}(\mathbf{x}) d\mathbf{x} , \quad (22)$$

where  $\chi_{V_0}$  is the characteristic function of  $V_0$  which, in spectral form, is:  $\chi_{V_0}(\mathbf{x}) = \sum_{\mathbf{k}} \chi_{\mathbf{k}}(L) e^{i\mathbf{k} \cdot \mathbf{x}}$ . Defining local vorticity, local palinstrophy and  $\alpha_L$ , respectively, as

$$\begin{aligned} Q_{1,L}(t) &= \int \omega^2(\mathbf{x}, t) \chi_{V_0}(\mathbf{x}) d\mathbf{x} , \\ Q_{2,L}(t) &= \int (\nabla \omega)^2(\mathbf{x}, t) \chi_{V_0}(\mathbf{x}) d\mathbf{x} , \quad \alpha_L(t) = \frac{\hat{p}_L(t)}{Q_{1,L}(t)} , \end{aligned} \quad (23)$$

with  $\omega = \nabla \times \mathbf{u}$ , we propose to take  $\eta_{V_0}(\mathbf{u})$  as proportional to the work per unit time performed by the external force within the region  $V_0$  divided by the corresponding local vorticity, i.e. we propose to take  $\eta_{V_0}(\mathbf{u})$  proportional to  $\alpha_L$ . This is suggested by the facts that such a quantity has a physical meaning, and that the phase space contraction rate can in many systems

be identified with the entropy production rate. In fact,  $Q_{1,L}$  can be called a “local temperature” being a quantity whose value measures the variations of the velocity field around its average. A possible alternative definition is a local version of Eq.(10), like (for instance)

$$\hat{\sigma}_L = 2 \left( \left( \frac{L}{2\pi} \right)^2 \sum_{|k_i| \leq N} |k_i|^2 - \frac{Q_{2,L}}{Q_{1,L}} \right) \cdot \alpha_L + \frac{\int \nabla f \nabla \omega \chi_{v_0} d\mathbf{x}}{Q_{1,L}}. \quad (24)$$

However, several other local versions of Eq.(10) could be defined: *e.g.* the last integral could be replaced by  $\int \nabla^2 f \omega \chi_{v_0} d\mathbf{x}$  or by  $\int f \nabla^2 \omega \chi_{v_0} d\mathbf{x}$ .

Since we approximate the various quantities introduced above by means of truncated Fourier expansions,  $L$  can only take the values  $l\pi/(N-1)$  with  $l = 1, \dots, 2(N-1)$ .

Studying the behaviour of  $\sigma_L = \hat{\sigma}_L / \langle \hat{\sigma}_L \rangle$ ,  $\langle \hat{\sigma}_L \rangle$  being the infinite time average of  $\hat{\sigma}_L$ , one realizes that  $\hat{\sigma}_L$  is essentially proportional to  $\alpha_L$ , with proportionality constant equal to the ratio  $\langle \hat{\sigma}_L \rangle / \langle \alpha_L \rangle$ , because the sum in (24) dominates over the other terms already at moderately large  $L$ . In particular, we performed a number of simulations with  $N = 7$  (i.e. 84 complex Fourier modes) and  $R^2 = 2048$ , and we found that  $\hat{\alpha}_L / \langle \hat{\alpha}_L \rangle$  and  $\hat{\sigma}_L / \langle \hat{\sigma}_L \rangle$  are practically indistinguishable from each other for  $L \geq 5\pi/6$ . The statistics of the fluctuations of  $\hat{\sigma}_L$  was built from a run of  $1.36 \cdot 10^8$  time steps, corresponding to  $2.4 \cdot 10^4$  in  $1/\lambda_{max}$  time units.

As in the case of global fluctuations (cf. Fig.4, and Ref.[22]), we found that the PDFs of the fluctuations of the average of  $\sigma_L$  over times  $T_0$  are not Gaussian (cf. Table 5, and Fig.7), and furthermore that the quantity

$$F(p; V) = \frac{1}{T_0 \langle \hat{\sigma}_L \rangle} \log \frac{\pi_V(p)}{\pi_V(-p)} \quad \text{with} \quad p = \frac{1}{T_0 \langle \hat{\sigma}_L \rangle} \int_t^{t+T_0} \hat{\sigma}_L(s) ds \quad (25)$$

is not linear in  $p$  at small  $V$  (i.e. small  $L$ , or small  $T_0$ ), but it appears to be better and better approximated by a straight line of slope  $c(V)$  as  $V$  grows. Moreover, the slopes of the linear fits of the data appear to converge to values  $c_L$  for  $T_0 \rightarrow \infty$ . Figure 6 illustrates the latter convergence at fixed box size  $L$  and growing  $T_0$ , showing that a linear fit of the data becomes acceptable at sufficiently large  $T_0$ , and suggesting that the slope of the fitting line may converge to a limit value.

Figure 7 shows that the same holds if  $T_0$  is fixed and  $L$  grows, indicating that the nonlinear tails of  $F$ , may possibly be ascribed to non negligible boundary contributions, which become less important at larger  $L$ . In fact, we notice

$T_0$	$L = \pi$	$L = 5\pi/3$
0.58	2.002	1.249
1.75	1.065	1.476
5.27	1.532	1.120
7.81	1.215	1.448
10.74	0.928	1.066

Table 5

Kurtosis of  $\pi_V$  for the cases of Fig.6. These values show that such PDFs are not Gaussian.

that, for any  $V$ ,  $F(p; V)$  is linear in a given neighborhood  $I_0$  of  $p = 0$ , even if strong nonlinearities characterize  $F$  outside  $I_0$ . As  $V$  grows, it seems that the linear region persists, although it changes slope, while the nonlinear tails of  $F$  gradually disappear. Therefore, our data for  $F$  justify a test of the local fluctuation formula (21), in analogy with the theory of Ref.[31]. The result is summarized in Fig.8, where the slopes  $c$  of the linear fits of our data, and their variation with growing  $\tau$  are portrayed. There, we observe that our results for the local fluctuations are consistent with the EC and EC', and with linear relations with limit slopes smaller than 1. Slopes  $< 1$  have also been previously found for local fluctuations in rather different systems, [32].

We conclude by remarking that:

**a.** Our definition of the local phase space contraction rate (24) equals (up to a scaling factor) the physically measurable quantity  $\alpha_L$  for sufficiently large  $L$ , which in our case amounts to  $L = l\pi/6$  for  $l = 5, 6, \dots, 12$ .

**b.** The fluctuations of the local quantities  $\hat{p}_L$  and  $\hat{p}_L/Q_{0,L}$ , with  $Q_{0,L} = \int \mathbf{u}^2(\mathbf{x}, t) \chi_{V_0}(\mathbf{x}) d\mathbf{x}$ , behave in a perfectly analogous way as the fluctuations of  $\hat{\sigma}_L$ . The latter remark is important because in the experimental work of Ref.[16] the quantity which is measured to attempt a check of the FR is essentially the work  $\hat{p}_L$  done by the external forces on a small region  $V_0$  per unit time, rather than the same quantity divided by an effective temperature.

**c.** The fluctuation laws tested in this Appendix concern the (*irreversible and constant friction*) NS equation, and not the (*reversible and fluctuating friction*) GNS dynamics. This is consistent with the validity of the EC, EC'.

Fig. 6. Numerically computed values of  $F(p; V)$ , and corresponding error bars, for  $L = \pi$  (left) and  $L = 5\pi/3$  (right). In each panel we have 5 curves, corresponding to  $T_0 \approx 0.58, 1.75, 5.27, 7.81, 10.74$  (in  $1/\lambda_{max}$  units), ordered clockwise with growing  $T_0$ . Only three curves are clearly distinguishable because the three of highest  $T_0$  practically overlap in their range of coexistence, which shrinks with increasing  $T_0$ .

Fig. 7. Values of  $F(p; V)$ , and corresponding error bars, for  $T_0 \approx 3.7$  (left) and  $T_0 \approx 7.0$  (right) in  $1/\lambda_{max}$  units. In each panel we have 3 curves, corresponding to  $L = \pi, 5\pi/3, 11\pi/6$ , and the values of  $\kappa$  represent the kurtosis of the corresponding PDFs.

Fig. 8. Slopes  $c(V)$  for fixed  $V_0$  as a function of  $T_0$  (in  $1/\lambda_{max}$  time units). The left panel has  $L = 3\pi/2$  and the data are interpolated by  $c = 0.0025 + 0.024/T_0$ . The right panel has  $11\pi/6$  and the data are interpolated by  $c = 0.0043 + 0.022/T_0$ .

## Acknowledgements

We are grateful to S. Ciliberto and C.P. Dettmann for highly stimulating discussions. LR gratefully acknowledges partial support from GNFM. We are particularly indebted to F. Bonetto for suggesting several improvements and for clarifying the meaning of the pairing rule, which resulted in the correction of an error in the manuscript. GG and LR thank B. Dorfman, P. Gaspard, R. Klages, H. van Beijeren and the Max Planck Institute for Physics of Complex Systems, Dresden, for their generous and warm hospitality during the conference “Microscopic Chaos and Transport in Many-Particle Systems”.
