12 Abstract

Cellulose from wood fibers, can be modified for use in flame retardant composites as an alternative to halogen-based compounds. For this purpose, sulfite dissolving pulp fibers have been chemically modified by phosphorylation and the resulting material has been used to prepare cellulose nanofibrils (CNF) having a width of approximately 3 nm. The phosphorylation was achieved using (NH₄)₂HPO₄ in the presence of urea, and the degree of substitution (DS) by phosphorus was determined by X-Ray Photoelectron Spectroscopy (XPS), Conductometric titration and Nuclear Magnetic Resonance (NMR) spectroscopy. The presence of phosphate groups in the structure of CNF has been found to noticeably improve the flame retardancy of this
material. The nanopaper sheets prepared from phosphorylated CNF showed self-extinguishing
properties after consecutive applications of a methane flame for 3s and did not ignite under a heat
flux of 35kW/m², as shown by flammability and cone calorimetry measurements, respectively.

5 Keywords: Cellulose nanofibrils, Flame-retardancy, Morphology, Phosphorylation

6 1. Introduction

During recent decades the extensive use of polymeric materials in fields such as transport, 7 military and furniture upholstery has led to extensive scientific activities to overcome the 8 9 tendency of this class of materials to easily decompose and ignite when heated. This has made it necessary to blend flame-retardants into the used polymers^{1,2}. Flame-retardants may be based on 10 halogens, phosphorus, nitrogen, metal ions or nanofillers³. The halogen-based compounds, which 11 are the most effective and cost-efficient flame-retardant additives, have been criticized for both 12 environmental and functional reasons. They can be leached from the polymer into the 13 14 environment and can accumulate inside human and animal bodies. Moreover, during combustion they release toxic gases^{2,4}. Phosphorus-containing flame retardants are more suitable than 15 halogen-based compounds. Phosphorus-based compounds favor the formation of char instead of 16 17 combustible volatile species⁵. The char, a multi-lamellar carbonaceous structure, acts as a thermal insulator and protects the surrounded polymer from further decomposition and thus has a flame-18 retardant effect^{6,7}. Phosphorus chemistry is usually stated to represent the new frontier in the 19 development of flame-retardant materials. 20

The use of phosphorus chemistry in combination with biomacromolecules is of great interest as it would give access to renewable resources characterized by intrinsic flame-retardant properties. Cellulose nanofibrils (CNF) are one of the most interesting biomaterials for this task. The unique properties of CNF, including excellent mechanical properties, high specific surface area and high length-to-diameter ratio⁸, have made it suitable for the preparation of multifunctional materials such as thin films⁹, nanopaper¹⁰, foams and aerogels^{11,12}. Imparting flame retardancy to cellulose fibrils will make these materials more feasible and safe for industrial applications.

Nanofibrils were first extracted from wood fibers by Turbak et al. in the early 1980s using 6 repeated mechanical treatment with a high-pressure homogenizer to produce cellulose micro 7 fibrils¹³ with a width between 25 and 100 nm¹⁴. But, due to the high cost of production and lack 8 of successful applications, these materials were not developed further. More recently it has been 9 shown that different pretreatments of delignified wood fibers including combinations of 10 enzymatic, mechanical and chemical modifications lead to a more energy-efficient production of 11 CNF by facilitating the homogenization process^{15,16}. The introduction of charged groups onto 12 pulp fibers through chemical modification is one way to enhance delamination of fiber walls by 13 increasing the osmotic pressure inside the fiber wall and hence their swelling¹⁷. This can facilitate 14 15 the disintegration of nanofibrils from the fiber wall, leading to less clogging and a lower energy consumption during the homogenization process^{14,18}. Examples of such chemical pretreatments 16 are the partial carboxymethylation of cellulose¹⁹ or the use of TEMPO (2,2,6,6-17 tertramethylpiperidine-1-oxyl)-mediated oxidation of cellulose, a regioselective reaction which 18 introduces carboxylate groups to primary hydroxyl groups at the C6 position of the cellulose 19 molecules¹⁵. 20

In this work, we propose a pretreatment of pulp fibers by phosphorylation which can facilitate the
preparation of CNF by pre-charging the fiber wall through the introduction of anionic phosphate

Figure 1. Schematic description of different steps for preparation of nanopaper sheet from phosphorylated CNF used in the present work: (a) Impregnation of fibers in a water solution of (NH₄)₂HPO₄ and urea; (b) curing of fibers; (c) Top, basic design of an interaction chamber of a homogenizer where fibers disintegrate to fibrils¹⁴ and bottom, TEM image of phosphorylated CNF; (d) Flame-retardant nanopaper sheet prepared in the Rapid –Köthen instrument (The KTH logo is used with permission from KTH Royal Institute of Technology)

7 groups and also contribute to the thermal stability and flame-retardant properties of the resulting material. Phosphorylation of cellulosic materials using phosphorylating agents such as 8 phosphorus oxychloride (POCl₃), phosphorus pentoxide $(P_2O_5)^{20,21}$, phosphoric acid $(H_3PO_4)^{22-24}$, 9 di-ammonium hydrogen phosphate (NH₄)₂HPO₄²⁵ and organophosphates²⁶ has been studied for 10 decades. It has been shown that the degree of substitution (DS) by phosphorus depends on the 11 molar ratio of the phosphorylating agent and anhydroglucose units of cellulose and the time and 12 temperature of the reaction^{20,21,23,27}. Phosphorylation usually takes place in the presence of an 13 organic solvent such as N,N-dimethylformamide (DMF), pyridine^{20,26}or urea^{22-25,27} which has a 14 swelling effect on the cellulose-rich fibers and is a medium for phosphorylation reaction²⁵. 15

Although extensive research has been devoted to the phosphorylation of cellulose, this approach 1 2 has, to the author's knowledge, never been used for the production of intrinsically flame-retardant CNF. In order to benefit from less toxic chemicals, an ammonium salt of phosphoric acid 3 ((NH₄)₂HPO₄) is used as the phosphorylating agent and this leads to less cellulose hydrolysis than 4 phosphoric acid. Figure 1 shows a diagram of the phosphorylation procedure followed by 5 preparation of phosphorylated CNF and the flame-retardant nanopaper sheet. The 6 phosphorylation process has been characterized by Attenuated Total Reflection Fourier 7 Transform Infrared (ATR-FTIR) spectroscopy, X-Ray Photoelectron Spectroscopy (XPS) and 8 Nuclear Magnetic Resonance (NMR) spectroscopy. In addition to its chemical composition, the 9 10 phosphorylated CNF has been characterized regarding the dimensions and extent of fibrillation, using cryo-TEM and Atomic Force Microscopy. Finally, the phosphorylated CNF has been used 11 12 to prepare nanopaper sheets that have been characterized with respect to their mechanical and flame retardancy properties. 13

14 Experimental

15 2.1. Materials. 2.1.1. Chemicals. Di-Ammonium hydrogen phosphate (ACS reagent grade)
16 was purchased from Merck Millipore, and urea (ReagentPlus ≥ 99.5%) was provided by Sigma
17 Aldrich. Deionized water was used in all reactions. Sodium bicarbonate, hydrochloric acid and
18 sodium hydroxide were all of analytical grade and supplied by Merck KGaA.

2.1.2. Fibers. A commercial sulfite softwood dissolving pulp (Domsjö Dissolving plus; Domsjö
Fabriker AB, Domsjö, Sweden) from 60% Norwegian spruce and 40% Scots pine, with a
hemicellulose content of 4.5% and a lignin content of 0.6% was supplied in a dried form.

1 2.2. Methods. 2.2.1. Preparation of fibers. Prior to chemical modification, fibers were re2 slushed and washed in deionized water, after which the carboxyl groups on the fibers were
3 converted to their sodium form using a standard washing process described earlier¹⁹. Once
4 washed, the fibers were refined in a PFI mill (HAM-JERN, Hamar, Norway) for 4000 rev.
5 Thereafter a fiber dispersion of 5g/L was fractionated by continuous washing with approximately
10 liters of deionized water in a Britt Drainage Jar fitted with a 50 mesh metallic wire to remove
7 the fines liberated during the refining.

8 2.2.2. Phosphorylation. Phosphorylation was carried out using (NH₄)₂HPO₄ in the presence of
9 urea. Assuming cellulose chains to be the main constituents of the pulp fibers (94.9%); two
10 different molar ratios of anhydroglucose units (AGU) to reagents were used as shown in Table 1.

Sampl	Sample	Molar ratio	Time (min) / Temperature (°C)
		AGU:(NH ₄) ₂ HPO ₄ :Urea	
	L10	1: 1.2: 4.9	10 / 150
	L30	1: 1.2: 4.9	30 / 150
	L60	1: 1.2: 4.9	60 / 150
	L90	1: 1.2: 4.9	90 / 150
	H10	1: 2.5: 10	10 / 150
	H30	1: 2.5: 10	30 / 150
	H60	1: 2.5: 10	60 / 150
	H90	1: 2.5: 10	90 / 150

11 **Table 1.** Molar ratios and reaction times used for phosphorylation of fibers

Excess amounts of urea are usually used in phosphorylation reaction ^{23,25,27} to prevent degradation of cellulose due to the release of phosphoric acid during curing at elevated temperatures. In each case, approximately 4 moles of urea were therefore used per mole of (NH₄)₂HPO₄. The phosphorylation process consisted of impregnation and curing. During impregnation, urea and (NH₄)₂HPO₄ were added to a fiber dispersion of 1 wt.% in deionized water under continuous stirring. The aqueous solution was then filtered to a 10 wt.% fiber dispersion. The fibers were then dried in an oven at 70°C followed by curing at 150°C for 10, 30, 60 or 90 minutes, denoted as L10/H10, L30/H30, L60/H60 and L90/H90 respectively. The phosphorylated fibers were then washed with 2 liters of boiling and 2 liters of cold deionized water to remove loosely attached chemicals.

2.2.3. Preparation of phosphorylated CNF. Phosphorylated CNF was prepared using a high 7 pressure homogenization technique²⁸. A 2 wt.% dispersion of L10, L30 or L60 was prepared in 8 deionized water, and the pH of the dispersion was set to 9.5 using 1 M NaOH to ensure complete 9 dissociation of carboxylate and phosphate groups. The fiber dispersion was then passed through a 10 11 high pressure homogenizer (Microfluidizer M-110EH, Microfluidics Corp.) equipped with two chambers of different sizes connected in series (200 and 100 µm). Full homogenization was 12 achieved with a single pass through the large chamber (200 µm) and six passes through the 13 14 smaller chamber (100 μ m).

15 2.2.4. Preparation of nanopaper sheet. Phosphorylated CNF produced from L10 was used to 16 prepare nanopaper sheets based on the method described elsewhere¹⁰. The sheets were prepared 17 using a semiautomatic sheet former (Rapid-Köthen, PTI, Vorchdorf, Austria) where the fibril 18 dispersion is filtered through a membrane and the wet gel obtained is dried under vacuum¹⁰. A 19 hydrophilic durapore membrane with a pore size of 0.45 μm was used.

20 **2.3. Characterization Techniques.** *2.3.1. Total charge determination.* The total charge 21 density of the phosphorylated fibers was determined by conductometric titration where fibers in 22 their proton form were titrated against NaOH. For this purpose, the fibers were dispersed in deionized water at a fiber concentration of 0.5-1g/l. The pH and salt (NaCl) concentration of the
fiber dispersion was adjusted to pH: 3.5 (using 0.01M HCL) and 2mM respectively. The total
charge was then determined by titration with 0.1M NaOH²⁸.

2.3.2. Attenuated Total Reflection Fourier Transform Infrared (ATR-FTIR) spectroscopy. ATRFTIR was performed using a Perkin-Elmer Spectrum 2000 FT-IR equipped with a single
reflection accessory unit having a diamond ATR crystal (Golden Gate) from Gaseby Specac Ltd.
(Kent, England). The ATR spectra were recorded at room temperature in the range of 4000-600
cm⁻¹ as the average of 16 scans and 4 cm⁻¹ resolution.

9 2.3.3. X-Ray Photoelectron Spectroscopy (XPS). The XPS spectra were collected with a Kratos Axis Ultra DLD electron spectrometer using a monochromatic Al Ka X-ray source operated at 10 150 W. An analyzer pass energy of 160 eV for acquiring wide spectra and a pass energy of 20 eV 11 for individual photoelectron lines were used. Fiber samples for the analysis were gently hand-12 pressed using a clean Ni spatula into a special powder sample holder. The surface potential was 13 stabilized by the charge neutralization system of the spectrometer. The binding energy (BE) scale 14 was referenced to the C_{1s} line of aliphatic carbon, set at 285.0 eV. The spectra were analyzed 15 with the Kratos software. 16

17 2.3.4. Nuclear Magnetic Resonance (NMR) spectroscopy. All samples were wetted with 18 deionized water to a water content of 40–60% and packed uniformly in a zirconium oxide rotor. 19 Recording spectra of wet rather than dry samples gives a higher apparent resolution²⁹. The 20 CP/MAS ¹³C-NMR spectra were recorded in a Bruker Avance III AQS 400 SB instrument 21 operating at 9.4 T. All measurements were made at 295 (±1) K with a MAS rate of 10 kHz. A 4-22 mm double air-bearing probe was used. Acquisition was performed using a CP pulse sequence,

i.e., a 2.95 micro-seconds proton 90° pulse and a 800 microseconds ramped (100-50%) falling 1 2 contact pulse, with a 2.5 seconds delay between repetitions. A SPINAL64 pulse sequence was used for ¹H decoupling. The Hartmann-Hahn matching procedure was based on glycine. The 3 chemical shift scale was calibrated to the TMS ($(CH_3)_4Si$) scale by assigning the data point of 4 maximum intensity in the α -glycine carbonyl signal to a shift of 176.03 ppm. A total of 4096 or 5 6 16384 transients were recorded for each sample, giving an acquisition time of approximately 3 h or 12 h. The software for spectral fitting was developed at Innventia AB, Stockholm, Sweden and 7 is based on a Levenberg-Marquardt algorithm³⁰. All computations are based on integrated signal 8 intensities obtained from the spectral fitting³¹. Cellulose I specific surface area was calculated 9 from the lateral fibril aggregate dimensions by assigning a density of 1500 kg/m³ to cellulose I^{32} . 10

2.3.5. Atomic Force Microscopy (AFM). CNF fibrils were adsorbed from a 1g/L aqueous
dispersion onto silicon wafers (Si-Mat Silicon Material, Germany) with an anchoring polymeric
surface layer (25 kD polyethylenimine, Sigma Aldrich). The adsorption time was 5min followed
by rinsing with Milli-Q water (18.2 MΩ). A Bruker multimode 8 AFM (Bruker Ltd. Germany)
with Bruker ScanAsyst-air tips was used for imaging in the ScanAsyst mode. DIPimage software
(Delft University of Technology, The Netherlands) was used to determine the width of fibrils
based on the image intensities.

18 2.3.6. Cryo-Transmission Electron Microscopy (cryo-TEM). An electron microscope (cryo-TEM, 19 CM120 Philips, The Netherlands) equipped with a post-column energy filter (Gatan GIF100) was 20 used. A cryoholder (CT-300 Oxford Instruments, U.K.) and its work-station were used to transfer 21 the specimen to the electron microscope. The acceleration voltage was 120kV and the images 22 were recorded digitally with a CCD camera under low electron dose conditions. Samples were 23 prepared in a controlled environment vitrification system, and 3µL of the sample was deposited on lacey carbon-sputtered copper grids and plunged into liquid ethane (-180°C), and stored under
liquid nitrogen until measurement. In order to determine the width of fibrils from TEM images,
ImageJ (National Institute of Mental Health, Maryland, USA) software was used.

2.3.7. Thermogravimetric analysis (TGA). The thermal and thermo-oxidative stabilities of the
filter paper and nanopaper sheet were evaluated in nitrogen and in air respectively, from 50 to
800°C with a heating rate of 10°C/min using a TAQ500 (Laboratory for Emerging Material and
Technology, South Carolina, USA) The samples (approx. 10mg) were placed in open alumina
pans in an inert or oxidative atmosphere (gas flow: 60ml/min). T_{onset10%} (temperature at 10% of
weight loss), T_{max} (temperature at maximum rate of weight loss) and the residue at 800°C were
obtained from the measurements.

11 2.3.8. Flammability. Flammability tests were carried out in a horizontal configuration applying a 12 methane flame for 3 s on the short side of the paper sheet samples (25x100 mm). The 13 experiments were repeated three times for each material on separate samples. Parameters such as 14 burning rate and final residual amount were evaluated.

15 2.3.9. Cone Calorimetry. The combustion of square paper sheets (filter and nanopaper sheet, 16 100x100 mm²) was investigated by cone calorimetry (Fire Testing technology, FTT, West 17 Sussex, UK) according to the ISO 5660 Standard. The samples were placed in a sample holder, 18 and an irradiative heat flow of 35 kW/m² was used in a horizontal configuration following the 19 procedure developed for thin samples described elsewhere³³. Parameters such as Time to Ignition 10 (TTI, s), Peak of Heat Release Rate (PHRR, kW/m²), Total Heat Release (THR, MJ/m²) and the 11 final residual amount were evaluated. Three independent samples were tested for each material. 2.3.10. Mechanical test. Tensile stress/strain at break and Young's modulus of nanopaper sheets
 were evaluated using the Instron 5944 (Instron, High Wycombe, UK) instrument equipped with a
 500N load cell. Specimens 40 mm in length, 60-70 µm thick and 5 mm wide were tested at a
 strain rate of 2 mm/min.

All the samples were conditioned at 23±1 °C and 50% R.H for at least 48 hr. prior to the
mechanical, flammability and combustion tests.

7 2. Results

3.1. Chemical characterization of phosphorylated fibers. 3.1.1. Determination of the total 8 *charge of the fibers.* Figure 2 shows the change in total charge ($\mu eq/g$) of the fibers measured by 9 conductometric titration as a function of curing time for phosphorylated fibers. For the fibers, 10 phosphorylated at a low molar ratio of AGU:(NH₄)₂HPO₄, the total charge increased up to 60 11 minutes curing followed by a slight decrease at longer curing times. With a higher molar ratio of 12 AGU:(NH₄)₂HPO₄ a maximum charge was achieved already after 30 minutes curing followed by a 13 large decrease with longer curing times, i.e. H60 and H90. The decrease in the total charge at 14 longer curing times may indicate cellulose dissolution following the phosphorylation reaction. This 15 is consistent with the 0.3% and 2.6% mass loss for H60 and H90 respectively after the reaction, 16 whereas a mass gain of 9.4% and 5.5% was observed for H10 and H30, probably due to grafting of 17 phosphate groups onto the cellulose. 18

11

Figure 2. Total charge (µeq/g) of phosphorylated fibers as a function of curing time: red line:
AGU:(NH4)₂HPO4:Urea molar ratio of 1:1.2:4.9; black line: AGU:(NH4)₂HPO4:Urea molar ratio

4 of 1:2.5:10

3.1.2. ATR-FTIR spectroscopy analysis. Figure 3 shows FTIR spectra of unmodified and 5 phosphorylated fibers (3a for fibers modified at a low molar ratio of AGU:(NH₄)₂HPO₄ and 3b at 6 a high molar ratio case). Within the selected region, IR spectra of unmodified fibers show 7 characteristic bands of cellulose chains including bands at 1165 and 1120 cm⁻¹ for C-O-C groups 8 from glycosidic units or from β -(1 \rightarrow 4)-glycosidic bonds²⁷. The appearance of a new band at 1710 9 cm⁻¹ corresponding to the C=O stretching mode²⁶ for all the phosphorylated fibers supports the 10 hypothesis that oxidation occurs during the reaction. Also the greater intensity of this band for 11 L60, L90, H60 and H90 than for fibers cured for shorter times shows that oxidation increases 12 with time, as expected. The phosphorylation is also supported by the appearance of a new band at 13 1230 cm⁻¹ corresponding to the P=O stretching mode^{24,27,34} in all the phosphorylated samples. 14 The appearance of new bands at 900-940 cm⁻¹ and 832 cm⁻¹ corresponding to the P-OH^{24,27} 15 stretching mode and the P-O-C aliphatic bond²⁷ respectively in the spectra of H10, H30, H60 and 16 H90 also indicates the incorporation of phosphate groups and this increases slightly with the 17

curing time. In contrast these bands are not clearly observed in the case of fibers phosphorylated
 at the lower molar ratio of AGU:(NH₄)₂HPO₄, probably because of the lower phosphorus content.

Figure 3. ATR-FTIR spectra of unmodified and phosphorylated fibers: (a) Fibers phosphorylated
at a low molar ratio of AGU:(NH₄)₂HPO₄; (b) Fibers phosphorylated at a high molar ratio of
AGU:(NH₄)₂HPO₄

3.1.3. XPS analysis. The XPS spectra of unmodified and phosphorylated fibers are shown in 7 Figure 4 (4a showing XPS spectra of fibers modified at a low molar ratio of AGU:(NH₄)₂HPO₄ 8 and 4b at a high molar ratio). Two distinct peaks of elemental C_{1s} and O_{1s} are present for 9 unmodified fibers^{34–36} as well as minor peaks which can be assigned to elemental S_{2s} , S_{2p} and 10 11 Ca_{2p} possibly caused by surface contamination. In addition to the contributions to the spectra from native cellulose, phosphorylated fibers show three new peaks at 134.4, 190.5 and 401.4 eV 12 which can be assigned to P_{2p} , ${P_{2s}}^{34,35,37}$ and ${N_{1s}}^{36} \text{species.}$ The appearance of elemental 13 14 phosphorus peaks strongly supports the hypothesis that phosphorus moieties have been successfully incorporated in to the cellulose. The N_{1s} species are most probably NH₄⁺ groups of 15 ammonium phosphate salt³⁶, since the N_{1s} peak due to surface contamination is probably washed 16

1 away in the same way as Ca and S, as shown in both Figures 4a and 4b where the Ca and S peaks

2 have disappeared for the treated samples which have been exposed to extensive washing.

The relative surface concentrations of C, O and P atoms can be calculated in situ by integrating the areas under the peaks associated with each atom, see SI (Table S1). The P surface concentration increases when the fibers are modified at the two different molar ratios of AGU:(NH₄)₂HPO₄, while the C surface concentration on fibers decreases. The highest C atomic percentage is on the unmodified fibers (70.4%) while H60 shows the lowest C atomic percentage (52.6%). The opposite effect was detected for surface concentration of O, where the atomic percentage increased from 29.6% on unmodified fibers to 43.8% on H60.

High resolution scan XPS spectra of C_{1s} , O_{1s} and P_{2p} are shown in Figure 5a, 5b and 5c respectively for unmodified fibers and H30 with the highest P surface concentration. The C_{1s} spectra are divided into four sub-peaks corresponding to different types of C-O bonds^{35,36}. The

unmodified fibers display strong peaks at 285 and 286.8 eV attributed to C-C/C-H and C-OH 1 2 bonds respectively and two shoulder peaks at 288.2 and 289.6 eV attributed to O-C-O and O=C-O bonds^{34–36}. Compared to the unmodified sample, the intensity of the C-C bond is much lower 3 in phosphorylated fibers, and the shoulder peak at 289.6 eV assigned to O=C-O bonds 4 (carboxylate functionalities) seems to be larger in the phosphorylated fibers, possibly due to 5 partial oxidation. A decrease in intensity of the C-C bond in the phosphorylated fibers is 6 reasonable, since the outer surface of the modified fibers/fibrils is probably covered by 7 phosphate³⁸ and carboxylate functionalities. 8

Figure 5. XPS spectra of unmodified and phosphorylated fibers (H30); high resolution scans of:
(a) C_{1s}; (b) O_{1s} and (c) P_{2p} (only modified fibers are shown for obvious reasons)

12 The O_{1s} spectra of unmodified and phosphorylated fibers show a strong peak at 533.2 eV 13 assigned to C-OH bonds^{35,36}, but the bands centered at 533.5 eV can also be assigned to C-O-P 14 groups^{36,37,39}, and in the case of the phosphorylated fibers it seems that this peak is overlapped by the peak associated with C-OH group. There is also a shoulder peak at 531.4 eV in both spectra assigned to P=O in phosphate and C=O groups^{35,36} for which the intensity is greater in the phosphorylated fibers. The P_{2p} spectra of phosphorylated fibers show non-resolved doublets corresponding to P_{2p1/2} at 135.2eV and P_{2p3/2} at 134.2eV^{35,36}. The binding energies at 134 and 135eV are usually assigned to P-O-C or -PO₃⁻² groups when phosphate components react with cellulose^{36,37}.

The bulk degree of substitution of phosphate groups (DS_{phosphate}) is estimated from the ratio of the
area under the P-O-C peak to the area under the C-OH peak in the XPS spectra. Due to the high
concentrations of O=C-O bonds on phosphorylated fibers, the bulk DS of carboxylate groups
(DS_{carboxylate}) is also estimated by the same method, see SI (Table S2). In addition to the
DS_{phosphate} and DS_{carboxylate}, the amount of charges introduced onto the fibers by each group,

calculated on the basis of the DS values are also included in Table S2.

12

3.1.4. ¹³C CP/MAS NMR analysis. The ¹³C CP/MAS NMR spectra of unmodified fibers and L30, 13 L90, H30 and H90 samples are shown in Figure 6. This study was carried out in order to estimate 14 15 the impact of the phosphorylation on the supramolecular structure of cellulose I and possibly any region selectivity of the phosphorylation reaction. It is apparent from the spectra that an increase 16 in the molar ratio of AGU:(NH₄)₂HPO₄ and in curing time leads to more extensive structural 17 changes in the phosphorylated fibers. The assignment of different carbons of anhydroglucose 18 units is also indicated in Figure 6, the region at 58-68 ppm is assigned to C6, the cluster of 19 signals at 68-80 ppm to C2, C3 and C5, the region at 80-91 ppm to C4 and the region at 101-109 20 ppm to $C1^{40}$. 21

.

1

Figure 6. ¹³C CP/MAS NMR spectra of unmodified and phosphorylated fibers (L30, L90, H30
and H90)

4 As mentioned, a loss of spectral detail accompanied with the increased degree of phosphorylation, interpreted as a gradual loss of order of the cellulose, is the most pronounced 5 tendency within the series³⁰. This effect is specifically shown in H30 with the highest DS_{phosphate} 6 7 of the tested samples. The sharper components of C4 and C6 regions assigned to the crystalline core of cellulose⁴¹ tend to broaden from unmodified fibers to H30. Although spectral 8 9 deterioration is most clearly observed in the C6 and C4 regions, phosphorylated fibers also show 10 broader peaks in other regions. It is not therefore possible to determine any region selectivity of 11 the phosphorylation reactions. Relative spectral change in the C4 and C1 regions which 12 correspond to carbons of the glycosidic bond which are not available for substitution, indicates a possible modification in the neighboring atoms of C2 and C3²¹. The spectra recorded on the 13 unmodified fibers were used for estimating the specific surface area of the water swollen 14 15 cellulose I. The obtained surface-to-volume ratio and specific surface area were 0.112 ± 0.003 and $134 \pm 4 \text{ m}^2/\text{g}$ respectively, calculated from the NMR-estimates of the average lateral 16 dimension of the cellulose I fibril aggregates^{31,32}. 17

3.2. Morphological characterization of phosphorylated CNF.

Using the micro-fluidization process phosphorylated fibers were defibrillated by the shear forces
producing a clear gel-like suspension of approx. 2 wt.%. Due to partial dissolution of fibers
phosphorylated at the higher AGU:(NH₄)₂HPO₄ molar ratio, only fibers phosphorylated with a
AGU:(NH₄)₂HPO₄ ratio of 1:1.2 were used to prepare CNF.

6 3.2.1. AFM & cryo-TEM analysis of fibrils. The phosphorylated fibrils prepared from L10, L30 7 and L60 denoted P-CNF10, P-CNF30 and P-CNF60 were imaged in solution using cryo-TEM and in the adsorbed state on dry surfaces using AFM, as shown in Figure 7. Individual fibrils are 8 observed in all the samples while fibril aggregates increase in size and amount from P-CNF10 to 9 10 P-CNF60. The width of the phosphorylated fibrils is estimated to be around 3 nm for all samples 11 based on AFM images, as indicated in Table 4. On the other hand, the length of the phosphorylated fibrils shows a rather large variation. Although the length of the most of the 12 fibrils is in the range of 500-1000 nm, there are fibrils with lengths less than 300 nm (especially 13 14 in the case of P-CNF60) and over 1µm.

1

Figure 7. Images of: (A,D) P-CNF10; (B,E) P-CNF30 and (C,F) P-CNF60. (A-C) Fibrils in 2 solution imaged with cryo-TEM and (D-F) fibrils adsorbed on silica surfaces imaged with AFM 3 The widths of phosphorylated fibrils were also measured based on cryo-TEM images, using a 4 limited number of particles, as presented in Table 4. In agreement with the results of the AFM 5 6 measurements, the width of the phosphorylated fibrils was independent of curing time and total charge of fibers, but it was not possible to evaluate an accurate length of fibrils from the cryo-7 TEM images, since individual fibrils often overlapped or ended in fibril aggregates in P-CNF 8 9 dispersions. Larger fibril aggregates were observed particularly in P-CNF60, generally 20-100 nm wide and often over 10 µm long, as measured by cryo-TEM. 10

3.2.2. Determination of gravimetric yield. The amount of stable CNF dispersion after
 homogenization and ultra-sonication, known as the gravimetric yield^{28,42}, was measured for P-

CNF10, P-CNF30 and P-CNF60 after the stable CNF dispersion had been separated from 1 aggregates and non-fibrillated fiber fragments by centrifugation⁴². The gravimetric yield of P-2 CNFs together with CNF prepared from enzymatically pretreated fibers, as evaluated by Fall et 3 al.⁴² are collected in SI (Table S3). The enzymatic CNF can be considered as a reference in this 4 5 work, since it was prepared from fibers with the same chemical composition and since the enzymatic pretreatment contributes to fiber swelling¹⁸ with no addition of ionic groups. It was 6 possible to gain yields above 50% for P-CNF samples (as shown in Table S3), which is greater 7 than with enzymatically prepared CNF. 8

9

3.3. Thermal stability and flame retardancy of phosphorylated CNF.

10 The thermal stability and flame retardancy of phosphorylated CNF were studied for nanopaper 11 sheets prepared from P-CNF10. Nanopaper sheets with a grammage of 90.2 ± 5.1 (g/m²) and a 12 thickness of 65 ± 6 (µm) were used, named P-nanosheets hereafter.

3.3.1. TGA analysis. The thermal and thermo-oxidative stabilities of the P-nanosheets were
assessed by thermogravimetric analysis in comparison with the properties of unmodified pulp
fibers, as shown in Figure 8 (TG and dTG/dT curves in nitrogen and air).

Figure 8. TG and dTG/dT curves of: (a) nanosheet of phosphorylated CNF (P-nansosheet) and
unmodified pulp fibers in nitrogen; (b) P-nansosheet and unmodified pulp fibers in air

The thermal degradation of cellulose in nitrogen proceeds in a single step, during which the maximum weight loss occurs (Figure 8a). The pyrolysis of cellulose in nitrogen is usually defined by two pathways involving the decomposition of the glycosyl units to char at a lower temperature and the depolymerization of such units to volatile products at higher temperatures^{2,5,43}. Compared to the unmodified pulp fibers, the presence of phosphorus in nanopaper sheet structure caused an earlier dehydration of cellulose toward char formation and a strong reduction in the cellulose decomposition temperature, as revealed by the T_{onset10%} and T_{max}

- 1 values (258°C vs 315°C and 283°C vs 358°C for the P-nanosheet and pulp fibers, respectively).
- 2 The final residue at the end of the test was 20% for pulp fibers and 40 % for P-nanosheet.

3 The thermo-oxidative stability was also investigated in air, where the dTG/dT curves show two decomposition peaks (Figure 8b), the first representing the creation of aliphatic char and volatile 4 products, and the second the conversion of aliphatic to aromatic char and the release of CO and 5 6 CO_2 as a result of the simultaneous carbonization and char formation^{2,5,43}. As in nitrogen, the presence of phosphorus induced an earlier cellulose dehydration and lower maximum weight loss 7 temperatures (T_{onset10%} and T_{max1} respectively) than unmodified pulp fibers. Compared to the pulp 8 fibers, the char formed during the first degradation step of the P-nanosheet was thermally more 9 stable, as indicated by the T_{max2} values (539°C for P-nanosheet vs 422°C for pulp fibers), leaving 10 11 a significantly greater residue from the nanopaper sheet at 800°C.

12 3.3.2. Flammability & Cone Calorimeter testing. In order to investigate the behavior of 13 phosphorylated CNF at early stages of burning, P-nanosheets were subjected to both 14 flammability and forced combustion tests. These two tests together provide complementary 15 information concerning the flame-retardant properties of the phosphorylated CNF.

The reaction of the P-nanosheet to direct flame exposure was studied in comparison with that of a filter paper of the same thickness through the flame spread test. It is important to test the sample behavior on exposure to a flame, in order to evaluate the propensity of the material to initiate fire. For this reason, both the P-nanosheet and the filter paper were subjected to a flammability test in horizontal configuration. Figure 9 presents snapshots taken at fixed times during the tests on the papers. When the flame was applied, the filter paper immediately ignited and burned with a flame which lasted throughout the test leaving 0% residue. In contrast, once the flame was applied to the P-nanosheet, it burned very slowly and it self-extinguished as soon as the flame was removed from the sample. Even after a second and third application of the flame, the P-nanosheet was able to stop the flame spreading and self-extinguished. Compared to the filter paper, a strong reduction in the burning rate (-33%) and a consistent final residue of 92% was found with the Pnanosheet.

6

7 Figure 9. Snapshots of: (a) filter paper; (b) P-nanosheet taken at fixed times during the

The resistance of the P-nanosheet to an irradiative heat flux of 35kW/m² was compared to that of 9 the filter paper through cone calorimetry tests. The exposure to the cone heat flux (35kW/m^2) , 10 typical of early developing fires) leads to a sudden increase in the surface temperature of the 11 12 sample (up to 400-500°C); and as a consequence the sample undergoes thermal degradation with the release of combustible volatile species that led to the ignition (TTI) in the case of the filter 13 paper and subsequent flaming combustion (pkHRR and THR). Figure 10 shows the HRR plots 14 15 for the filter paper and the P-nanosheet as a function of time. The filter paper yielded an average TTI of 44 s with pkHRR of 42.7 kW/m² and THR of 0.7 MJ/m². Surprisingly, the nanopaper 16 sheet exhibited no ignition at all under the cone calorimeter, preserving more than twice as much 17

material after the test compared to the filter paper. This behavior is quite unusual for a cellulosic
material which normally burns quickly when it is exposed to the cone calorimetry heat flux. Cone
calorimeter data (Table S6) and images of the filter paper and the P-nanosheet before and after
cone calorimetry (Figure S1) are provided in SI.

8 **3.4.** Mechanical properties of nanopaper sheets.

The mechanical properties of the P-nanosheets were determined and compared with earlier 9 reported values⁴⁴. In earlier work, Henriksson et al.⁴⁴ used enzymatically treated softwood 10 dissolving pulps with different degrees of polymerization (DP) of the constituent cellulose. The 11 DP of the phosphorylated CNF is calculated from intrinsic viscosity data, η where $\eta = 0.42$ DP for 12 DP < 950 and $\eta = 2.28 DP^{0.76}$ for $DP > 950^{28,44}$. The viscosity measurement was performed at 13 MoRe Research AB (Örnsköldsvik, Sweden) where the CNF samples were dissolved in a copper 14 ethylenediamine solution (ISO-5351). The samples were never allowed to completely dry before 15 dissolution which is a derivation from the standard viscosity measurement²⁸. The DP of the 16

fibrils, film density as well as specific strength and specific modulus (normalized values) of P-1 nanosheet and nanopapers from the earlier work are presented in the SI (Table S4) 28,44 . It is 2 shown by Henriksson et al. that an increase in DP is followed by an increase in the strength of the 3 nanopapers. DP-580 (Henriksson et al.) was prepared from fibrils with the closest DP to the 4 phosphorylated fibrils of the present work. In comparison, the P-nanosheet has a relatively good 5 specific strength (1.49 (Nm/kg)*10⁻⁵ vs 1.39 (Nm/kg)*10⁻⁵ for P-nanosheet and DP-580, 6 respectively) and shows an even higher strain at break (7.5% vs 6.4% for P-nanosheet and DP-7 580 respectively). In contrast the specific modulus is lower in the P-nanosheet (6.11 (Nm/kg)*10⁻ 8 ⁶ vs 9.39 (Nm/kg)*10⁻⁶), representing a film with lower stiffness²⁸. The strain rate applied in the 9 present work was lower than that applied in the work of Henriksson et al.⁴⁴ which can also lead to 10 a lower modulus. 11

12 4. Discussion

13

4.1. Chemical structure of the phosphorylated fibers/fibrils.

Pulp fibers were successfully phosphorylated using (NH₄)₂HPO₄ and urea as reagents as was 14 shown by conductometric titration, FT-IR and XPS analysis. A large increase was generally 15 16 observed in the total fiber charge upon phosphorylation, which is a sign of attachment of phosphate groups and which was increased using a higher molar ratio of AGU:(NH₄)₂HPO₄:Urea 17 and a longer curing time. The results of the total charge measurement indicate that it is not 18 possible to reach charges higher than 1.84 meq./g by increasing the curing time, probably because 19 of cellulose dissolution due to the high DS values reached at this high charge. Other 20 consequences of a higher charge are an increased swelling of the fibers and an easier 21 delamination of the fiber wall during subsequent homogenization¹⁴. The dissolution of the 22

cellulose at higher DS is also increased in the presence of urea, which is known to be a solvent
 aid for cellulose ⁴⁵⁻⁴⁷.

Results of FT-IR spectroscopy showed the average chemical structure of the phosphorylated 3 4 fibers and the chemical composition and structure of the fiber surface were shown by XPS. The appearance of P=O and P-OH bonds provided support for the phosphorylation and the absence of 5 P-H bond adsorption (2280-2440 cm^{-1 27,34}) in the FT-IR spectra of the modified fibers suggests 6 that most of the phosphorus is attached to cellulose in the form of phosphate groups containing 7 two acidic protons. The same results were obtained in the XPS study where the appearance of 8 bands centered at 134.5eV shows that phosphorus exists in its pentavalent state in the form of C-9 $O-P=(O)(O)_2^{-1}$ on modified fibers³⁷. The decrease in the atomic percentage of carbon and increase 10 in the atomic percentage of oxygen with increasing AGU:(NH₄)₂HPO₄:Urea molar ratio and 11 12 curing time, as shown in Table 2, are also in agreement with surface phosphorylation. For each grafted phosphate group, one free hydroxyl group is substituted by two new hydroxyl groups and 13 one phosphoryl group, and this leads to an increase in the atomic concentration of oxygen⁴⁸. The 14 15 decrease in the atomic percentage of P in L90 and H90 is also in agreement with the results of the conductometric titration where longer curing times led to a lower total charge of the fibers. 16

FT-IR and XPS studies also show that partial oxidation occurs on the fibers during phosphorylation. The appearance of a sharp carbonyl peak in the FT-IR spectra and an increase in intensity of the O=C-O band in high resolution XPS spectra of phosphorylated fibers compared to unmodified fibers show the creation of carboxylate functionalities in addition to phosphate attachment on the cellulose. In an oxygen-rich atmosphere at 150°C, oxidation of functional groups of cellulose is assumed to progress slowly with a variety of transitional products⁴⁹, and partial oxidation of the fibers is expected to occur, considering the phosphorylation reaction conditions. The O=C-O band is also observed in high-resolution XPS spectra of unmodified
fibers, as shown in Figure 5b. But, compared to phosphorylated fibers the intensity is
significantly lower and can be explained by a low hemicellulose content of unmodified fibers.
These hemicelluloses are probably removed during the phosphorylation reaction.

According to Table 3, the total charge of unmodified and phosphorylated fibers is the sum of 5 charges associated with phosphate and carboxylate functionalities, as determined by XPS and 6 7 also demonstrated by the conductometric titration. The discrepancy in absolute values between these methods can be traced back to the complexity of evaluating the degree of substitution with 8 9 these methods. In the conductometric titration both monobasic (carboxylate groups) and dibasic (phosphate groups) acids are contributing to the total charge and it is very difficult, if not 10 11 impossible, to separate the different groups with only the titration since the groups have average pK_a values not too far apart, especially for these types of polyelectrolytic surfaces. The XPS 12 study, on the other hand, specifically measures the phosphorus content even though the intensity 13 integration is not an exact method either to determine the absolute concentration of the 14 phosphorus in the fibers. But, due to the specificity of the XPS for phosphorus this method was 15 chosen over conductometric titration for the determination of the bulk DS_{phosphate}. 16

17 **4.2.** Estimation of the surface substitution of phosphate groups of the fibrils.

18 When discussing the location of the phosphate groups in the fiber wall, it is important to 19 remember the hierarchical structure of the cellulose fibers. In the delignified fiber wall, the 20 average lateral fibril dimensions are approximately 4x4 nm, and fibrils are aggregated into fibril 21 aggregates with an average lateral dimension of about 20x20 nm³² and it has recently been found 22 that, even at high levels of substitution, these aggregates are kept together so that the interior of the aggregates is inaccessible to the chemical reagents³¹. This means that the phosphorylation of
the fiber wall is primarily a surface modification of the fibril aggregates.

3 In order to calculate the surface DS_{phosphate}, the fraction of AGU accessible for modification (surface-to-volume ratio, q) must be taken into account. Assuming a simple model for fibril 4 aggregates where they have a square cross-section, the average surface-to-volume ratio of the 5 fibril aggregates can be determined from signal intensities of the C4 region of the ¹³C CP/MAS 6 NMR spectra of cellulose^{30,31}. The surface DS_{phosphate} of the cellulose fibril aggregate can be 7 estimated by dividing the bulk DS_{phosphate} by the so obtained q value. For the phosphorylated 8 fibers examined by ¹³C CP/MAS NMR, the relative surface DS_{phosphate} based on q value of 9 unmodified fibers are given in SI (Table S5). The reason for this approximation is that it was not 10 11 possible to determine q values of H30 and H90 due to extensive broadening of the C4 region in ¹³C CP/MAS NMR spectra. If the supramolecular structure of cellulose I during the 12 phosphorylation is similar to the supramolecular structure in the water swollen state, this 13 approximation will not introduce any significant error. 14

15 The surface DS_{phosphate} on the fibril aggregates of unmodified fibers, L30, L90, H30 and H90 together with the total charge of fibers and bulk DS_{phosphate} calculated previously from XPS are 16 listed in Table S5. As expected, DS_{phosphate} is higher for the fibril aggregate surface than the bulk 17 DS_{phosphate} as determined from XPS measurements³². Even with a large total charge (1.84 meq./g 18 for H30), the surface DS_{phosphate} did not exceed 0.5. This suggests that even at very high levels of 19 modification not more than one hydroxyl group per surface anhydroglucose unit was 20 phosphorylated which could be a sign of some region-selectivity of the phosphorylation reaction, 21 as shown by Bozic et al.³⁴, Wanrosli et al.⁵⁰ and Granja et al.²¹. Among available reaction sites, 22 23 the probability of phosphorylation on C6 hydroxyl groups is highest, since this group is least sterically hindered of all the available hydroxyl groups in the glucose moiety⁵⁰. A surface DS_{phosphate} of 0.41 obtained for H30 thus corresponds to selective phosphorylation of the C6 groups at the surface of their fibril aggregates. It is hence important to note that despite a low average concentration of the phosphate in the fiber material there is a rather high surface substitution of the phosphate groups on the fibrils. This will naturally be very important when trying to understand the properties of the modified fibrils.

7

8 4.3. The effect of chemical reaction conditions on the fibrillation of fibers.

The measured gravimetric yield shows the extent of fibrillation for the enzymatically treated and 9 10 for the phosphorylated fibers. It has previously been shown that charge density of pulp fibers is one of the properties most affecting the fibrillation process ^{28,42}. It is well known that an increase 11 12 in charge leads to a higher osmotic pressure inside the fiber wall and hence a higher fiber 13 swelling and this in turn leads to a more efficient liberation of the fibrils during homogenization¹⁴. It has also been shown that, once liberated, the fibrils with a higher charge will 14 have a greater stability against aggregation ^{14,42}. P-CNF30 prepared from fibers with higher 15 16 charge density had a greater gravimetric yield than P-CNF10. But the same trend was not 17 followed for P-CNF60, for which the pulp fibers contained an even greater number of charges, which indicates that other factors than the charge are of importance for the efficiency of the 18 fibrillation process. 19

Cryo-TEM images of P-CNF dispersions (Figure 11) show less individual fibrils, especially for
 P-CNF60 for which a lower gravimetric yield is expected. While fibril aggregates are loosened
 up for P-CNF10 and P-CNF30 dispersions, they are in a more aggregated state for P-CNF60

showing that fibrillation has not occurred evenly throughout the fibers. One possible reason for 1 2 this is that despite of high charge density; P-CNF60 is prepared from fibers which were exposed to high temperature oven curing for a longer time than the other two samples. When cellulose 3 substrates are dried from water under severe conditions, hornification occurs. This phenomenon, 4 which is an irreversible closure of fiber wall pores, results from the removal of water and the 5 formation of new intermolecular links between cellulose fibrils³². Fibers cured for a longer time 6 at 150°C also have their fiber wall collapsed to a greater extent. Therefore once wetted, they 7 cannot re-swell to the same degree and this leads to a stiffer fiber wall which is not easily opened 8 during the homogenization process. 9

10

12 P-CNF30 dispersion; (C) P-CNF60 dispersion

13 4.4. Thermal stability and Flame-retardant performances.

The enhanced thermal and flame- retardant performances of phosphorylated CNF presented in the form of nanopaper sheet, compared to unmodified fibers and normal filter paper can be explained by the presence of a high concentration of phosphate groups on the surface of the fibrils which catalyze the dehydration and prevent thermal decomposition of cellulose^{5,43}. As a

consequence of the temperature increase, the cellulose undergoes pyrolysis as a result of which 1 2 heterolytic bond scission along the molecular chain occurs. This leads to the generation of levoglucosan, a volatile monomer which is a 1,6-anhydro ring formed by glucose. The instability 3 of the cellulose C6 hydroxyl group then plays a crucial role in cellulose depolymerization⁵¹. If 4 phosphorylation of fibers mainly occurs on C6 hydroxyl groups, the main depolymerization 5 6 mechanism of CNF is blocked. Furthermore, compared to unmodified fibers, the earlier thermal 7 and thermo-oxidative degradation of phosphorylated fibrils is also attributed to the release of phosphoric acid which catalyzes the dehydration of cellulose to form an aromatic carbonaceous 8 structure such as char^{2,5}. 9

All this means that when subjected to a flame or a heat flux the P-nanosheet can hence rapidly form a thermally stable char, inhibiting production of volatile components and protecting the uncombusted material from direct flame contact, thus resulting in a self-extinguishing behavior during flammability tests and preventing ignition during cone calorimetry. This also means that by grafting 0.85 % (w/w) phosphate groups to fibers; they are converted to a flame-retardant material.

16 **4.5. Mechanical performance.**

The specific strength and strain at break of nanopaper sheets prepared from phosphorylated CNF are comparable to those of earlier reported nanopapers with outstanding mechanical properties⁴⁴. This is naturally important since the flame-retardant materials also need to have a mechanical integrity when applied in more complex material concepts. In this respect the liberation of the fibrils from fibril aggregates into free fibrils is important since a higher number concentration of the fibrils will lead to a higher number of fibril contacts in the prepared nanopaper. The

phosphorylated fibrils used to prepare nanopaper sheets have a high surface DS of phosphate and 1 2 carboxyl groups and this will lead to a lower ordering of the molecules on the surface of the fibrils allowing for a more efficient contact between the fibrils in the dry nanopaper and hence a 3 stronger nanopaper sheet. On the other hand, the existence of fibril aggregates and fewer free 4 fibrils, as in the case of P-CNF10, has a negative effect on the number of fibril/fibril contacts and 5 6 a less efficient contact between the fibrils which could be the reason for the lower stiffness of the P-CNF10 nanopaper²⁸. The most important finding is however that the flame-retardant nanopaper 7 8 also has very good mechanical properties compared to other types of nanopapers from CNF.

9 **5.** Conclusions

A controlled phosphorylation of pulp fibers containing mainly cellulose was achieved using 10 (NH₄)₂HPO₄ in the presence of urea, as shown by FT-IR, XPS and solid state NMR spectroscopy. 11 12 Upon phosphorylation, the fibers become highly charged due to the attachment of phosphate and carboxylate functionalities, and this makes phosphorylation a suitable chemical pre-treatment for 13 the preparation of phosphorylated CNF through a homogenization process. With this technique it 14 15 was possible to prepare phosphorylated fibers with different degrees of substitution with phosphate and carboxylate groups (bulk DS_{phosphate} from 0.014 to 0.047 and DS_{carboxylate} from 16 0.024 to 0.05). By using the results obtained from ¹³C CP/MAS NMR spectra in combination 17 with the results from XPS study the degree of substitution of polymers located at the surface of 18 fibril aggregates (surface DSphosphate) could be determined. The maximum surface DSphosphate 19 obtained was 0.41 which suggests that phosphorylation occurs mainly at the surface of fibril 20 21 aggregates and a high surface DS can hence be achieved at a still very moderate bulk modification of the cellulose. 22

For the first time, to the knowledge of the authors, cellulose nanofibrils were prepared from the 1 2 phosphorylated fibers using no other pretreatment, yielding fibrils with widths of approximately 3 nm and lengths between 500 and 1000 nm. The CNF dispersions prepared from different 3 phosphorylated fibers have been shown to contain more than 50% colloidally stable nanofibrils. 4 Different reaction conditions affect fibrillation in a significant way and curing times (at 150°C) of 5 6 less than 1 hour lead to a more efficient fibrillation during the homogenization process. It was 7 also shown that the thermal stability and flame-retardant properties of nanopaper sheets prepared from phosphorylated CNF were largely improved compared to unmodified pulp fibers and filter 8 paper. The nanopaper sheets showed a self-extinguishing behavior during flammability tests and 9 10 did not ignite when subjected to the cone calorimeter heat flux despite have a substitution by weight as low as 0.85%. It was also shown that the mechanical properties of the modified fibrils 11 are indeed comparable to earlier published data for CNF-based nanopapers. These findings are of 12 great importance and clearly indicate that phosphorylated CNF represents an intrinsic cellulose-13 based flame-retardant material. While the nanopaper sheet presented in this work is the proof of 14 concept, the material in the form of fibrils has a potential for use in more sustainable and 15 comparatively environment friendly flame-retardant composites and nano coatings which are for 16 instance made through layer by layer technique. 17
