(Received 26 January 2009; published 2 July 2009)

We analyze heat and work fluctuations in the gravitational wave detector AURIGA, modeled as a macroscopic electromechanical oscillator in contact with a thermostat and cooled by an active feedback system. The oscillator is driven to a steady state by the feedback cooling, equivalent to a viscous force. The experimentally measured fluctuations are in agreement with our theoretical analysis based on a stochastically driven Langevin system. The asymmetry of the fluctuations of the absorbed heat characterizes the oscillator’s nonequilibrium steady state and reveals the extent to which a feedback cooled system departs from equilibrium in a statistical mechanics perspective.

DOI: 10.1103/PhysRevLett.103.010601

Cold-damping feedback efficiently reduces the thermal noise motion of an oscillator by applying a viscous force. Since its first application in electrometers [1], it succeeded in a wide variety of devices [2,3], from nano- to macroscopic resonators, and in a variety of implementations, including both optical and electrical forces. In basic research, cold damping is considered in order to reduce below the level of intrinsic quantum fluctuations the uncertainty due to thermal noise of the position of macroscopic bodies [4], and to improve the behavior of gravitational wave detectors [5]. In this Letter we experimentally investigate the fluctuations of thermodynamic quantities of a cold-damped electromechanical oscillator: the resonant-bar gravitational wave detector AURIGA [6]. In particular we verify that they are consistent with recent theories of nonequilibrium phenomena.

After the seminal works of Ref. [7], which introduced the fluctuation relation (FR) concerning the probability density function (PDF) of the entropy production rate in nonequilibrium systems, a large number of papers have been devoted to similar problems (see, for instance, Ref. [8] for a review). One finds that the FR for some properly identified observable (called dissipation function) is quite generally valid in systems of physical interest [9]. After the experimental evidence obtained for dragged colloidal particles [10], electrical circuits [11], and mechanical oscillators [12], the FR has become a standard tool to characterize nonequilibrium systems. Here, following Ref. [13], we focus on the FR for the PDF of the power necessary to maintain a dissipative system in a nonequilibrium steady state (NESS). A specific FR, obtained for the fluctuations of the injected power in a stochastically driven Langevin system [14], was recently confirmed in a simple electrical realization of that model [15]. Actually, this FR accurately fits the fluctuations of the injected power in wave turbulence as well [16]. We also show that the AURIGA detector, which is maintained in a NESS by an external driving in a feedback cooling scheme, can be described as a mechanical oscillator forced by a stochastic driving. We then analyze its behavior and demonstrate that (a) the statistics of its thermodynamic variables show a characteristic asymmetry between positive and negative fluctuations and (b) the statistics of the injected power are in agreement with the FR of Ref. [14]. These results reveal the extent to which a feedback cooled system departs from equilibrium in a statistical mechanics perspective and prove the limits of usual assumption that cold-damped oscillators at temperature $T_0$ are equivalent to higher-loss ones, in thermodynamic equilibrium at a temperature $T_{\text{eff}} < T_0$.

AURIGA is based on a 2.2 $\times$ 10$^3$ kg, 3 m long bar made of a low-loss aluminum alloy (Al5056), cooled to liquid helium temperature $T_0 = (4.6 \pm 0.2)$ K. The fundamental longitudinal mode of the bar, sensitive to gravitational waves, has effective mass $M = 1.1 \times 10^3$ kg and resonance frequency $\omega_0/2\pi \sim 900$ Hz. The bar resonator motion is detected by a capacitive transducer followed by a double stage dc-SQUID amplifier; the displacement sensitivity is about 5 $\times$ 10$^{-20}$ m/Hz over a $\sim$ 100 Hz bandwidth around $\omega_0$, largely limited by thermal noise. The detector can be modeled by three coupled low-loss resonators: two mechanical ones (the bar and a plate of the capacitive transducer) and an LC electrical one [17,18]. The dynamics is described by three normal modes at

Cold-damping feedback efficiently reduces the thermal noise motion of an oscillator by applying a viscous force. In this Letter we experimentally investigate the fluctuations of thermodynamic quantities of a cold-damped electromechanical oscillator: the resonant-bar gravitational wave detector AURIGA [6]. In particular we verify that they are consistent with recent theories of nonequilibrium phenomena.

After the seminal works of Ref. [7], which introduced the fluctuation relation (FR) concerning the probability density function (PDF) of the entropy production rate in nonequilibrium systems, a large number of papers have been devoted to similar problems (see, for instance, Ref. [8] for a review). One finds that the FR for some properly identified observable (called dissipation function) is quite generally valid in systems of physical interest [9]. After the experimental evidence obtained for dragged colloidal particles [10], electrical circuits [11], and mechanical oscillators [12], the FR has become a standard tool to characterize nonequilibrium systems. Here, following Ref. [13], we focus on the FR for the PDF of the power necessary to maintain a dissipative system in a nonequilibrium steady state (NESS). A specific FR, obtained for the fluctuations of the injected power in a stochastically driven Langevin system [14], was recently confirmed in a simple electrical realization of that model [15]. Actually, this FR accurately fits the fluctuations of the injected power in wave turbulence as well [16]. We also show that the AURIGA detector, which is maintained in a NESS by an external driving in a feedback cooling scheme, can be described as a mechanical oscillator forced by a stochastic driving. We then analyze its behavior and demonstrate that (a) the statistics of its thermodynamic variables show a characteristic asymmetry between positive and negative fluctuations and (b) the statistics of the injected power are in agreement with the FR of Ref. [14]. These results reveal the extent to which a feedback cooled system departs from equilibrium in a statistical mechanics perspective and prove the limits of usual assumption that cold-damped oscillators at temperature $T_0$ are equivalent to higher-loss ones, in thermodynamic equilibrium at a temperature $T_{\text{eff}} < T_0$.

AURIGA is based on a 2.2 $\times$ 10$^3$ kg, 3 m long bar made of a low-loss aluminum alloy (Al5056), cooled to liquid helium temperature $T_0 = (4.6 \pm 0.2)$ K. The fundamental longitudinal mode of the bar, sensitive to gravitational waves, has effective mass $M = 1.1 \times 10^3$ kg and resonance frequency $\omega_0/2\pi \sim 900$ Hz. The bar resonator motion is detected by a capacitive transducer followed by a double stage dc-SQUID amplifier; the displacement sensitivity is about 5 $\times$ 10$^{-20}$ m/Hz over a $\sim$ 100 Hz bandwidth around $\omega_0$, largely limited by thermal noise. The detector can be modeled by three coupled low-loss resonators: two mechanical ones (the bar and a plate of the capacitive transducer) and an LC electrical one [17,18]. The dynamics is described by three normal modes at
separate frequencies, 865.7, 914, 953 Hz, with quality factors, respectively, of $1.2 \times 10^6$, $0.88 \times 10^6$, $0.77 \times 10^6$, determined by mechanical losses in the bar and the transducer and by dielectric losses in the electrical components. Each mode is modeled as a series-RLC electrical oscillator with an effective inductance $L$, capacitance $C$, and resistance $R$, which assume different values for the 3 oscillators (Fig. 1). These modes are electromechanical rather than purely mechanical, but each one collects a significant fraction of the energy of the two mechanical resonators. From the detector calibration we estimate that the energy injected by an impulsive excitation of the longitudinal mode of the bar is shared by the 3 modes in the ratio $48:36:16$.

For the sole purpose of improving the electronics stability and easing the data analysis, AURIGA employs an electronic feedback cooling scheme on the detector (Fig. 1), which is equivalent to a viscous force on the oscillators [19]. The dynamics of each electromechanical oscillator is described by the equations

$$
\left( L - L_{in} \right) \frac{d^2 q(t)}{dt^2} + R \frac{dq(t)}{dt} + \frac{q(t)}{C} = V_{T}(t) - V_{d}(t), \quad (1a)
$$

$$
V_{d}(t) = L_{in} \frac{dI_{d}(t)}{dt}, \quad (1b)
$$

$$
I(t) + I_{d}(t) = I_{s}(t), \quad (1c)
$$

where the current $I_{s}$ is the observable, $q$ is the charge on the capacitor, $I = \frac{dq(t)}{dt}$ the current through the inductance $L$, $V_{d}$ is the voltage at the node where the feedback is applied, and $L_{in}$ is the input inductance of the SQUID amplifier. In thermodynamic equilibrium, each oscillator is driven by the stochastic voltage: $V_{T}(t) = \sqrt{2k_{B}T_{0}R}\Gamma(t)$, where $\Gamma$ is a Gaussian white process. This should hold even in our nonequilibrium case, since the feedback cooling concerns only 3 modes, out of the very many degrees of freedom of the thermal bath, and is not expected to significantly affect the thermal noise due to the bath. The noise due to the SQUID can be neglected at moderate feedback gains, as those used in this experiment. The very high quality factor of the oscillators implies that the currents $I_{s}$, $I_{d}$, and $I$ oscillate at $\omega_{s} = 1/\sqrt{LC}$ with amplitude and phase changing appreciable only on time scales of several cycles. Thus, the quasiharmonic approximation $I(t) = \hat{I}(t) \times \sin(\omega_{s}t + \phi(t))$, like the analogous ones for $I_{s}$ and $I_{d}$, seems appropriate. Operatively this is implemented by considering the signal only in a narrow frequency band around $\omega_{s}$. Near resonance, a feedback force equivalent to a viscous damping can be obtained with the feedback current

$$
I_{d}(t) = GI_{s}(t - t_{d}), \quad (2)
$$

where $t_{d} = \frac{\pi}{\omega_{s}}$, and $G \ll 1$. Equation (1b) includes memory effects due to contributions from times $t - t_{d}$, because of the constraints (1c) and (2); in the quasiharmonic approximation we have $I_{s}(t - t_{d}) = \omega_{s}q_{s}(t)$. Hence each oscillator obeys

$$
L \frac{dI_{d}(t)}{dt} + I_{d}(t)[R + R_{d}] + \frac{q_{s}(t)}{C} = \sqrt{2k_{B}T_{0}R}\Gamma(t) \quad (3)
$$

where $I_{d}(t) = \frac{d\hat{q}(t)}{dt}$. Here $R_{d} = G\omega_{s}L_{in}$ expresses the viscous damping on the oscillator due to the feedback loop; the feedback efficiency is defined as $g = R_{d}/R$. The quasiharmonic approximation is valid as long as the feedback damped oscillator is still a low-loss one. In Eq. (3) the driving is the same white process of Eq. (1): this is confirmed experimentally by the Lorentz-shaped power spectrum of the current $I_{s}$ around the resonance [19]. Equation (3) is not invariant under time reversal ($q'_{s} = q_{s}$, $I'_{s} = -I_{s}$, $t' = -t$) and does not satisfy the Einstein relation. Nevertheless, it is formally identical to that describing an oscillator with damping $R + R_{d}$, in equilibrium at the fictitious “effective temperature” $T_{eff} = T_{0}/(1 + g)$. The discrepancy between $T_{eff}$ and the thermal bath temperature $T_{0}$ reveals the nonequilibrium nature of the phenomenon. Hence, the feedback cooled oscillator is usually treated as an equilibrium system, with $T_{eff}$ derived from the experimental value of $\langle I_{s}^{2}(t) \rangle = \frac{2k_{B}T_{0}}{L^2}$, even if no bath at $T_{eff}$ is present.

Multiplying Eq. (3) by $I_{s}(t)$ and integrating between $t$ and $t + \tau$, in the quasiharmonic approximation we get an expression for the average power $P_{\tau} = \frac{1}{2} \int_{t}^{t+\tau} I_{s}(t')V_{T}(t')dt'$ injected by the stochastic thermal force during a time $\tau$:

$$
P_{\tau} = \Delta U_{s} + R + \frac{R_{d}}{\tau} \int_{t}^{t+\tau} I_{s}^{2}(t')dt', \quad (4)
$$

where $\Delta U_{s} = \frac{U(t+\tau) - U(t)}{\tau}$, $U(t)$ being the stored energy

$$
U(t) = \frac{1}{2} L I_{s}^{2}(t) + \frac{1}{2} \frac{q_{s}^{2}(t)}{C} = \frac{1}{2} L I_{s}^{2}(t). \quad (5)
$$

The term proportional to $R$ represents the heat dissipated by the oscillator toward the bath, while that proportional to
By energy conservation we obtain the heat $Q$, absorbed by the oscillator from the bath and averaged in a time $\tau$:

$$Q_\tau = \Delta U_\tau + W_\tau. \quad (8)$$

To study nonequilibrium properties, we focused on the lowest frequency mode out of the three, which is well separated in frequency from the other two and is thus our best approximation of a single oscillator. The sampled current $I_s(t)$ was processed via the AURIGA data analysis and integrated over the resonance in a 10 Hz bandwidth to obtain the current amplitude $\tilde{I}_s(t)$ in the harmonic approximation. From dedicated calibration of AURIGA we measure $L = (1.67 \pm 0.01) \times 10^{-4}$ H and $L_{in} = (1.48 \pm 0.01) \times 10^{-6}$ H. A first set of data covers a continuous 10 day time span in March 2008. The data yield $\omega_r/2 \pi = 865.7$ Hz, $T_{eff} = (21.1 \pm 0.2)$ mK, and decay time $\tau_{eff} = (2.36 \pm 0.04)$ s; hence we estimate $g = 207 \pm 10$, $R = (6.8 \pm 0.5) \times 10^{-3}$ $\Omega$, and $G = (1.74 \pm 0.06) \times 10^{-2}$. The quality factor $\omega_r \tau_{eff}/2 \approx 6.5 \times 10^3$ is high enough to justify the quasiharmonic approximation leading to Eq. (3). Figures 2(a) and 2(b) show the PDF of the energy difference $\Delta U_\tau$ and of the work done by the oscillator $W_\tau$ averaged over growing times $\tau$: they are calculated from Eqs. (5) and (7) after dividing the experimental data in contiguous time intervals of duration $\tau$. Figure 2(c) shows the corresponding heat $Q$, exchanged by the oscillator with the bath averaged over the time $\tau$, computed via the energy conservation of Eq. (8). The fluctuations of $Q$, are asymmetric, as expected for a NESS. Figure 2 also shows excellent agreement with numerical simulations of Eq. (3).

The PDF of $\Delta U_\tau$ is symmetric with respect to zero, as for an equilibrium oscillator. It has exponential tails which decay faster for longer $\tau$. The PDF of $W_\tau$ is highly asymmetric. From Eq. (7) and $\langle \tilde{I}_s^2(t) \rangle = 2k_BT_{eff}/L$ we infer that $W_\tau$ is positive and has mean value $\approx 0.84 k_BT_{eff}/s$. Hence, $Q_\tau$ takes negative values only for short integration times, with the characteristic time scale given by the cold-damped oscillator decay time $\tau_{eff} = 2L/(R + R_d)$. For $\tau \gg \tau_{eff}$ the contribution of the time averaged energy is negligible.

So in the presence of feedback ($R_d > 0$) there is a net heat transfer from bath to oscillator: this is the energy flux that feeds the NESS and makes the PDF of the heat asymmetric. On the contrary, if the feedback were switched off, we would have $R_d = 0$ and $W_\tau = 0$; hence $Q_\tau = \Delta U_\tau$ from Eq. (8). In this case the PDF of $Q_\tau$ would be symmetric with respect to its (zero) mean value, as in Fig. 2(a), but with $T_{eff} = T_0$.

The PDF of the injected power $P_\tau$ is essentially identical to that of $Q_\tau$, shown in Fig. 2(c), since $P_\tau = Q_\tau$ when $g \gg 1$. Notice that of the two terms in Eq. (4), only $\Delta U_\tau$ is responsible for the negative values of $P_\tau$. Thus, large positive values of $P_\tau$ are dominated by the contribution of the dissipated power [the integral in (6)] more than they are for small values of $P_\tau$. The transition between these two regimes affects the shape of the PDF, which has been calculated in Ref. [14]. In a limit of large integration times it obeys

$$f(\tilde{\tau}) = \lim_{\tau \to \infty} \frac{\ln{PDF(\tilde{\tau})}}{\tau} = \begin{cases} -\gamma(1 - 2\tilde{\tau}) & \text{if } \tilde{\tau} \leq 1/2 \\ -\frac{\gamma}{4\tilde{\tau}}(\tilde{\tau} - 1)^2 & \text{if } \tilde{\tau} \geq 1/2 \end{cases},$$

(9)

where $\tilde{\tau} = P_L/(k_BT_0R)$ is the reduced injected power and $\gamma = (R + R_d)/L = 2/\tau_{eff}$. A remarkable singularity, located at $\tilde{\tau} = 1/3$, is present in the second derivative.
of \( f(\tilde{\varepsilon}_\tau) \). In Fig. 3(a) we plot the quantity \( D_2(\tilde{\varepsilon}_\tau) = \partial^2 f(\tilde{\varepsilon}_\tau)/\partial \tilde{\varepsilon}_\tau^2 \) evaluated from the output of AURIGA in the time span May 2005–May 2008; here \( T_{\text{eff}} = (22 \pm 1) \text{ mK} \) and \( \tau_{\text{eff}} = (2.4 \pm 0.2) \text{ s} \). A valley is clearly visible in the experimental data, which we interpret as a precursor of the asymptotic singularity. The agreement with the asymptotic theory consistently improves as \( \tau/\tau_{\text{eff}} \) grows. This indicates that the asymptotic relation of Eq. (9) holds even in the presence of a harmonic pinning potential [14] (Fig. 3). In conclusion, we demonstrate that the actively cooled AURIGA detector is well described by the Langevin model of Eq. (3), which led us to evaluate the power \( P_\tau \) injected by the stochastic thermal force, the work \( W_\tau \) done on the feedback, and the heat \( Q_\tau \) exchanged with the thermal bath. The statistics of \( P_\tau \) are consistent with Eq. (9), and with the consequent nonlinearity of the FR. The fluctuations of \( Q_\tau \) are asymmetric as expected for a NESS.

We acknowledge the contribution of the European Research Council under the European Community’s Seventh Framework Programme (FP7/2007–2013)/ERC grant agreement no. 202680.

FIG. 3 (color online). Comparison between theory (dashed lines) and experimental data at increasing values of the ratio \( \tau/\tau_{\text{eff}} \) = 1.2, 2.0, 2.9, 3.7: the data set is, respectively, 828, 768, 729, 457 days long. (a) Plot of second derivative \( D_2(\tilde{\varepsilon}_\tau) \); the experimental data of \( D_2 \) for \( \tau/\tau_{\text{eff}} = 2.0 \) are not shown for clarity. (b) Plot of \( \rho(\tilde{\varepsilon}_\tau) \). Vertical error bars on experimental points of both plots come from statistical uncertainty. The shaded areas on the theoretical curves represent the uncertainty due to the experimental errors on the parameters, \( \tau_{\text{eff}}, T_{\text{eff}}, \) and \( T_0 \).
