Abstract

The present paper discusses the sensitivity of the global and local stability of a hybrid single layer grid shell to a set of equivalent geometric nodal imperfections representative of the actual structural and construction imperfections. Since imperfections are hard to be measured and controlled in experimental facilities, the stability of the structure is extensively investigated in numerical experiments. The imperfections are set by means of the so-called Eigenmode Imperfection Method. The method parameter space is densely sampled, and different structural models are adopted. The results are given in terms of two bulk parameters: the well established Load Factor and the proposed Buckling Shape Length, the latter being introduced to provide a continuous measure of the degree of “globalness” of the instability. Significant and non monotonic changes in both the Load Factor and Buckling Shape Length are observed versus the growth of the imperfection amplitude. Further, a local metrics of the grid shell geometry, named nodal apex, is introduced for each structural node. Special emphasis is given to the analysis of the correlation between the apex of the initial imperfect geometry and the apex of the deformed shape at collapse. The observed high correlation suggests that the mechanical behaviour of the imperfect grid shell is significantly influenced by this local geometrical feature.

Keywords: single layer grid shell, buckling instability, equivalent geometric nodal imperfection, Eigenmode Imperfection Method

Nomenclature

κ	cotangent of the nodal angle
0	superscript for the perfect geometry

1. Introduction

Buckling instability is the Ultimate Limit State (ULS) that drives the design of Single Layer Grid Shells (SLGS) [1]. The SLGS buckling instability has been early recognized to be highly sensitive to imperfections [1]. Codes and Standards (e.g. [2],[3]) actually recommend to take into account the effects of imperfections in the structural design of grid shells. Imperfections can be ascribed to imperfect constraints, single member mechanical imperfections, loading imperfections, or geometrical ones. In particular, geometrical imperfections can be induced by single member curvature or nodal imperfections, e.g. the ones due to factory defects or assembly tolerances. Generally speaking, the geometrical imperfections result in a nodal deviation from design. To the authors' best knowledge, a statistical characterization of these nodal deviations as a field of nodal random variables is not available in the literature for SLGS, while detailed measurements and related statistics have been recently proposed for continuous shells (e.g. [4]). Hence, a so-called Equivalent Geometric Nodal Imperfection (EGNI) is usually adopted in the design practice of SLGS. In a worst case scenario perspective, EGNI is assumed to be a deterministic, semi-empirical imperfection field aimed at inducing the lowest load factor. In some early studies, e.g. [5], the worst shapes of imperfections for simple space trusses have been obtained in closed form solution. At the same time, others studies, e.g. [6], initiated the search of the worst case imperfection field by means of numerical experiments.

Different methods are currently available to assign the design EGNI. Some authors [7, 8] classify these methods into three categories: i. the so-called random imperfection mode method, ii. the Consistent Imperfection Mode

18 Method (CIMM) and iii. the Eigenmode Imperfection Method (EIM). According to both CIMM and EIM, the imper-
 19 fection field is described in term of a deterministic spatial distribution normalized to unit (or imperfection shape, in
 20 literature) and of an imperfection amplitude. The EIM is the most popular one in the design practice. It is critically
 21 reviewed, applied and discussed in the present study.

22 The normalized *spatial distribution* is assumed to be equal to one of the buckling eigenmodes of the perfect struc-
 23 ture evaluated by a Linear Buckling Analysis (LBA). The first eigenmode corresponds to the lowest eigenvalue, i.e.
 24 to the lowest load multiplier. For this reason, it is conjectured to be representative of the most critical imperfection
 25 shape, at least at the initial stage of the buckling. Using the first eigenmode is common design practice, and has
 26 been used for instance in the design of existing grid shells, e.g. [9, 10]. Nevertheless, some researchers [11, 12, 13]
 27 have obtained lower failure loads adopting higher mode shapes as the imperfection. The EIM can be extended by
 28 shaping the imperfection according to a linear combination of two or several mode shapes. According to Bulenda and
 29 Knippers [14], “there are apparently no rules on how to combine the eigenmodes to find the decisive imperfection.
 30 Thus the engineer has to go the long way of computing the failure loads for different combinations of eigenmodes to
 31 develop a feeling for the imperfection sensitivity of the structure and for the choice of the proper imperfection”.

32 The *imperfection amplitude* is usually defined as the maximum deviation from the perfect geometry along the
 33 direction normal to a reference surface. It is usually scaled with respect to the SLGS span length L , even if some
 34 authors, e.g. [15], normalize it by the equivalent shell thickness. A huge variability of the imperfection amplitude can
 35 be recognized in the design practice. Let us provide some examples: in their seminal work, Bulenda and Knippers
 36 [14] provide $L/500$ as an example of reasonable value; more recently, an imperfection of 3 mm has been chosen in
 37 [16], looking at the tolerance used in the construction of two steel grid shells, the Schubert Band [17] and the Great
 38 Court at the British Museum [9]. Bearing in mind that a spherical cap with $L = 30.5$ m is adopted in [16], a very small
 39 imperfection amplitude of about $L/10000$ follows. Face to such a variability, a number of recent parametrical studies
 40 [14, 8, 13, 15, 18, 7] have investigated the sensitivity of the SLGS instability to the EGNI amplitude. In the cited
 41 studies, the sensitivity of the Load Factor (LF), i.e. the load multiplier at the critical point, is quantitatively evaluated,
 42 while the corresponding deflection field is discussed in qualitative terms only. A non exhaustive collection of the
 43 results available in literature is provided in Figure 1, where the Load Factor LF/LF^0 is plotted versus the scaled im-
 perfection amplitude α/L , being LF^0 the load factor of the perfect SLGS, i.e. at $\alpha = 0$. The studied synclastic SLGS

Figure 1: Scaled Load Factor (LF/LF^0) versus the scaled imperfection amplitude α/L : studies in literature

44 are first categorized in two types according to the geometry of the reference surface, i.e. domes with double curvature
 45 and barrel vaults with single curvature. A further categorization refers to the truss arrangement: Schlaich and Schober
 46 (SS, [19]) hybrid SLGS having quadrangular fields diagonally braced by prestressed cables, and Kiewitt-8 (K8) or
 47 reticulated (RET) grid shells having triangular fields. The reviewed studies adopt Geometrically Nonlinear Analysis
 48 (GNA) and/or Geometrically and Materially Nonlinear Analysis (GMNA) to evaluate the effect of the imperfection

50 on the buckling instability. It is worth pointing out that, in the cited studies, the amplitude is assumed to be signed.
 51 Domes are by far less sensitive than barrel vaults to the sign of the amplitude. The LF for barrel vaults shows a
 52 monotonic decreasing trend for positive amplitudes. The LF for domes abruptly decreases for small amplitudes, but
 53 its trend versus α is no longer monotonically decreasing at least for two setups when GNA is adopted and medium
 54 to large amplitudes (e.g. $\alpha \geq 1/500$) are considered. Face to this general trend, local minima or maxima cannot be a
 55 priori excluded because the considered range of imperfection amplitude is not densely sampled.

56 To the authors' best knowledge, the EIM is currently codified in two standards, i.e. the Eurocode 3: Design of
 57 steel structures - Part 1-6: Strength and stability of shell structures [3] and the Technical specification for reticulated
 58 shells JGJ61-2003 [2]. While in [2] the fundamental mode shape is prescribed, in [3] the "eigenmode-affine pattern",
 59 i.e. the buckling mode shape associated to the lowest eigenvalue, should be used as the imperfection shape "unless a
 60 different unfavourable pattern can be justified". In particular, [3] echoes Bulenda and Knippers: "If the most unfavor-
 61 able pattern cannot be readily identified beyond reasonable doubt, the analysis should be carried out for a sufficient
 62 number of different imperfection patterns, and the worst case should be identified." The imperfection amplitude for
 63 SLGS is explicitly codified only in [2]: the maximum geometric imperfection that is caused by construction should
 64 be restricted within $L/300$. Finally, both codes allow to adopt different kind of structural analysis with increasing
 65 expected accuracy, i.e. LBA, GNA, GMNA, to evaluate the effects of the EGNI on the buckling stability.

66 According to the writers, some questions immediately follow the state of the art shortly reviewed above.
 67 Does the conjectured rule "the higher the imperfection, the lower the load factor" always hold? Or, in other terms, do
 68 local maxima or minima exist in the trend of the LF versus the imperfection amplitude? Does such a trend reflect a
 69 change in the buckling shape at collapse? And does the imperfection amplitude also involve a switch from global to
 70 local instabilities? Does a value of the imperfection amplitude exist below which the buckling stability is not affected
 71 by the imperfections? In which way the choice and combination of the buckling mode shapes affect the buckling sta-
 72 bility? In which way the different methods of structural analysis propagate the effects of the EIM-based imperfections
 73 on the buckling stability? Finally, does a general connection based on a sound mechanical reading can be recognized
 74 between the adopted EGNI field and the simulated Buckling Limit State?

75 The present study aims at shedding some light on such issues. In particular: i. the EIM is critically discussed
 76 by densely sampling its free parameters, i.e. the imperfection amplitude and its spatial distribution. The effects on
 77 the buckling ULS are scrutinized, in terms of both load factor and deformed shape of the SLGS; ii. the sensitivity of
 78 different structural models (LBA, GNA, GMNA) to the EIM parameters is investigated; iii. the EGNI amplitude and
 79 its spatial distribution are correlated with the mechanical response of the grid shell, and with its deflection at collapse
 80 in particular.

81 In Section 2 the modelling and computational approach are briefly recalled. The structural setup selected for the
 82 application is described in Section 3 together with the parametric analysis plan and the bulk parameters selected for
 83 post processing. The results of the sensitivity analysis are provided in Section 4.3, while a mechanical insight on the
 84 results is proposed in Section 4.4. Finally, conclusions and perspectives are outlined in Section 5.

85 2. Modelling approach

86 2.1. Structural modelling

87 Three structural models of increasing complexity and accuracy are considered and briefly recalled in the following
 88 in their discrete form:

89 **Linear Buckling Analysis (LBA)** The linear buckling analysis solves the eigenvalue problem

$$90 \quad \left[\mathbf{K}_e + \lambda \mathbf{K}_g(\sigma) \right] \Phi = 0, \quad (1)$$

91 where λ is the vector of load factors and Φ is the matrix of the associated buckling mode shapes. The geometric
 92 stiffness $\mathbf{K}_g(\sigma)$ is a function of the stress field σ . \mathbf{K}_g is evaluated through a static analysis that solves the
 equation

$$93 \quad \left[\mathbf{K}_e + \mathbf{K}_g(\sigma_0) \right] \delta = \mathbf{Q}$$

where \mathbf{K}_e is the elastic stiffness, $\mathbf{K}_g(\sigma_0)$ accounts for the initial prestress σ_0 , if any, and \mathbf{Q} is the applied load.

Geometrically Nonlinear elastic Analysis (GNA)

$$[\mathbf{K}_e + \mathbf{K}_g(\delta)] \delta = \mu \mathbf{Q} \quad (3)$$

where the geometric stiffness $\mathbf{K}_g(\delta)$ is a function of the displacement field $\delta(\sigma)$ and μ is the load multiplier that increases along the simulation.

Geometrically and Materially Nonlinear Analysis (GMNA)

$$[\mathbf{K}_e(\delta) + \mathbf{K}_g(\delta)] \delta = \mu \mathbf{Q} \quad (4)$$

In the study, the steel nonlinear stress-strain relation is modelled by a bilinear law (elastic-perfect plastic). Due to the progressive yielding of members under monotonically increasing load, the overall structural behaviour is described by a tangent stiffness matrix \mathbf{K}_e which softens for increasing displacement field $\delta(\sigma)$.

In the following, when applied to the imperfect geometry, the above structural models are named LBIA, GNIA and GMNIA, according to [3].

The structural analysis is performed by means of the finite-element code ANSYS ©v14.0. The Load Control (LC-NR) and the Arc-Length (AL-NR) path-following procedures are applied, where the iterative convergence is accomplished in both cases at each step by means of the standard Newton Raphson (NR) method [20].

The computations are carried out on a single Intel i7-4702MQ, 2.20 GHz CPU with 8 GB of RAM memory.

2.2. Definition of the observables

Besides local observables in space, two bulk parameters are adopted in order to provide a synthetic description of the mechanical behaviour of the grid shell versus the nodal imperfections. They are defined in the following with reference to a grid shell with P structural nodes having coordinates $\mathbf{X}(p) = \{x_p, y_p, z_p\}$ ($p = 1, P$).

Load Factor (LF). The load factor is the most relevant parameter usually considered in Buckling Limit State. Its definition is herein recalled:

$$\mathbf{Q}^u = LF \mathbf{Q} \quad (5)$$

where \mathbf{Q}^u is the ultimate buckling load and \mathbf{Q} is the load condition as defined in Section 3. Within LBA, the Load Factor is equal to $LF = \lambda^1$, i.e. the lowest eigenvalue, which corresponds to the buckling mode shape ϕ^u . Within both GNA and GMNA, the Load Factor is equal to $LF = \mu^u$, being μ^u the load multiplier that induces the collapse ($dQ/d\delta = 0$ in a selected reference node), i.e. reaching a limit point, and δ^u the corresponding displacement field.

Buckling Shape Length (BSL). Usually grid shell instability is categorized according to the amount of nodes or structural members involved in the collapse. Besides the single-member buckling [21], “local” or “global” instabilities can occur, where the former involves the snap-through of a single node or of the surrounding ones, while in the latter the structure buckles as a whole. More precisely a global collapse is the one having large nodal displacements almost uniformly spread along the whole structure. Conversely, a local collapse is the one having large nodal displacements clustered in limited regions. Furthermore, a combination of the above can occur, because SLGS optimization tends to produce a condition in which local and global collapses are close to each other [5, 1]. In order to provide a quantitative, continuous measure of the degree of “globalness” of the instability, or conversely of its “localness”, a new observable, called Buckling Shape Length, is proposed. The BSL is defined here as

$$BSL = \frac{3}{P^2 L} \sum_{i=1}^P \sum_{j=1}^P \left[\sqrt{(x_i - x_j)^2 + (y_i - y_j)^2 + (z_i - z_j)^2} \frac{|\varphi_j|}{|\hat{\varphi}|} \right], \quad (6)$$

where subscripts i and j refer to two generic nodes, x , y and z are their coordinates, φ_j is the value in the j -th node of the generic buckling shape φ and $|\hat{\varphi}|$ is the maximum value of the latter. φ can be the buckling mode

129 shape ϕ'' or the structural deflection at collapse δ'' , depending on the adopted structural model. According to
 130 Eq. (6), the BSL is bounded within the range [0 1].
 131 The higher the BSL, the higher the degree of globalness of the collapse mechanism, in the sense that the
 132 deflection shows high values at spaced structural nodes. For the sake of clarity, the BSL is applied to some
 synthetic 1D deflection fields $\varphi(x)$ in the following, and the results are shown in Figure 2. In particular, in

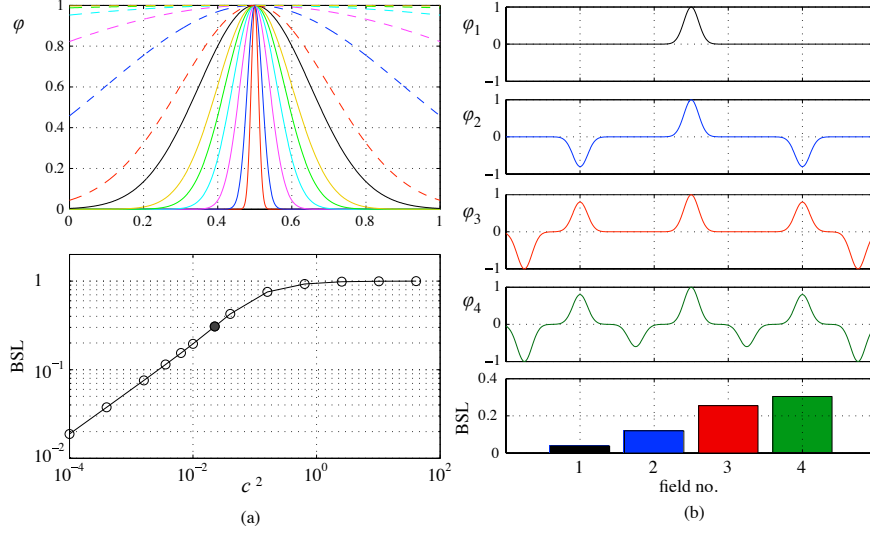

Figure 2: Buckling Shape Length evaluated for test case 1D fields: gaussian field (a), multi maxima field (b)

133 Figure 2-a the field is analytically expressed by the normalized gaussian function $\varphi(x) = \exp -\frac{(x-b)^2}{2c^2}$ having
 134 constant localization parameter $b = 0.5x/L$ and increasing size parameter $1e - 2 \leq c \leq 6.5$. The larger the bell
 135 width, the higher the BSL value, and $\lim_{c \rightarrow 0} BSL = 0$, $\lim_{c \rightarrow \infty} BSL = 1$. In particular, if most of the bell is
 136 within the x range ($c \leq 0.15$, black line and point), the BSL linearly depends on c^2 . The synthetic fields φ_i in
 137 Figure 2-b mimic in 1D the typical buckling mode shapes of SLGS domes (see e.g. Fig. 8-3a for the perfect
 138 setup adopted in this study). They are characterized by multiple local maxima (or minima) and are arranged for
 139 increasing degree of globalness. Once more, BSL shows its ability to provide a measure of such a globalness.
 140 Once the BSL for the perfect structure is defined, the effects of the EGNI on the degree of globalness of the
 141 collapse mechanism can be quantitatively assessed.
 142

143 3. Benchmark description

144 The choice of the geometrical and structural setups of the perfect SLGS to be adopted as benchmark aims at
 145 obtaining a form-resistant and slender structure, for which the buckling instability in the elastic regime is expected
 146 to prevail on the yielding failure. The perfect geometry in relation to the load condition, the structural element cross
 147 section, the internal joints are all chosen for this purpose. A Schlaich and Schober [19] hybrid SLGS is selected as a
 148 suitable reference to build the benchmark setup coherently with the aims above.

149 3.1. Geometrical setup

150 The perfect geometry of the investigated single-layer grid shell is shown in Figure 3. The analytical form of the
 151 reference continuous dome (Fig. 3-a) belongs to the translational surface type, having a parabola as both the directrix
 152 and generatrix, i.e. it is a paraboloid. Its main geometrical parameters are: span length $L = 30$ m, span to rise ratio
 153 $L/f = 8$ (Fig. 3-d).

154 The perfect discrete grid shell geometry results from the point wise sampling of the dome surface in P structural
 155 nodes ($p = 1, P$) along the directions of the directrix and generatrix having coordinates $\mathbf{X}^0(p) = \{x_p^0, y_p^0, z_p^0\}$, where the

superscript 0 refers to the perfect setup. The nodal coordinates are rounded to 6 decimal places in order to describe the perfect geometry with a precision higher than the considered lowest imperfection amplitude ($\alpha = 1e - 5$ m, see Sect. 3.3). The nodes are connected along the directions of the directrix and generatrix by straight segments resulting in elemental planar quadrangular fields [22], having a characteristic length $l \approx 1.5$ m (Fig. 3-b). Each quadrangular field is braced by two diagonal cables, as shown in Figure 3-c.

Figure 3: Setup geometry: reference continuous shell surface (a), discrete grid shell surface (b, shown without cables), close-up view of a part of the dome including diagonal cables (c), section along the meridian vertical plane (d)

The mechanical performances of both continuous shells and grid shells, including their stability, are mainly driven by their geometry. While the geometry of continuous dome shells is described by well-defined quantities, their application to discrete grid shells is not straightforward. The angle between members located along the meridian lines has been defined by [23] for single-layer spherical domes having triangular grid arranged along meridians and rings. This angle mimics the meridian simple curvature of the corresponding reference surface. It is recognized to be highly influential on the grid shell buckling instability. In the following, a preliminary attempt is paid to define nodal quantities analogous to the gaussian curvature and the surface normal unit vector. The definition holds for any kind of shell geometry and for grids having four members connected in each node. The nodal apex $K(p)$ [m^{-2}] (Figure 4) mimics at each node p the gaussian curvature in the continuous analogy. The nodal direction $\nu(p)$ mimics at each node the normal unit vector. With reference to Figure 4-a, which represents the p -th node and its four adjacent nodes, the nodal apex $K(p)$ is defined as follows:

$$K(p) = \kappa_1 \kappa_2, \quad (7)$$

where $\kappa_1 = \cot(\mathcal{W}\widehat{p}\mathcal{E}/2)$ and $\kappa_2 = \cot(\mathcal{S}\widehat{p}\mathcal{N}/2)$ (Fig. 4-b). The choice of the cotangent function assures the value of K is in the range $[0 \infty]$. In particular, $K = 0$ if one of the angles above is equal to π , while $K = \infty$ if one of the angles is equal to 0. As for the nodal direction, the unit vector $\nu(p)$ is determined from the intersection of two planes λ and β (Fig. 4-c), respectively normal to the planes $(\mathcal{W}\widehat{p}\mathcal{E})$ and $(\mathcal{S}\widehat{p}\mathcal{N})$. The positive direction of $\nu(p)$ is upward and follows from counterclockwise ordering of the adjacent nodes, i.e. $\mathcal{E}-\mathcal{N}-\mathcal{W}-\mathcal{S}$. The signs of κ_1 and κ_2 is determined through projection of the $(\mathcal{W}\widehat{p}\mathcal{E})$ and $(\mathcal{S}\widehat{p}\mathcal{N})$ bisectors on $\nu(p)$. In Figure 5, the gaussian curvature of the reference continuous shell surface and the nodal apex of the discrete grid shell are compared showing a perfect equivalence.

3.2. Structural setup

The grid of quadrangles is formed by steel beams. These are diagonally braced by prestressed cables. The structures are covered with glass. The glass panels do not have structural function but have to be intended as dead load only.

The main properties of the structural elements are given in Table 1, together with the corresponding Finite Element adopted in the ANSYS® code. The beam cross section mimics the ones usually used by [19, 14], i.e. a solid rectangular cross section. The 3D beam elements are based on Timoshenko beam theory and adopts a cubic shape function. The cables are modelled by 3D tension-only trusses within non linear analysis.

The whole structure is assumed to be hinged at the boundaries, while the joints between steel bars are modelled as rigid, as usually done in the literature [14, 18, 8]. In fact, the joint type is expected to lightly affect the buckling

Figure 4: Definition of the nodal direction $v(p)$ and the nodal apex $K(p)$

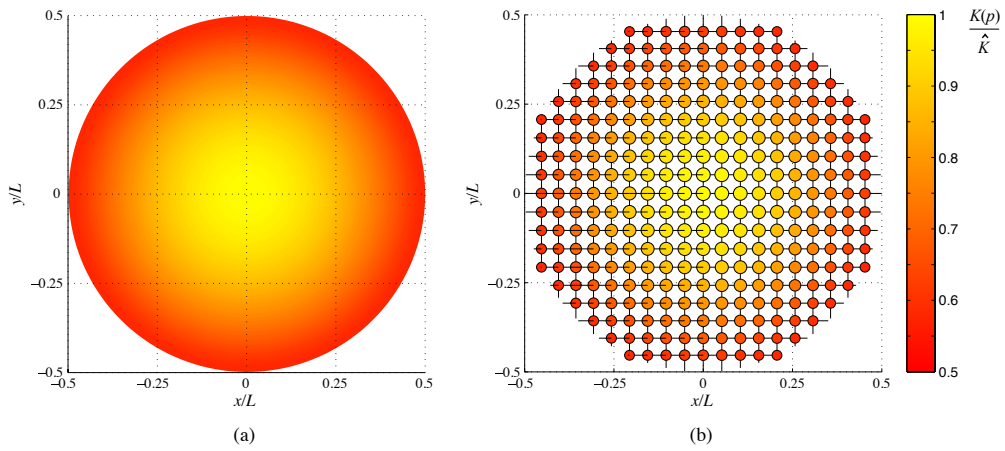

Figure 5: Setup geometry: gaussian curvature of the reference continuous shell surface (a), nodal apex $K(p)$ of the grid shell (b)

189 behaviour of the SLGS for the specific adopted geometrical and structural setup.

The constitutive model of the steel is linear elastic - perfect plastic, with a yield strength equal to $f_y = 355$ MPa,

Table 1: Mechanical properties of the structural elements

element type (ANSYS©nomenclature)	Area [m ²]	Inertia [m ⁴]	mass [kg/m]
beam (BEAM188)	$2.5e-3$	$5.2e-7$	19.6
truss (LINK180)	$1.6e-4$	–	1.25

190 Young's modulus $E = 2.1e+5$ MPa and Poisson's ratio $\nu = 0.3$. The diagonal cable prestressing is equal to $\sigma_0 = 100$
 191 MPa. The dead load g of structural steel members and of 20 mm-thick glass glazing is set equal to 0.5 KN/m².
 192 As for the live load s , a uniform snow load $s = 0.75$ kN/m² is applied on the structure. A symmetrical load case
 193 $q = 1.3g + 1.5s$ is applied to the structure. The resultant p -th nodal load is defined as $Q_p = \int_A q da \approx 4000$ N, being A
 194 the quadrangle surface.
 195

196 **3.3. Parametric analysis plan**

197 Following the Eigenmode Imperfection Method, the equivalent nodal imperfection field $\eta(p)$ is generally ex-
 198 pressed as

$$\eta(p) = \alpha \left[k \phi^{0,i}(p) + (1 - k) \phi^{0,j}(p) \right], \quad (8)$$

199 where $\phi^{0,i}(p)$ and $\phi^{0,j}(p)$ are two buckling mode shapes of the perfect structure, k is the weighting factor of the
 200 two mode shapes, $\alpha = \alpha^* L$ is the amplitude of the imperfection, and α^* its dimensionless counterpart. The nodal
 201 coordinates of the resulting imperfect grid shell are $\mathbf{X}(p) = \mathbf{X}^0(p) + \eta(p)$.

202 Figure 6-a,b shows the performed computational experiment grid in the $\alpha - i$ (setting $k = 1$) and $\alpha - k$ (setting
 203 $i = 1, j = 2$) parameter planes, respectively. The investigated values range in the intervals $1e - 5 \leq \alpha \leq 3e - 1$ m,
 204 corresponding to $1/3e - 6 \leq \alpha^* \leq 1/100$, $0 \leq i \leq 20$, and $0 \leq k \leq 1$. In other terms, first a single mode shape is
 205 adopted as imperfection shape for each of the first 20 buckling modes and for 29 different values of the imperfection
 206 amplitude. Second, 2 modes are retained, and 11 convex combinations between them are adopted as imperfection
 207 shape for 29 different values of the imperfection amplitude. A total number of 957 imperfect setups is considered.
 208 Each setup is analyzed by means of the three structural models described in Section 2.1, i.e. by performing 2871
 209 computational simulations. The stacked histograms of the CPU time are shown in Figure 6-c for each structural
 210 model. The mean values of the CPU time required for a single LBA, GNA and GMNA are $\bar{\Delta}t = 3.9, 46.26$ and 48.5
 211 s, respectively. The overall CPU time is equal to about 26h 13' 27".

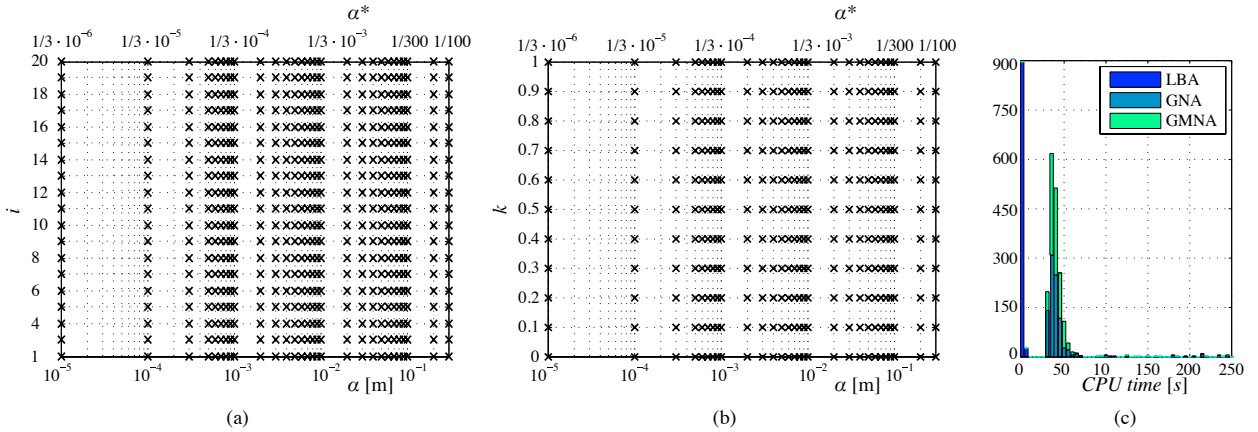

Figure 6: Discretization of the $\alpha - i$ parameter plane (a), $\alpha - k$ parameter plane (b), stacked histograms of the CPU time for a single simulation (c)

212

213 **4. Application and results**

214 **4.1. Perfect setup**

215 The eigenvalues λ (a) and BSL (b) of the first 20 buckling modes of the perfect structure obtained by LBA are
 216 collected in Figure 7. The modes are categorized with respect to the main features of their shapes, i.e., by identifying
 217 symmetric patterns with respect to the generatrix and directrix or to the diagonals of the quadrants defined by the
 218 generatrix and directrix. The first seven modes have eigenvalues very close to each other, while from mode 9 an
 219 abrupt increase in the LF value can be observed (Figure 7-a). It is worth pointing out that the modes labelled with red
 220 circles appear in couples with the same eigenvalue and mode shapes rotated of 90 degrees. Figure 7-b highlights the
 221 presence of both global and local modes. The first two modes show the highest degree of globalness.

222 A deeper insight into the first three buckling mode shapes is shown in Figure 8. On one hand the first and second
 223 mode shapes are clearly global, i.e. the values close to unit are almost uniformly spread along the whole structure
 224 (Sect. 2.2). On the other hand, the third mode shape (Fig. 8-c1) has the values close to unit clustered in two limited

Figure 7: Eigenvalues λ (a) and BSL (b) of the first 20 buckling modes of the perfect structure by LBA

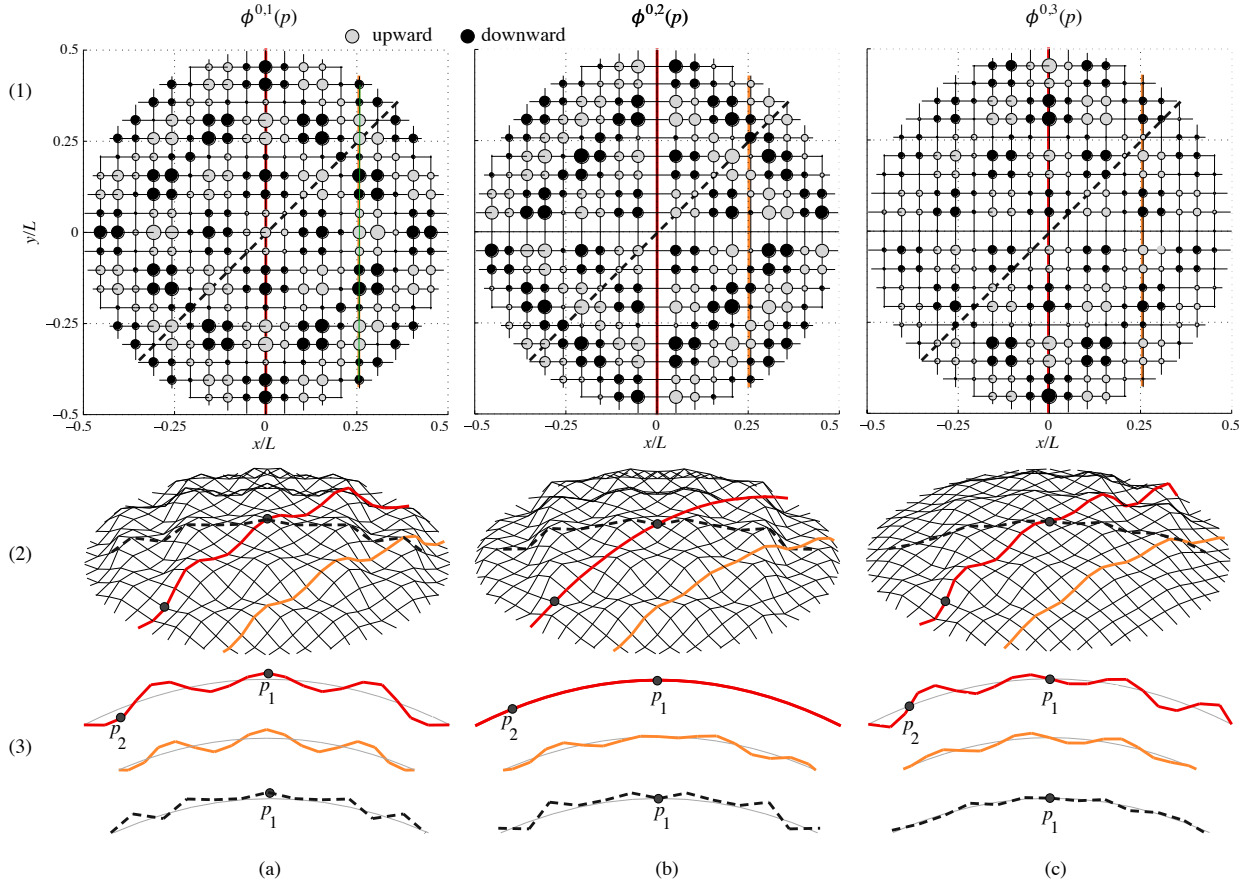

Figure 8: First ($\phi_{1,0}$, a), second ($\phi_{2,0}$, b) and third ($\phi_{3,0}$, c) buckling mode shapes of the perfect structure by LBA

225 regions. These features agree with the low value of the BSL measure. The first one has a symmetrical mode shape
 226 with respect to the directrix and generatrix directions, while the second mode shape is antisymmetric with respect

227 to both directrix and generatrix, while it is symmetric with respect to the diagonals of the quadrants defined by the
 228 directrix and generatrix. The third mode shape is symmetric with respect to the directrix and antisymmetric with
 229 respect to the generatrix (or vice versa).

230 Furthermore, the eigenvalues of the modes have nearly the same value ($\lambda^{0,1} = 3.774$, $\lambda^{0,2} = 3.776$, $\lambda^{0,3} = 3.788$),
 231 even though the corresponding mode shapes are quite different. This confirms what already observed in [14]: several
 232 buckling modes can occur at nearly the same load level and can nearly equally contribute to the deformed shape
 233 at collapse. In other words, a selection criterion based on LF only is not decisive, and at the same time the BSL
 234 values provide more information about mode properties, but they do not directly suggest any complementary criteria.
 235 Hence, in the perspective of the EIM application, the first mode(s) criterion remains the default one usually adopted in
 236 practice. We believe that a correct a-priori choice among modes having almost the same eigenvalue requires additional
 237 knowledge and selection criteria.

238 The load multiplier μ - nodal deflection δ paths of the perfect grid shell obtained by GMNA analysis are plotted
 239 in Figure 9-a, for both Load Control (LC-NR) and Arc-Length (AL-NR) path-following procedures. The nodal
 deflection refers to the node where the displacement is known to be the maximum (red circle in Fig. 9-b). For

Figure 9: Load multiplier - deflection paths (a) and ultimate deflection field $\delta^u(p)$ (b) of the perfect structure by GMNA

240 the sake of brevity, the results obtained by GNA are not included, being nearly the same to the ones by GMNA. In
 241 other words, plasticity does not take place in the adopted perfect setup, coherently with its slenderness (Section 3).
 242 As anticipated, a predominant single mode contribution cannot be recognized in the ultimate deflection field $\delta^u(p)$,
 243 (cfr. Fig. 9-b in comparison with Fig. 8). This is expected bearing in mind the very close values of λ for the first
 244 modes (Fig. 7-a). While the LC-NR is able to follow the μ - δ up to the critical point u , the AL-NR is able to describe
 245 the post critical branch too. Both numerical approaches approximate the same critical limit point. Bearing in mind
 246 that the study is focused on the critical condition, that it implies a large number of numerical experiments, and that
 247 the AL-NR involves computational costs approximatively 50 time higher than the LC-NR, the latter is retained in the
 248 following.
 249

250 4.2. Imperfect setup: α - i sensitivity analysis

251 In this section, we first evaluate the dome stability in the parameter plane α - i . The nodal imperfection field results
 252 from an imperfection shape equal to the buckling shape of a single mode among the first 20 ones discussed in the
 253 previous section, i.e. in formulas $k = 1$, $1 \leq i \leq 20$ (eq 8). For each imperfection shape, the imperfection amplitude
 254 ranges in $1e - 5 \leq \alpha \leq 3e - 1$ m. For the sake of conciseness, only the load factor is examined in this section. For
 255 each structural model, it is normalized with reference to the LF of the perfect structure (LF^0). Figure 10 shows the
 256 evolution of the normalized LF versus the imperfection amplitude and for each mode shape (grey lines). The envelope
 257 of the minima of LF (i.e. the worst case scenario) at each imperfection amplitude is highlighted in red, together with
 258 the mode that gives the minimum value (filled markers). It is worth pointing out that:

Figure 10: Load Factor versus the nodal imperfection for each modal imperfection shape and for each model: ensemble of the obtained results and envelope of the LF minima

- 259 • the higher the imperfection amplitude, the more scattered the LF resulting from different modes. In particular, a
 260 significant scatter takes place for $\alpha > 0.01$ m in LBIA, but occurs earlier in GNIA and GMNIA for $\alpha > 0.0001$
 261 m;
- 262 • the worst case scenario is given by different mode shapes for varying imperfection amplitude. In particular, the
 263 nonlinear models (GNIA, GMNIA) predict a high number of mode shapes (4 in LBIA, 8 in GNIA and GMNIA)
 264 and the mode switching occurs for low values of the imperfection amplitude;
- 265 • the first mode provides the lowest LF only at very low imperfection amplitude by LBIA, while further ones (e.g.
 266 2 and 5) and high modes (e.g. 10,11,14,15,16) provide the lowest LF by GNIA and GMNIA;
- 267 • contribution of mode numbers higher than 20 to the worst case scenario cannot be excluded a priori;
- 268 • the modes which contribute to the worst case scenario belong to all the different shapes categorized in Figure 7.
- 269 • most of the modes which contribute to the worst case scenario are characterized by high BSL (e.g. 1, 2, 5, 6,7,
 270 9, 14) but some modes antisymmetric w.r.t. directrix or generatrix are not (e.g. 10,11 and 15,16).

271 In short, a single worst buckling mode to the stability of the structure cannot be identified even for the adopted
 272 benchmark, nor a valuable choice criterion can be inferred by the present numerical experiments, although modes
 273 having a high degree of globalness (high BSL) seem to prevail. The multiple switches from a worst buckling mode to

274 another varying the imperfection amplitude is a critical issue in the design perspective. Bearing in mind the features
 275 above, the single-mode EIM demonstrates its scarce robustness and predictability of the worst case scenario. The
 276 multiple switches, especially at the imperfection amplitudes of design interest ($\alpha^* > 1/500$), are due to the scattered
 277 value of the LF obtained by different modes for a given amplitude, and to the occurrence of local maxima in the LF
 278 trend versus the imperfection amplitude for a number of modes. In order to shed some more light on this feature, the
 279 LF(α) curves are grouped according to the occurrence of local maxima or not. They are plotted in Figure 11 for each
 structural model. The linear analysis (LBIA) mostly simulates a monotonic trend of LF(α) for all the modes, except

Figure 11: Load Factor versus the imperfection amplitude for each mode shape and structural model: trends with and without local maxima

280
 281 for one mode (mode 12). Conversely, the more accurate non linear models point out local maxima for the majority
 282 of modes at high value of the imperfection amplitude (about $3 \leq \alpha \leq 10$ cm, i.e. $1/1000 \leq \alpha^* \leq 1/300$). Generally
 283 speaking, GNIA and GMNIA provide analogous results from a qualitative point of view. In other terms, the effects of
 284 the geometric non linearity largely prevail on the mechanical ones for the adopted benchmark, as expected. However,
 285 some differences occur at high values of α , e.g. $\alpha \geq 7$ cm, i.e. where local maxima take place. These differences
 286 induce some modes to move from one group to another. In particular, mode 1 give rise to two high peaks in LF by
 287 GNIA, and a single one in GMNIA. Analogously, mode 2 involves two weak peaks in GNIA, but the same mode
 288 shows a monotonic trend in GMNIA. Such differences are due to localized plastic behavior of structural members,
 289 which reduce the limit load, properly simulated by GMNIA. In short, it is worth pointing out that local maxima: i.
 290 mostly occur at relatively high values of the imperfection amplitude of interest for designers; ii. affect both low mode
 291 numbers, notably mode 1, and high ones, e.g. node 20. In other terms, the rule "the higher the imperfection amplitude,
 292 the lower the load factor" is mostly unfulfilled. The designer is in the uncomfortable position of having to deal both
 293 with the choice of the single mode to be adopted as imperfection shape and of the imperfection amplitude. Both seem

294 uncertain and strongly affect the load factor.

295 4.3. Imperfect setup: α - k sensitivity analysis

296 Having in mind the results obtained for single-mode imperfection shapes, we aim at further assess the dome sta-
 297 bility by adopting a combination of two modes. Mode 1 and mode 2 involve a monotonic trend of $LF(\alpha)$ in LBIA, and
 298 one or more local maxima of $LF(\alpha)$ in GNIA. Furthermore, in GMNIA mode 1 causes a local maximum of $LF(\alpha)$,
 299 while mode 2 causes a monotonic trend of $LF(\alpha)$. Hence, we cover a wide casuistry by selecting mode 1 and mode
 300 2, or in formulas $i = 1, j = 2$ (eq 8). The LF and BSL are evaluated for each imperfect setup in the $\alpha - k$ plane, and
 for each structural model. They are plotted in Figure 12 for the sake of completeness and brevity. In order to allow a

Figure 12: Synopsis of the bulk parameters versus the nodal imperfection and the structural models

301 more detailed reading, the trend of the bulk quantities versus the imperfection is separately plotted for each model in
 302 Figure 13. Moreover, the trend of the bulk parameters versus α is plotted for each structural model in Figure 14 at the
 303 extreme values of the weighting factor $k = 1$ and $k = 0$, corresponding to the imperfection field equal to the first and
 304 second buckling mode, respectively.

305 The load factor LF resulting from LBIA is nearly insensitive to the imperfection shape, i.e. for constant α and varying
 306 k . An analogous overall trend holds for BSL, even if it is no longer fully monotonic versus α and not exactly constant
 307 versus k for $\alpha \geq 1$ cm. Conversely, the non linear analyses GNIA and GMNIA reveal a higher sensitivity of both
 308 the bulk parameters to the imperfection shape. The BSL value of the perfect grid shell predicted by GNIA/GMNIA
 309 (BSL ≈ 0.47) is higher than the one predicted by LBIA (BSL ≈ 0.35), that is, a higher degree of globalness at col-
 310 lapse results from the geometric non linearity. The growth of the imperfection amplitude α significantly reduces the
 311 globalness to BSL ≈ 0.1 In other terms, the imperfection generally induces a localization of the collapse.

312 In Figure 13 the local maxima of LF are highlighted by circular blue markers. Local maxima are significantly scat-
 313 tered within the whole k range and for $\alpha \geq 0.3$ by both the nonlinear models.. In particular, in the GMNIA model,
 314 the local maximum for $k = 1$ (mode 1) intermittently occurs also for $k = 0.9, 0.8, 0.3, 0.2, 0.1$, while a monotonic
 315 trend is observed for the remaining values of k , including mode 2 ($k=0$). In other terms, even though mode 1 ($k = 1$)
 316 and mode 2 ($k = 0$) cause different trends of $LF(\alpha)$, decreasing k does not progressively smooth the peak from mode
 317 1 to mode 2. Once more, the designer who applies a two-mode imperfection shape within EIM approach is in the
 318 uncomfortable position of having to deal with a further choice about the value of k , beside the selection of the modes
 319 i, j and the imperfection amplitude α .

320 In summary of Sections 4.2 and 4.3, no general criteria can be drawn from the numerical experiments and for the
 321 adopted setup to properly choose the buckling mode shape(s) i , the value of the imperfection amplitude α , and to get
 322 the weighting factor k . These difficulties are expected to be even greater for more complex structural forms.

Figure 13: Trend of the bulk parameters versus the nodal imperfection for the three structural models

Figure 14: Trend of the bulk parameters versus the imperfection amplitude for the three structural models. Imperfection patterns coincident to the 1st ($k = 1$) and 2nd ($k = 0$) mode shape

325 4.4. Imperfect setup: mechanical reading

326 This section aims at providing a deeper insight in the ultimate mechanical behaviour of the grid shell for varying
 327 α in order to point out the causes of the high sensitivity to the imperfection highlighted in the previous Section. In
 328 the following the most detailed mechanical model is retained (GMNIA) and the weighting factor is set equal to $k = 1$
 329 ($\eta/\alpha = \phi^{1,0}$).

330 To investigate the existence of a relationship between LF and BSL, the former is plotted against the latter in Figure
 15. Both parameters are scaled with respect to their values obtained for the perfect setup (LF^0 and BSL^0). In spite

Figure 15: GMNIA model: LF versus BSL

331 of a certain dispersion of data, a clear trend can be recognised: the higher the LF, the higher the BSL, and vice versa.
 332 This result can be interpreted as a general trend towards high degree of localness of the deformed shape at collapse
 333 for decreasing value of the LF.
 334

335 4.4.1. Regime identification

The evolution of the main bulk parameters versus the imperfection amplitude α is plotted in Figure 16. Homogeneous

Figure 16: Recognized regimes for $k = 1$

336 intervals of α are recognized with respect to the trend of the LF. It is worth pointing out that BSL shows coherent
 337 trends. The α intervals and the corresponding boundary values are labelled by latin letters and numbers, re-
 338 spectively. Five ranges are selected. Regime “a” corresponds to very low values of the imperfection magnitude
 339 ($1e - 5 \leq \alpha \leq 5e - 4$) and its lower bound “0” can be confused with the perfect geometry: in this range, the imper-
 340 fection does not have effects on LF and does not significantly impact on BSL. The regime “b” ($5e - 4 \leq \alpha \leq 1e - 3$)
 341 is a transition one where the slight descent of LF corresponds to an analogous growth of BSL. The regime “c”
 342 ($1e - 3 \leq \alpha \leq 4e - 2$) shows the significant exponential decrease of both LF and BSL. The watershed “4” between
 343

344 regimes “d” and “e” is defined at the local maximum of both LS and BSL. Finally, the “f” regime corresponds to a
 345 smooth decrease of the LF and a corresponding constant trend of BSL. It is worth pointing out that the watershed val-
 346 ues between two successive regimes, and the existence of regimes “d” and “e”, depend on the value of the weighting
 347 factor k for the selected benchmark (see Figure 13), and they are expected to vary with the geometrical and mechanical
 348 parameters of the grid shell.

349 The load multiplier μ - nodal deflection δ paths obtained by GMNIA analysis at the recognized regime bounds are
 350 plotted in Figure 17-a. The nodal deflection refers to the node where the displacement is known to be the maximum
 at each bound. The setups corresponding to the regime bounds show different initial stiffness (Figure 17-b), generally

Figure 17: Load - deflection paths by GMNIA and $k = 1$ for the recognized regime bounds (a) and corresponding initial stiffness k (b)

351 decreasing with the increase of the imperfection, except in the range between regime bounds 4 and 5, where a small
 352 growth appears. The same occurs for the non linear evolution of the deflection: the ultimate displacement before
 353 collapse is dramatically increased by the presence of imperfections, except in case of regime bound 5. The perfect
 354 setup is highly stiff, due to its parabolic shape, but collapse is more sudden than in the imperfect ones.
 355
 356

357 4.4.2. Correlation between the imperfection pattern and the deformed shape at collapse

358 Figure 18 represents the spatial distribution of the “input” imperfection and the resulting spatial distribution of
 359 the mechanical “output” for each one of the identified regime transitions. The imperfection is expressed by both
 360 the component of the nodal imperfection $\eta_v(p)$ evaluated along the direction v , and by the nodal apex K , calculated
 361 for the imperfect geometry. Correspondingly, the collapse shape is expressed by both the component of the nodal
 362 displacement $\delta_v^u(p)$ evaluated along the direction v , and by the nodal apex $K^u(p)$. The figure aims at highlighting the
 363 imperfection and ultimate deflection patterns, therefore all quantities are normalized to their maximum value. Hence,
 364 the field $\eta_v/\hat{\eta}_v$ is common to every regime transitions.
 365

The following remarks can be outlined:

- 366 • a qualitative visual comparison between the nodal imperfection and ultimate displacement patterns reveals poor
 367 correlation between them;
- 368 • the pattern of the nodal displacement at collapse $\delta_v^u(p)$ strongly varies across the regimes. In general, the higher
 369 the magnitude of the imperfection, the more localized the displacement and the lower the degree of globalness
 370 (BSL, Fig. 16), with the exception of bound 4, where a local maximum of the BSL has been detected. In
 371 particular, at bound 3 the displacement field is localised in four regions in the neighbourhood of node p_2 and its
 372 counterparts along the directrix and the generatrix;
- 373 • the pattern of the nodal apex $K(p)$ varies across the regimes, and a high correlation can be qualitatively recog-
 374 nized with the nodal displacement at collapse $\delta_v^u(p)$. The closer to zero the nodal apex of the imperfect shell,
 375 the higher its nodal displacement at collapse;

Figure 18: Regime transitions: imperfection, displacements at collapse, nodal apex of the imperfect geometry, and nodal apex of the collapse shape

376 • the patterns of the nodal apex $K(p)$ and the one of nodal apex at collapse $K^u(p)$ show the highest correspondence.
 377 This means that the deformation at collapse maintains and slightly modifies the apex of the initial imperfect
 378 geometry.

379 In order to check in a synthetic and quantitative way the correlation heuristically pointed out above, let us introduce
 380 the correlation coefficient $R(i, j)$ $[-1 : 1]$ classically defined as

$$R(i, j) = \frac{cov(i, j)}{\tilde{i} \tilde{j}} = \frac{E[(i - \bar{i})(j - \bar{j})]}{\tilde{i} \tilde{j}} \quad (9)$$

381 where $i(p)$ and $j(p)$ refer to the fields to be compared, \tilde{i} is the standard deviation, \bar{i} is the mean value, E is the expected
 382 value operator, cov is the covariance. In particular, the correlation coefficient is adopted in order to check the correla-
 383 tion of the input imperfection field with the output ultimate deflection. Hence $i = \eta_v(p)$ and $j = \delta_v^u(p)$, or $i = K(p)$
 and $j = K^u(p)$. The correlation coefficients defined above are plotted versus k and α in Figure 19. The obtained results

Figure 19: Correlation coefficient $R(i, j)$ for the analysed pairs of metrics of input imperfection and output deflection at collapse as a function of α and k (a,b) and for $k = 1$ (c)

384 clearly and quantitatively testify that a low correlation exists between the input-output pair $\eta_v - \delta_v^u$, while the $K - K^u$
 385 pair is highly correlated. The diminished correlation at about $0.04 < \alpha < 0.07$ is due to the significant geometric non
 386 linear effects taking place because of the large displacements at collapse.

387 Beside the above correlation, in the following some light is shed on the mechanical role played by the apex. Generally
 388 speaking, when the apex in a node vanishes, the grid shell locally approaches a flat grid and its geometrical stiffness
 389 tends to zero. Such a trend reflects the well-known shape-resistant behaviour of domes. In particular, the apex of the
 390 imperfect shape depends both on the perfect shape and on the applied imperfection. Its upward or downward direction
 391 induces the local increase or the decrease of the perfect apex, respectively. In order to give evidence to these issues,
 392 the evolution of K , K^u and δ_v^u versus the imperfection amplitude α is plotted in Figure 20 for the nodes p_1 and p_2
 393 (Fig. 3). In p_1 (Fig. 20-a) the nodal apex of the perfect structure has the maximum value (Fig. 5-b) and the nodal
 394 imperfection is upward according to the shape of the first mode (Fig. 8-a). Hence the imperfection increases the nodal
 395 apex and the local geometrical stiffness of the shell in turn, resulting in a “imperfection stiffening”. Conversely, in
 396 p_2 (Fig. 20-b) the nodal imperfection is downward according to the shape of the first mode. Hence the imperfection
 397 reduces the nodal apex and the local geometrical stiffness of the shell in turn, resulting in a “imperfection softening”.
 398 In this second case, if the nodal apices of the perfect geometry and of the imperfection are opposite, the apex of the
 399 imperfect geometry tends to zero and so the local stiffness. From Fig. 20-b a significant growth of the displacement
 400 takes place at $\alpha_A = 0.02 \leq \alpha \leq \alpha_B = 0.03$, before the nodal apex $K(p_2)$ reaches zero ($\alpha_C = 0.07$). Such shift effect
 401 can be explained as follows. At both α_A and α_B the nodal apex K changes significantly at collapse: in the first case it
 402 becomes negative ($sign(\kappa_1) \neq sign(\kappa_2)$), in the second the shell convexity is oriented downward ($\kappa_1 < 0, \kappa_2 < 0$). In
 403

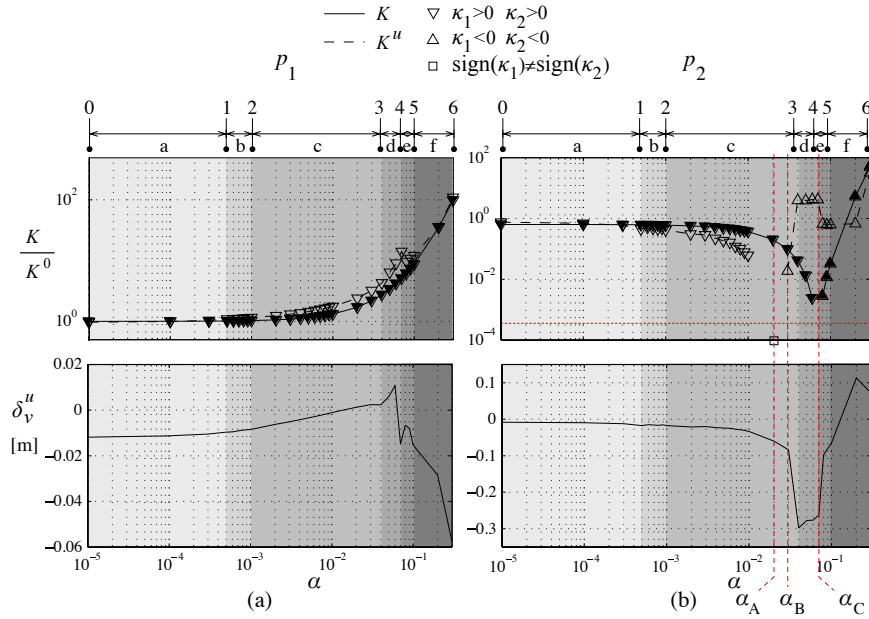

Figure 20: Sensitivity of the initial and ultimate nodal apex, and of the ultimate displacement to the imperfection magnitude for the nodes p_1 and p_2 (see Fig. 3)

404 such situations, a small but not zero nodal apex K on the imperfect shell involves $K^u = 0$ at collapse.

405

406 5. Conclusions

407 The present study is addressed to contribute to the deep understanding of the effects of the Equivalent Geometric
 408 Nodal Imperfections on the buckling instability of a hybrid single layer grid shell by means of the Eigenmode Imper-
 409 fection Method. A given SLGS dome is adopted as a benchmark. The imperfection shape is obtained by adopting
 410 single modeshape among the first 20 ones and by weighting the shapes of two modes. The range of the weighting
 411 factor and of the imperfection amplitude is densely resolved compared to the previous studies available in literature.

412 The EIM has been critically reviewed on the basis of the results of numerical experiments. The main findings are
 413 summarized in the following:

- 414 • the growth of the imperfection amplitude does not necessarily involve the decrease of the Load Factor: in fact,
 415 local maxima of LF take place along a general decreasing trend versus α . Hence, assuming high imperfection
 416 amplitude is not an a priori conservative choice that involves the worst case scenario;
- 417 • a single worst buckling mode to the stability of the structure cannot be identified, because different modal
 418 imperfection shapes contribute to the worst case scenario at different values of the imperfection amplitude;
- 419 • imperfection shapes resulting from the combination of two mode shapes additionally suffer the uncertainty
 420 about the weighting coefficient.

421 In short, the EIM does not seem to be grounded on general phenomenological bases and its extension to the ultimate
 422 buckling state is questionable even for the relatively simple grid shell scrutinized in this study. Generally speaking,
 423 the EIM is affected by epistemic uncertainties about its main parameters (imperfection shape and amplitude) which
 424 severely affect its predictability. The huge variety of grid shell typologies and of structural shapes it is expected to
 425 make even more questionable the extension of the results to a wider domain of application. For the time being, special

care should be paid for EIM application in the design practice. More general and more robust models of the Equivalent Geometric Nodal Imperfection in a worst case scenario perspective are needed in the near future.

Bearing such a need in mind, we have intended to contribute to the understanding of the buckling instability of the adopted benchmark. The main findings are summarized in the following:

- a new observable, called Buckling Shape Length, has been introduced to quantify the degree of globalness of the deformed shape at collapse. The BSL appears to be somewhat related with the Load Factor. A general trend has been identified, where lower values of the LF correspond to decreasing values of the BSL: in other words, the reduction of the ultimate carrying capacity of the structure - generally related to increasing imperfection amplitudes - corresponds to the occurrence of more local deformed shapes at collapse;
- a new metric, called nodal apex, has been identified as the local geometrical parameter that mainly drives the buckling of the studied single layer grid shell. This result suggests to define and set the nodal imperfection in terms of such a metric rather than in terms of the deviation from the perfect geometry along the direction normal to the reference surface.

We hope that making reference to these metrics could allow to phenomenologically ground future models of the Equivalent Geometric Nodal Imperfection able to predict the worst case scenario.

Acknowledgements

The authors wish to thank Claudio Canuto, Department of Mathematical Sciences at Politecnico di Torino, for the fruitful discussions about the topics of the paper.
