TERMIS

6TH WORLD CONGRESS

MAASTRICHT

THE NETHERLANDS

BOOK OF ABSTRACTS

termis

version 1.0.1

PREFACE LOCAL ORGANISING COMMITTEE

Dear participants of the 6th World TERMIS Conference 2021,

How we would have loved to meet you all in Maastricht, in a region where three countries meet, characterized by tradition and innovation. The Romans settled this region and for centuries, it was one of the most important political centers of Europe. Even today, Maastricht had an important role in making it possible through the Maastricht Treaty, which still represents today the cornerstone of collaboration, cooperation, and co-development across Europe.

How we would have loved to show you this special region, at the heart of Europe, where the Dutch University of Maastricht, the Belgian Universities of Liege and Leuven and the German RWTH Aachen University have created an epicenter of Tissue Engineering and Regenerative Medicine like only a few in the world. A fertile international ecosystem of academic, industrial, and governmental stakeholders that could be renamed the “Regenerative Valley” of Europe.

And how we would have loved to discuss, argue, network, laugh and celebrate with you during the breaks, evening events and casual meetings in the cafés of this wonderful old city of Maastricht; just what a lively (scientific) society like TERMIS is all about.

We had prepared all this for you and now this little coronavirus has thrown a spanner in the works. Nevertheless, or even more so now, we want to make the World TERMIS Conference a special event for you. An event that is still being held, but online leading us out of the isolation in our institutes back to scientific communing.

The general theme of the congress is “Biologically inspired technology driven regenerative medicine”, which is fully reflected in the 9 parallel thematic sessions. We want to stimulate a fruitful discussion between scientists and clinicians and industry representatives to foster the translation of ground-breaking ideas into clinical practice.

Enjoy the World TERMIS conference 2021…

…and we hope to see you soon face-to-face again!

Lorenzo Moroni ***Liesbet Geris*** ***Stefan Jockenhövel***

PREFACE TERMIS PRESIDENT AND INCOMING PRESIDENT

Dear Participants of the TERMIS World Congress 2021,

On behalf of Geoff Richards, Tony Weiss and the entire governing board, we would like to thank our three organisers, Lorenzo Moroni, Liesbet Geris and Stefan Jockenhoevel for the TERMIS World Congress. It requires large amounts of work to host a TERMIS World Congress physically, but these three also had the extra work to then prepare for a hybrid meeting and unfortunately finally a fully online meeting. Our personal experiences of hosting meetings remind us how much work is involved but we did not have to prepare for a hybrid and/or online meeting. A big thank you to the three of you!

Thank you all who have prepared and submitted abstracts, symposia and workshops, for all those who have taken time to help review these abstracts and to all of you who have supported this congress by both registering and encouraging others to register.

It has been very difficult to run a Society during the pandemic without our usual three physical Chapter meetings and now with the World Congress going virtual, we have not had a face-to-face meeting since Brisbane in October 2019. Our normal income from these meetings was wiped out from one day to another, and we had to work hard to develop an alternative and more robust way to finance the Society that would work in all situations. The Governing Board decided to move to an annual membership structure for TERMIS, as most international societies have, to help our Society survive during difficult times. We therefore thank all of you who have paid your membership fees in 2020 and 2021 and encourage you to pay early in 2022 – these are essential to run the Society. This will allow you to attend all TERMIS conferences (face-to-face and virtual meetings such as webinars) at a special member rate.

In 2022 we will personally try to attend all three TERMIS Chapter meetings in Poland (TERMIS EU), Toronto (TERMIS AM) and Korea (TERMIS AP) and we hope many of you will be participating to help rebuild our in-person networking to strengthen our Society.

Geoff: As my last TERMIS Congress as the Society President I wish you a great online experience and hope to see you face to face in 2022.

Tony: As the incoming President of TERMIS, I welcome you to our World Congress online and look forward to seeing you in person at future meetings.

R. Geoff Richards, President of TERMIS 2019,2020,2021.

Tony Weiss, incoming President of TERMIS.

ENABLING TECHNOLOGIES FOR DEVELOPMENT OF BIOARTIFICIAL ORGANS

Corresponding author's email: d.stamatialis@utwente.nl

In the coming years, due to the aging of the population and the low availability of donor organs there will be urgent need for bioengineered organs to assist, mimic or replace failing patient organs.
These organs could be artificial, based on novel biomaterials and designs, to assist or mimic a patient organ or bioartificial: combining biomaterials and biologics (cells and tissues) to fully replace failing patient organs. In this talk, we will discuss enabling technologies for development of bioartificial organs with specific attention to bioartificial kidney, bioartificial pancreas.

Abstract **#2**

TRANSLATIONAL SYSTEMS BIOLOGY OF INFLAMMATION AND WOUND HEALING: FROM DATA TO MODELS TO DIGITAL TWINS

Corresponding author's email: vodovotzy@upmc.edu

Properly regulated inflammation is central to homeostasis, but in adequate or overly robust inflammation can lead to disease. Like many biological processes, inflammation and its various manifestations in disease are both multi-dimensional and multi-compartmental. Our group has carried out studies aimed at obtaining high-dimensional, dynamic data on the etiology and progression of various inflammatory processes and diseases in samples derived from cells, animals, and people; creating computational models based on these data as well as on key principles of immunology, as well as developing novel software tools for data aggregation and analysis; and modulating the inflammatory response in an optimal spatial, temporal, and individual- / disease-specific manner. These studies center on various disease states, especially trauma/hemorrhage, infection, wound healing, and liver failure, as well as the application of computational approaches to regenerative medicine, biomarker discovery, and rational drug/device design. Our ultimate goal is to gain a translational systems perspective on the inflammatory response (1,2).

Abstract **#3**

RECENT ADVANCE OF TISSUE ENGINEERING TO ENHANCE NATURAL-HEALING POTENTIALS FOR REGENERATIVE MEDICINE

Corresponding author's email: yasuhiko@infront.kyoto-u.ac.jp

A new therapeutic trial based on the natural-healing potential of body itself to induce tissues regeneration and repairing, has been recently expected. To realize this regenerative therapy, there are two approaches of cell transplantation and tissue engineering. Tissue engineering is a biomaterial technology or methodology to artificially create a local environment which enables cells to enhance their proliferation and differentiation for tissue regeneration. If a cell scaffold or a key bio-signaling molecule is supplied to the right place at the right time period or concentration, the body system initiates to physiologically function, resulting in the natural induction of cell-based tissue regeneration.
The biological functions of bio-signaling molecules can be promoted with drug delivery system (DDS) technology. Biodegradable hydrogels enabled the controlled release of various growth factors and chemokines to succeed in the healing potential -based regeneration and repairing of various tissues through the recruitment and activation of cells. This release and/or cell scaffold technologies can be combined with cell transplantation to significantly enhance the therapeutic efficacy in tissue regeneration. The biomaterials technology of regenerative medicine is also applicable to the basic researches of stem cells biology. The further development of stem cells biology will be effective in enhancing the therapeutic efficacy of cell-based tissue regeneration.
In this paper, several applications of DDS and cell scaffold technologies to the tissue regeneration therapy as well as the basic research of stem cells are introduced to emphasize clinical significance of biomaterials technologies in tissue regenerative therapy.

Abstract **#4**

AUTOMATED PROCESS DEVELOPMENT AND MANUFACTURING STRATEGIES FOR CELL AND GENE THERAPIES

Corresponding author's email: q.rafiq@ucl.ac.uk

Genetically-modified cellular immunotherapies, including chimeric antigen receptor T-cells (CAR-T) and natural killer cells (CAR-NK), have generated significant clinical and commercial outcomes due to their unparalleled response rates against cancer. However, the development and manufacture of these advanced therapies face a number of translational bottlenecks that must be addressed to ensure long-term commercial viability.

We have undertaken extensive studies to investigate the impact of key culture parameters on the yield and quality of CAR-T cells, including medium screening studies, medium feeding strategies, dissolved oxygen concentrations, pH and culture mode of operation. The outcome of these studies has been the development of a novel process control strategy that has resulted in a process intensification efficiency of >40% whilst maintaining the critical quality attributes of the CAR-T cells. We have also established a criteria for scaling the process in stirred-tank bioreactors, ranging from 15mL to 1L, resulting in equivalent growth kinetic and cell quality profiles.

This talk will introduce the process control and intensification strategy established to improve CAR-T yield, outlining the importance of monitoring and control capability. The role of manufacturing technologies will be discussed with data presented from a range of expansion platforms. Finally, the talk will outline the challenges of scalable CAR-T manufacture, particularly for allogeneic (universal donor) applications, and present data from 1L stirred-tank bioreactor studies.

Abstract **#5**

DESIGN OF PHYSIOLOGICAL BIOREACTORS THOUGH IMAGE ANALYSIS AND COMPUTATIONAL MODELLING

Corresponding author's email: m.allenby@uq.edu.au

Cell and tissue biomanufacturing currently rely on cultures suspensions which are inherently expensive, time-consuming, and variable in comparison with how tissue products are grown naturally. These inefficiencies have become critical bottlenecks for human cell and tissue biomanufacturing, restricting the future industrial and clinical translation of lab-grown organs. Few human cell culture products deliver sufficient benefit, value, and consistency to offset their high manufacturing costs to produce useful clinical or biomedical solutions. Recent advances in biomedical image analysis and computational modelling can enhance the design and operation of high-efficiency tissue biomanufacturing platforms, as well as the high-content characterisation and monitoring of culture performance to enable bioprocess control, optimisation, and automation. These computational technologies aim to maximize culture outcomes while minimizing variability and process development expense. In this talk, we outline several approaches which harness biomedical imaging and image-based computational models to design, fabricate, and demonstrate efficient and robust human cell and tissue biomanufacturing platforms.

Abstract **#6**

CRITICAL QUALITY ATTRIBUTES OF CARDIOVASCULAR CELLS DIFFERENTIATED FROM HUMAN PLURIPOTENT STEM CELLS

Corresponding author's email: sppalecek@wisc.edu

The process for manufacturing specialized cell types from human pluripotent stem cells (hPSCs) typically involves guiding the cells through developmentally-relevant cell states via temporal presentation of microenvironmental cues in the bioreactor. However, even with precise control over the cell environment, differentiation is prone to cell line-to-line and batch-to-batch variability because of heterogeneity in the cell population. Failed and inefficient manufacturing runs contribute to the high cost of cell therapies. A move toward closed loop cell manufacturing processes with real-time integrated analytics that inform on population composition and state would presumably increase differentiation efficiency and reproducibility. Here I will discuss efforts to discover cell quality attributes during hPSC differentiation to cardiomyocytes through a multi-omics analysis of cell populations and extracellular media at different stages of differentiation. First, we identified that successful vs. failed differentiations, defined as the purity of cTnT+ cardiomyocytes at the end of the differentiation, can be predicted early in differentiation by metabolite profiling of the media. This suggests that failed differentiations can be identified early and stopped or perhaps corrected through process interventions. We also identified metabolomic and proteomic signatures that correlate with cardiomyocyte maturation state, achieved through extended culture. These results suggest that metabolic pathways can be used to identify cardiomyocyte differentiation efficiency and potency metrics, and that metabolic pathways may be useful control points to improve cardiomyocyte manufacturing for in vitro and in vivo applications.

Abstract **#7**

SUPRAMOLECULAR DESIGN OF HYDROGEL BIOMATERIALS

Corresponding author's email: mwebber@nd.edu

Host–guest supramolecular recognition affords a useful tool in the physical crosslinking of macromeric precursors to create hydrogels with dynamic properties and tunable functions for a range of biomedical applications. The recognition affinity of certain macrocycle hosts in binding to a suite of different guests offers a tool to rationally design materials from the molecular scale so as to empower specific and tunable functionality. In the context of their use as biomaterials and drug delivery devices, the modularity of these interactions facilitates opportunities to combine multiple bioactivities or therapeutic payloads within a single delivery platform, as well as routes to the facile incorporation of targeting motifs for functional delivery even in the complex biological milieu. A subset of macrocyclic host–guest chemistries are able to achieve affinities approaching that for biotin-avidin, offering a non-covalent approach to enable recognition in complex environments. Whereas conventional ligation reactions can be kinetically limiting, the association of host–guest motifs occurs near the diffusion limit. Accordingly, these interactions form quickly, and at high affinities may have considerable lifetime. In this work, we describe our efforts to use supramolecular chemistry to empower new biomaterials and drug delivery devices. This approach is also useful in the context of protein modification as a means of altering the stability and pharmacokinetics of therapeutic drugs. Finally, we demonstrate the use of supramolecular recognition to facilitate homing and retention of systemically administered small molecules at desired sites in the body, and in the process overcome dilution and physiologic competition to achieve site-specific accumulation.

3D PRINTABLE HYBRIDS FOR ARTICULAR CARTILAGE REGENERATION

Corresponding author's email: julian.r.jones@imperial.ac.uk

There is unmet clinical need for materials that can help torn cartilage regenerate. Our new Bouncy Bioglass (silica/polycaprolactone-polytetrahydrofuran) hybrid materials [1] can be made to have a coefficient of friction matching that of articular cartilage (in media) [2]. Hybrids have co-networks of inorganic and organic components. This gives unprecedented combination of mechanical properties and control of biodegradation. Hybrid inks were 3D printed in log-pile-like architectures and responded well to cyclic loads [1]. We found that the 3D printed scaffolds guide bone marrow stem cells differentiated down a chondrogenic route in vitro, producing articular cartilage-like matrix, rich in Collagen II, Aggrecan and GAG, but only when the pore channel size was 250 microns [3]. When the pore size was larger, Collagen I was prevalent [3]. However, when polycaprolactone control scaffolds where used, Collagen I was also prevalent. Pore architecture, surface chemistry and stiffness therefore affected cellular response. In vivo sheep studies showed similar results, wherein scaffolds with 250 micron pores showed excellent cartilage regeneration after 3 months, while defects remained when scaffolds with 500 micron pores were used.

Abstract **#12**

A NOVEL CONCEPT OF CELL MANUFACTURABILITY AND ITS IMPACT FOR AUTOMATED CELL PRODUCTION

Corresponding author's email: KINO-OKA@BIO.ENG.OSAKA-U.AC.JP

Regenerative medicine and cell therapy use the cell transplants which are manufactured, requiring interdisciplinary activities not only from medicinal and biological fields but also from manufacturing field. The 'cell manufacturability', which is defined as capability of cell manufacturing through the processes by bridging between biological and process aspects, is proposed to be the new concept for discipline of cell production [1]. And "Design for cell manufacturability" is to be manufacturing design of cell-based products in such a way that they are easy to manufacture through simple, safe and efficient (cost-saving) process with stable product quality and secure to customer by considering transportation and preparation outside factory, acting practically the system optimisation for the efficiency and stability of the process by understanding the requirement gap between biological and engineering aspects and reducing output fluctuation, This action will lead to cost saving of the products through the process simplification and governing the kinetics of cell behaviour.

Based on the concepts and our back ground for the development of flexible modular plat form [2], we develop the novel automation (machinery) culture system for retina epithelial pigment cells (RPE cells) derived from iPS cells to realise robust processing by measuring the motion. The system performed the successful production of RPE cells, compared with operation by experts in the laboratory. This result concludes the importance of machinery system for the cell manufacturing.

SUPRAMOLECULAR BIOFABRICATION: FROM MOLECULAR CONTROL TO MACROSCOPIC FUNCTIONALITY

Alvaro Mata[P][1]

[1] *University of Nottingham*

Corresponding author's email: a.mata@nottingham.ac.uk

Nature has evolved to grow and regenerate tissues and organs using self-assembling processes capable of organizing a wide variety of molecular building-blocks at multiple size scales. As the field of biofabrication progresses, it is essential to develop innovative ways that can enhance our capacity to build more complex macroscopic structures using molecular and nanoscale components organized across size scales and in a rational manner. The talk will present our efforts to develop biofabrication processes integrating supramolecular chemistry, structural biology, and engineering principles to create structures with innovative properties such as hierarchical organization, the capacity to grow or heal, tuneable mechanical properties, and selective bioactivity.

MESENCHYMAL STEM CELL-DERIVED EXTRACELLULAR VESICLES: EFFECTIVE MODULATORS OF THE IMMUNE SYSTEM

Bernd Giebel[P][1]

[1] *Instute for Transfusion Medicine, University Hospiatal Essen*

Corresponding author's email: bernd.giebel@uk-essen.de

Extracellular vesicles (EVs), especially harvested from supernatant of human mesenchymal stem/stromal cells (MSCs) provide a novel tool in regenerative medicine and immune therapy. Compared to cellular therapeutics, EV-based therapeutics provide several advantages. Amongst others due to their small size (70-150 nm) they can be sterilized by filtration, lack any endogenous self-replication potential and are much easier to handle than cells. Data will be presented demonstrating the therapeutic potential of MSC-EVs including their immunomodulatory properties. Furthermore, challenges in the field will be discussed

Introduction: The goal of the present study was to compare the efficacy of CEA overlaid on excised full-thickness burn wounds grafted with either AD or cadaver skin in sheep.

Methods: Six full thickness burn wounds (5×5cm) were induced at the dorsum of sheep. After 24 hours, the eschar was excised down to the fascia, and covered with ovine frozen cadaver skin (CS); or AD. The skin were harvested for isolation of autologous keratinocytes to be cultured on temperature-responsive dishes until forming the multilayer sheets. Three weeks after grafting, the keratinocyte sheets were overlaid onto the wounds covered with either CS or AD. The wound epithelialization were assessed for 14 days using intermittent planimetric assay and histological analysis.

Results: Epidermis of grafted CS started rejecting after 10 days, and its complete rejection was observed within 21 days. AD was gradually changed to dermis-like tissue. The dermis thickness was comparable between CS and AD groups at 7, 14, or 20 days. The percentage of wound epithelialized area after keratinocyte sheet grafting was also comparable between CS and AD groups at 7 days (50.1±7.8% vs 54.2±10.5%, p=0.76) or 14 days (91.2±4.1 vs 87.4±5.8%, p=0.60). The transmission electron microscopy analysis revealed no significant difference in the percentage of lamina densa and number of hemidesmosomes between CS and AD groups.

Conclusions: Our results also demonstrate that AD and autologous keratinocyte sheets can substitute autologous skin grafts.

Abstract **#17**

TENDON STRUCTURE FUNCTION RELATIONSHIPS: INJURY AND THE INTERFASCICULAR MATRIX

Hazel Screen$_P$[1]

[1] *Queen Mary, University of London*

Corresponding author's email: h.r.c.screen@qmul.ac.uk

Tendon injury is debilitating and recalcitrant. It is primarily associated with energy storing tendons, likely related to the greater mechanical demands placed on these tendons. However, the mechanobiology of tendon injury remains unclear. The presentation will focus on the structural specialisms associated with tendon energy storage, and how poor specialisation or ageing changes may in turn be associated with increased injury risk.

Our data demonstrate that energy storing tendon specialism is focused in the non-collagenous matrix between the fascicles, termed the interfascicular matrix (IFM). In energy storing tendons, the IFM is elastin- and lubricin-rich, facilitating sliding and recoil between fascicles with increased fatigue resistance [1-3]. The IFM is highly cellular, and is repaired and maintained at a faster rate than the collagen fascicles. It is also the first region of tendon to respond to overload damage, suggesting injury may initiate in the IFM.

Tendons from older, more injury prone individuals show loss of IFM structural specialization and reduced tendon fatigue resistance [4,5]. We also see reduced turnover rate of the IFM suggesting less capacity for IFM renewal [6].

Taken together, our data indicate an active and mechanoresponsive IFM cell population maintaining the heavily loaded IFM region of energy storing tendons in health, and a mechanical and cellular response to overload focused in the IFM and leading to tendon injury.

We now focus our attention towards developing in vivo and in vitro models to explore IFM mechanobiology and potential treatments for tendon injury, in further detail.

ENGINEERING THE CELL-MATRIX INTERFACE - UNDERSTANDING AND GUIDING CELL FUNCTION

Claudia Loebel$_P$[1]

[1] *University of Pennsylvania*

Corresponding author's email: loebelcl@seas.upenn.edu

The native extracellular microenvironment is dynamic, as cells synthesize, assemble, and remodel their surroundings during tissue development, injury, and repair. Biomaterials, such as hydrogels, have evolved as valuable tools to both investigate mechanisms of cell-extracellular matrix (ECM) interactions (e.g., mechanobiology) and to guide desired cell behavior towards the development of new therapies (e.g., tissue repair/regeneration); however, the dynamic nature of the cell-ECM interface has been underappreciated. To address this, we are utilizing metabolic labeling techniques to visualize secreted matrix components to better understand how this nascent matrix influences cellular behavior and we are designing proteolytically degradable and viscoelastic hydrogels that harness dynamic cell-hydrogel interactions. We have used these techniques to explore questions related to cellular mechanosensing in 3D(1), to better understand the evolution of matrix in modifying the cell-hydrogel interface in the engineering of tissues (e.g., cartilage(2)), and to develop microfabricated hydrogel platforms for the culture of organoids towards cellular therapies and as in vitro models of tissue repair. Our evolving understanding of this cell-material interface will not only open up new avenues for engineering functional biomaterials, but will allow us to design better systems for medical therapies.

Abstract **#19**

THE SWEET SIDE OF BIOMATERIALS: CLARIFY THE ROLE OF GLYCANS

Francesco Nicotra[P][1,2]

[1] *University of Milano-Bicocca*

2 IUPAC

Corresponding author's email: francesco.nicotra@unimib.it

The morphology and biomolecular composition of ECM induces cell fate, resulting in tissue regeneration or in pathological events. Glycans are indispensable components of ECMs, to which they provide not only structural and even mechanical properties, but also biological signals. It is interesting to observe how Nature has orchestrated cell homing, proliferation and morphogenesis exploiting the two major classes of biomolecules, protein and glycans, with synergistic but also quite different roles. Structural features, swelling properties, capacity to perform stronger or weaker interactions, with lower or higher specificity, are alternatively governed by glycans versus proteins. Clarify the contribution of glycans is even more challenging due to the heterogeneity and dynamism of their composition in the ECM components and at the cell surfaces. Evidences indicate that aging, diet, environmental factors and pathologies significantly influence the glycosignature, in a cause-effect relationship not yet clarified. In order to spread light in this very intrigued matter, strategies are needed to generate ECMs functionalized with different glycans, and study the specific cell responses. The functionalization approaches to conjugate biomaterials with glycidic cues and to crosslink polysaccharide to proteins or synthetic polymers will be described and their role to induce specific cell fate analyzed.

ENGINEERED SKIN GRAFT WITH STROMAL VASCULAR FRACTION CELLS ENCAPSULATED IN FIBRIN–COLLAGEN HYDROGEL: A CLINICAL STUDY FOR DIABETIC WOUND HEALING

Mahsa Mollapour Sisakht[P][1,2]

[1] *Skin and Stem Cell Research Center, Tehran University of Medical Sciences, Tehran, Iran*

[2] *Department of Biochemistry, Erasmus University Medical Center, Rotterdam, the Netherlands*

Corresponding author's email: m.molapoursisakht@erasmusmc.nl

Despite the abundance of skin substitutes in the worldwide market, major hurdles in developing more complex tissues include the addition of skin appendages and vascular networks as the most important structure. The aim of this research was a clinical feasibility study of a novel prevascularized skin grafts containing the dermal and epidermal layer using the adipose stromal vascular fraction (SVF)-derived endothelial cell population for vascular network regeneration. Herein, we characterized hydrogel with emphasis on biological compatibility and cell proliferation, migration, and vitality. The therapeutic potential of the prevascularized hydrogel transplanted on five human subjects as an intervention group with diabetic wounds was compared with nonvascularized skin grafts as the control on five patients. Wound planimetric and biometric analysis was performed using a Mann–Whitney nonparametric t-test ($p \leq .05$). The fibrin–collagen hydrogel was suitable for skin organotypic cell culture. There was a significant ($p \leq .05$) increased in skin thickness and density in the vascular beds of the hypodermis measured with skin scanner compared with that in the control group. No significant macroscopic differences were observed between the intervention and control groups ($p \leq .05$). In summary, we report for the first time the use of autologous dermal–epidermal skin grafts with intrinsic vascular plexus in a clinical feasibility study. The preliminary data showed that SVF-based full-thickness skin grafts are safe and accelerate the wound healing process. The next stage of the study is a full-scale randomized clinical trial for the treatment of patients with chronic wounds.

STEM CELLS AND BIOMATERIALS FOR THE REGENERATIVE MEDICINE OF INTERVERTEBRAL DISC: A PARADIGM SHIFT IN SPINE SURGERY

Jerome Guicheux[P][1]

[1] *INSERM U1229-RMeS, Regenerative Medicine and Skeleton research Centre, Nantes University & Hospital, ONIRIS, Nantes, France.*

Corresponding author's email: jerome.guicheux@inserm.fr

Degenerative disc disease (DDD), shares a lot of its pathogenic mechanisms (tissue degeneration, inflammation..) with osteoarthritis (OA) and is one of the major causes of low back pain (LBP). Currently, LBP is primarily managed by pharmacological treatments and if unsuccessful by surgical procedures (spine fusion or arthroplasty). To clinically address LBP earlier in the degenerative cascade of IVD, biology-inspired regenerative strategies could offer less invasive and etiological alternatives to spinal reconstructive surgery (1). Considering their tissue regenerative abilities, anti-inflammatory and immunomodulatory properties and their promising clinical outcomes in knee OA, the intradiscal injection of mesenchymal stem/stromal cells (MSC) have been contemplated with a growing interest.

In this context, we will first share our view of the mesenchymal stromal cells (MSC)-based therapeutic approaches that have been preclinically developed and, for some of them, clinically transferred in patients with DDD-associated LBP (2). Then, we will comment on the recent biomaterial-assisted MSC therapies that recently enter the preclinical and clinical scene and discuss whether injectable biomaterials that could be used as cell carriers and percutaneously transplanted into degenerated IVDs may be a relevant therapeutic strategy. We will also discuss whether induced pluripotent stem cells (iPS) could be a relevant cell source for the production of regenerative IVD cells (3) and whether iPS-derived disc cells may warrant clinical use.

Finally, we will present some recent perspectives (3D Bioprinting, extracellular vesicles, endogenous regeneration (4), annulus repair (5)..) and whether these concepts may pave the way of future therapeutic developments for DDD-associated LBP.

Low back pain resulting from intervertebral disc (IVD) degeneration is a global problem. In the field of disc degeneration, several cell-based technologies have reached the clinical trial stage [1,2]. While these are exciting times in the field, it is unclear whether cell-based approaches will lead to improved patient outcomes within reasonable timeframes. An important factor that may limit the potential of all cell-based regeneration strategies is the intrinsic harsh microenvironment that exists within the degenerated intervertebral disc, which is characterised by reduced oxygen, reduced glucose, matrix acidity and inflammation [3]. Biomaterials, and in particular injectable hydrogel-based systems, have played an important role over the past decade overcoming some of the issues associated with cell leakage, by providing a protective niche during intradiscal delivery as well providing important physicochemical cues to transplanted or resident cells. Advances have also been made in designing and developing composite biomaterials to direct specific biological responses or by enhancing biomechanical properties using fibre-like materials. More recently, advances have been made in tissue engineering the entire disc including the annulus fibrosus and cartilage endplates. While this ambitious goal is still in its infancy, it is a significant advancement and refinements are likely to emerge in the coming years.

This talk will highlight some of the important advances in biomaterials and existing challenges in the field of intervertebral disc regeneration and discuss emerging technologies and strategies that include advanced biomaterials, cell priming, predictive in silico modelling and biofabrication technologies.

THE POTENTIAL OF THE MESENCHYMAL STROMAL CELL SECRETOME IN EQUINE REGENERATIVE MEDICINE

Gerlinde Van de Walle[P][1]

[1] *Cornell University*

Corresponding author's email: grv23@cornell.edu

The secretome is defined as the global group of bioactive factors secreted by cells which regulates a variety of biological and physiological process, thus making it a clinically relevant source to identify potential therapeutics. To explore the potential of the equine MSC secretome as a safe and effective therapy in equine medicine, our lab studies its functional effects in the context of wound healing. The prevalence of impaired cutaneous wound healing in horses is high, and treatment is difficult and often ineffective. In addition to bioactive molecules with regenerative properties, we also identified secreted factors with antimicrobial properties against bacteria that commonly infect wounds, including the methicillin-resistant Staphylococcus aureus (MRSA), both in planktonic form and when organized in biofilms. For the latter, we found that equine MSC secrete cysteine proteases that destabilize MRSA biofilms, thereby increasing the efficacy of antibiotics that were prior tolerated by the biofilms. Collectively, our results demonstrate the potential of the equine MSC secretome as a promising new therapy in equine wound management.

REGENERATIVE CELL THERAPY FOR OSTEOARTHRITIS

Gunil Im[P][1]

[1] *Dongguk University*

Corresponding author's email: imgunil@hanmail.net

When cell therapy was first reported to treat cartilage defects and osteoarthritis, an optimistic view prevailed which held that implanted cells could be incorporated into defects and regenerate AC. The main focus was on how to ensure that the implanted stem cells possess the full properties of articular chondrocytes. As it became evident that almost all IA-administered stem cells rapidly undergo apoptosis and that their principal mode of action is paracrine, two strategies rose up to help enhance the effects of cell therapeutics: 1) enhance the survival of stem cells by pretreatment with factors known to promote cell survival or by administration of stem cells in physical states that favor longer-term survival, such as the spheroid form or encapsulated in a hydrogel, and 2) apply stem cells in a high concentration and prevent dispersal into the joint using a bioadhesive .Given that the mechanisms underlying necrosis versus survival of implanted stem cells are not well-established, future studies should focus on how the fate of IA-administered stem cells is affected by factors such as the physical status of the cells, mode of implantation, and adjuvant biomaterials.

PROGENITOR CELLS OF THE INTERVERTEBRAL DISC FOR TISSUE ENGINEERING – FAKE OR SOON A REALITY FOR THE CLINICS?

Benjamin Gantenbein$_P$[1,2]

[1] *Department for BioMedical Research (DBMR) University of Bern*

[2] *Department for Orthopedics & Traumatology, Insel Hospital, University of Bern*

Corresponding author's email: benjamin.gantenbein@dbmr.unibe.ch

Stem cell therapy for the intervertebral disc (IVD) is highly debated but holds great promises. From previous studies, it is known that notochordal cells are highly regenerative and may stimulate other differentiated cells to produce more matrix [1,2]. Lately, a particular tissue-specific progenitor cell population has been identified in the centre of the intervertebral disc (IVD [3]. The current hope is that these nucleus pulposus progenitor cells (NPPC) could play a particular role in IVD regeneration.

Current evidence confirms the presence of these cells in murine, canine, bovine and in the human fetal/surgical samples [4]. Noteworthy, one of the main markers to identify these cells, i.e., Tie2, is a typical marker for endothelial cells. Thus, it is not very clear what their origin and their role might be in the context of developmental biology. In human surgical specimens, their presence is, even more, obscured depending on the donor's age and the particular condition of the IVD [3, 4] and other yet unknown factors

Here, I revisit the recent literature on regenerative cells identified for the IVD in the past decades. Current evidence how these NPPC can be isolated and detected in various species and tissues will be recapitulated. Future directions will be provided on how these progenitor cells could be used for regenerative medicine and tissue engineering.

ENGINEERING BIOMIMETIC FIBER SCAFFOLDS: FROM MIMICKING THE EXTRACELLULAR MATRIX TO NEURONAL AXONS

Sing Yian Chew$_P$[1]

[1] *Nanyang Technological University*

Corresponding author's email: sychew@ntu.edu.sg

Fiber constructs closely mimic the size-scale and architecture of the natural extracellular matrix. When presented to appropriate cell types, engineered fibers may also pose as artificial axons. These platforms represent a unique class of materials in regenerative medicine and non-viral drug/gene delivery. Fibrous topography can direct cell fate. Combined with the incorporation of gene silencing molecules, such as small non-coding RNAs, these scaffolds provide synergistic topographical and biochemical cues to cells. Here, we will present our recent findings on the roles of fiber-mediated mechanotransduction on oligodendrocyte differentiation and myelination, as well as gene silencing on nerve regeneration and remyelination, using spinal cord injury as a proof-of-principle.

BIOMATERIALS THAT ENABLE AND DRIVE SCAFFOLD-FREE TISSUE FORMATION

Eben Alsbeerg$_P$[1]

[1] *University of Illinois at Chicago*

Corresponding author's email: ealsberg@uic.edu

Scaffold-free cultures of cells can mimic immature condensates that initiate many developmental and healing processes. Providing specific soluble signals, such as growth factors, exogenously in tissue culture media to regulate cell behavior and promote new tissue formation may be limited by transport issues, lack of spatial control over signal presentation, and required repeated dosing. The first part of this talk will be a report on systems that incorporate biomaterial microparticles containing bioactive signals within scaffold-free cell cultures, permitting localized spatiotemporal control over the presentation of these regulatory cues to the cells to engineer a variety of tissues. Three-dimensional bioprinting has been pursued as a method of building functional scaffold-free tissue constructs with sophisticated geometries without an intervening scaffold that can interfere with critical cell-cell interactions. However, to date it has not been possible to print individual cells directly, as preculturing was required to first form cell aggregates or strands prior to printing. The latter part of this talk will cover the first bioprinting platform using single cells alone, without a macromer solution, as bioink that can maintain printed geometries. A shear-thinning and self-healing biomaterial support bath was engineered to permit high-resolution printing into precise geometries, maintenance of cell viability, cellular condensation formation and long-term culture of constructs for development of engineered tissues. Collectively, these platforms may advance cellular condensation-based regenerative medicine strategies, enhance drug-screening capabilities and provide new tools for addressing questions in developmental biology.

Gene therapy provides a wide range of opportunities to improve treatment of patients with different diseases and even change the face of medicine. In 2011, a gene-therapeutic drug based on plasmid DNA encoding VEGFA gene was approved for treatment of patients with chronic lower limb ischemia ("Neovasculgen", HSCI, Russia). To date, thousands of people who suffered from this disease have been treated in Russia, with significant clinical improvement. In a long-term clinical study, the therapeutic effect persisted 5 years post the injection course (NCT03068585). A second clinical trial showed efficacy of Neovasculgen for diabetic foot syndrome treatment (NCT02538705) where wound healing was observed in 65.7% of patients with chronic ulcerative defects and the target limb salvage rate was 84%.Angiogenic effect induced by plasmid DNA carrying VEGFA has been utilised in development of gene-activated bone substitute based on octacalcium phosphate scaffold ("Histograft", Histograft, Russia). We conducted an open-label non-randomised clinical trial. 20 patients with alveolar ridge atrophy and jawbone defects were enrolled and underwent bone grafting. There were no adverse events or serious adverse events during the clinical trial or the follow-up period (more than 4 years). Newly formed tissues had a density similar to native bone (908.13±114.40 HU) that ensured the patients to receive dental implants. The histological analysis showed that the bone grafting zone consisted of newly formed bone tissue with some fragments of the gene-activated bone substitute partially-resorbed and integrated with native bone without fibrous tissue in between. To date, numerous patients underwent bone grafting with Histograft.

Corresponding author's email: linjianhao@pkuph.edu.cn

Osteoarthritis (OA) is a slowly progressive disease which ultimately leads to degeneration of articular cartilage. Mesenchymal stem cells (MSCs) have been tested over the last decade as a potential regenerative therapy for treat- ing OA. Preclinical and clinical studies have recently demonstrated some favorable effects on cartilage repair when MSCs were injected into OA joints in animal models and in humans. In our studies, we firstly confirmed the early effects of MSCs on the progress of OA. We, then, investigated an improved strategy for cell delivery to OA joint through the use of three-dimensional (3D) microcryogels. Recently, we found that the 3D microcryogels with MSCs assembled into a tissue construct, which has been used in cartilage regeneration.

[1] *Helmholtz Zentrum Geesthacht, Metallische Biomaterialien*

Corresponding author's email: regine.willumeit@hzg.de

Magnesium based implants are a new class of degradable metallic medical devices. Their performance and degradation properties depend on a plethora of factors. To understand the complex interaction of the material with the environment, ex situ and in situ techniques like synchrotron radiation based µCT can be applied to study the degradation of the material over time. This data can then be used to model the degradation process which in turn can be coupled to a model which describes the biochemical effects of Mg and alloying elements on tissue regeneration. Based on this approach a clearer view on the dynamic interaction between metal and tissue will be presented.

PCP/VANGL2 SIGNALLING REGULATES WNT CYTONEMES

Steffen Scholpp[P][1], Lucy Brunt[1]

[1] *Living Systems Institute, University of Exeter*

Corresponding author's email: s.scholpp@exeter.ac.uk

After secretion, developmental signals known as morphogens must travel distances to form a concentration gradient that the responding tissue uses to acquire positional information. The role of morphogen transport in this process is the subject of intense debate. Wnt proteins regulate developmental processes, tissue regeneration and stem cell maintenance. It has been postulated that Wnt/beta-catenin signalling form concentration gradients across responsive tissues and act as morphogens. However, little is known about the transport mechanism for these lipid-modified signalling proteins in vertebrates.

Here we show that Wnt proteins are transported on short, actin-based cytonemes to contact responding cells and activate signalling. We further demonstrate that the transmembrane protein Vangl2 in concert with the receptor Ror2 activates the beta-catenin independent PCP pathway to regulate the formation of these signalling cytonemes. We show that PCP/Vangl2 signalling in the Wnt producing cells controls the effective signalling range of Wnt in zebrafish embryos, in the mouse intestinal crypt and in human gastric cancer cells.

We conclude that cytoneme-based trafficking is fundamental for Wnt signalling in vertebrates.

IMAGING MASS SPECTROMETRY OF THREE DIMENSIONAL CELL CULTURES AND ORGANOIDS

Amanda Hummon[P][1]

[1] *The Ohio State University*

Corresponding author's email: hummon.1@osu.edu

Three dimensional cell cultures are attractive models for biological research. They combine the flexibility of cell culture with some of the spatial and molecular complexity of tissue. For example, colon cancer cell lines form spheroids, in vitro mimics of poorly vascularized tumors. The spheroids are composed of a central necrotic core, a middle quiescent layer and an outer proliferative layer of cells, similar to a rapidly growing colon tumor. Our laboratory has characterized the distribution of endogenous proteins via MALDI imaging mass spectrometry in colon spheroids and determined that the molecular gradients correlate with the pathophysiological changes in the structure. We have also developed an approach to employ 3D cell cultures to evaluate the penetration of compounds into cellular masses. Most novel drugs are initially evaluated with 2D cultures before moving directly to costly animal studies. 3D cultures provide an ideal testbed to minimize these studies. Working with the chemotherapeutics oxaliplatin and irinotecan, our data supports differential penetration of these clinically relevant drugs. We are employing microfluidic devices to enable dynamic dosing, thus investigating the pharmacokinetics and pharmacodynamics of chemotherapy regimes in these attractive model systems. We have also extended our imaging mass spectrometry platforms to the study of patient and mouse-derived organoids, examining the distribution and metabolism of drugs compounds in these clinically relevant specimens.

Abstract **#34**

A BIOMIMETIC MACROPOROUS HYBRID SCAFFOLD WITH SUSTAINED DRUG DELIVERY FOR ENHANCED BONE REGENERATION

Seunghun S Lee[P][1], Matthias Santschi[1], Stephen J Ferguson[1]
[1] *Institute for Biomechanics, ETH Zurich, Zurich, Switzerland*
Corresponding author's email: seunglee@ethz.ch

Bone regeneration is a highly complex physiological process regulated by several factors. In particular, bone-mimicking extracellular matrix and available osteogenic growth factors such as bone morphogenetic protein (BMP) have been regarded as key factors to induce bone regeneration. In this study, we developed a biomimetic hybrid scaffold (CEGH) with sustained release of BMP-2 that would result in enhanced bone formation. This hybrid scaffold, composed of BMP-2 loaded cryoelectrospun poly ε-caprolactone (PCL) (CE) surrounded by a macroporous gelatin/heparin cryogel (GH), is designed to overcome the drawbacks of the relatively weak mechanical properties of cryogels and poor biocompatibility and hydrophobicity of electrospun PCL. The GH component of the hybrid scaffold provides a hydrophilic surface to improve the biological response of the cells while the CE component increases the mechanical strength of the scaffold, to provide enhanced mechanical support for the defect area and a stable environment for osteogenic differentiation. After analyzing characteristics of the hybrid scaffold such as hydrophilicity, pore difference, mechanical properties and surface charge, we confirmed that the hybrid scaffold group shows enhanced cell proliferation rate and apatite formation in simulated body fluid. Then, we evaluated drug release kinetics of CEGH and confirmed the sustained release of BMP-2. Finally, the enhanced osteogenic differentiation of CEGH with sustained release of BMP-2 was confirmed by Alizarin Red S staining, and real-time PCR analysis.

This project has received funding from the European Union's Horizon 2020 research and innovation programme under the Marie Skłodowska-Curie grant agreement No 812765.

RESETTING THE EPIGENETIC CLOCK: DNA METHYLATION CHANGES IN REPROGRAMMING AND DIFFERENTIATION OF IPSCS

Wolfgang Wagner[P][1], Julia Franzen[1], Yang Han[1]

[1] *RWTH Aachen Medical School*

Corresponding author's email: wwagner@ukaachen.de

Aging of the organism as well as culture expansion of primary cells is associated with highly reproducible DNA methylation (DNAm) changes at specific sites in the genome – therefore these processes can be tracked by different epigenetic predictors. The so called “epigenetic clocks” provide biomarkers to either gain insight into aging or for quality control of cells in culture. In this presentation, I will show ongoing work to further optimize epigenetic clocks with barcoded bisulfite amplicon sequencing (1, 2). Upon aging/passaging the DNAm patterns of neighboring CpGs become more complex, while they do not appear to be coherently regulated. During reprogramming into induced pluripotent stem cells (iPSCs) the age-associated as well as long-term culture-associated DNAm changes are reversed simultaneously with pluripotency-associated DNAm changes. Interestingly, iPSC-derived cells remain epigenetically rejuvenated for age-associated changes, whereas upon differentiation particularly the culture-associated DNAm changes are again gradually acquired. Chromatin immunoprecipitation demonstrated that CTCF binds particularly in the vicinity of genomic regions that become hypomethylated upon aging, whereas it is rather enriched at regions that become hypermethylated during long-term culture. Thus chromatin conformation seems to have a different impact on epigenetic clocks for aging and in vitro expansion.

IMPLANTABLE THERAPEUTIC RESERVOIR SYSTEMS FOR DIVERSE CLINICAL APPLICATIONS IN LARGE ANIMAL MODELS

Garry P. Duffy[P][1,2]
[1] *National University of Ireland Galway*
[2] *CURAM SFI Centre for Medical Devices*
Corresponding author's email: garry.duffy@nuigalway.ie

Significant potential has been attributed to regenerative medicine approaches, specifically stem cell technologies, to treat a diverse array of pathologies, however the functional outcomes of such approaches have been limited as studies have unanimously shown poor retention/survival of delivered cells. A delivery system that facilitates regional and repeated delivery to target tissues can provide enhanced clinical efficacy of cell therapies when localized delivery of high doses of cells are required.
We have developed a regenerative reservoir platform (Regenervoir) for use in small and large animal models, with relevance to cardiac, abdominal, and soft tissue pathologies. Regenervoir incorporates multiple novel design features essential for clinical translation, with a focus on scalability, mechanism of delivery, fixation to target tissue, and filling/refilling with a therapeutic cargo, and is demonstrated in an array of clinical applications that are easily translated to human studies.

Abstract **#37**

THE DEVELOPEMENT AND TRANSLATION OF TISSUE ENGINEERED CONSTRUCTS FOR USE IN CONGENITAL HEART SURGERY

Christopher Breuer[P][1]

[1] *Nationwide Children's Hospital*

Corresponding author's email: christopher.breuer@nationwidechildrens.org

Congenital cardiac anomalies represent the most common birth defect, affecting approximately 1% of live births. Despite advances in surgical and medical management, these conditions remain a leading cause of death in newborns. A significant source of postoperative morbidity and mortality in this patient population arises from the use of prosthetic materials, in the form of vascular grafts, cardiovascular patches, and replacement heart valves, which are associated with an increased risk of thromboembolic events, poor durability, susceptibility to infection, and lack of growth capacity. In contrast, tissue engineering offers a promising strategy for creating improved biomaterials to repair or replace tissues in children undergoing congenital heart surgery. Our research team pioneered the development and clinical translation of tissue engineering technologies to create improved vascular grafts, cardiovascular patches, and replacement heart valves for the surgical repair of congenital cardiac anomalies. Using the tissue engineered vascular graft (TEVG) as the archetype for tissue engineered cardiovascular constructs, we demonstrated the feasibility of using this technology. Our tissue engineering approach uses a biodegradable scaffold upon which an individual's cells can be seeded. Neotissue forms as the scaffold degrades, ultimately creating a living autologous structure called a neovessel, which is devoid of synthetic components and possesses an ability to repair, remodel, and grow. In this presentation, we will describe the development, translation, and refinement of the TEVG. Having viable cardiovascular constructs with growth potential enables reconstructive procedures at an early age, mitigates the potential for additional surgeries due to overgrowth, and could improve patient outcomes.

Since skeletal muscles contribute to metabolic, neuromuscular, and dystrophic disorders, tissue-engineered muscle tissue models will become a powerful tool to elucidate the mechanisms of muscle diseases and facilitate the development of new drugs for their treatments. Several research groups including us have reported innovative strategies to artificially regenerate the native-like aligned structure of muscle tissues. On the other hand, engineered human muscle tissues remain difficult to be matured significantly in vitro, compared with rodent muscle tissues. In order to hurdle this issue, some defined culture methods have been recently developed. Our group has also reported a new culture method for the production of human muscle tissue construct with biomimetic features.1 Whereas these techniques would be applied for the studies of muscle physiology and pathology in human body, they are ill-equipped to pursue new findings in the study of neuromuscular diseases including a process requiring the development of neuromuscular junction (NMJ). Since muscle wasting and weakness in motor neuron diseases (MNDs) arise predominantly from the loss of normally function motor neurons, some research groups are currently focusing on the development of NMJs in tissue constructs. Particularly, when coupled with the ability to obtain iPS cells from patients with MNDs such as amyotrophic lateral sclerosis (ALS) and spinal muscle atrophy (SMA), the tissue engineering technology will make it possible to produce diseased NMJ systems in vitro. In conclusion, these newly developed methods exhibit potential to produce muscle tissue models which will become a new platform for the biological studies of neuromuscular pathophysiology.

PERSONALIZED TUMOR ORGANOIDS FOR ADVANCEMENT OF CANCER TREATMENTS

Shay Soker[P][1,2]
[1] *Wake Forest School of Medicine*
[2] *Wake Forest Institute for Regenerative Medicine*
Corresponding author's email: shaysoker@yahoo.com

Major challenges in cancer therapy are to determine if a local disease will progress to a malignant phenotype, and how to best 'match' treatments to an individual patient. For many years, basic cancer research and anti-cancer drug development utilized primary cancer cells and cell lines cultured in vitro on tissue culture plastic dishes. Cell culture is a poor analogue of tumor growth in vivo, in part because it doesn't replicate the microenvironment of a tumor, a complex space typified by stromal cells, ECM components, and a cocktail of signaling factors. Newly developed bioengineered tissue platforms, such as 3D orgaonids, open new opportunities for tumor modeling, especially incorporating the complex cellular and physical tumor microenvironment that are known to drive cancer cells in a specific manner. For example, the tumor stroma can activate or inactivate cancer-related pathways, alter ECM components, thereby making migration more or less difficult, as well as secrete signaling factors that guide cancer cells in a multitude of ways. A significant advantage of the tumor organoids is that they can be derived from individual patients and enable personalized testing of drug response, including immunotherapies. Furthermore, personalized tumor organoids have the potential to serve as a drug discovery platform and identification of new therapeutic targets, based on individual pathology, mutational profiles and tumor cell clonality.

Recapitulation of developmental processes is discussed as a potential key to cartilage regeneration.
The aim of the presented study was therefore to test the effect of fetal secretomes on inflamed chondrocytes in vitro.
A comprehensive in vitro experiment was carried out employing gene expression analysis (sheep specific whole genome microarrays), protein secretion analysis (label free bottom-up shot gun proteomics by high resolution orbitrap mass spectrometry), proliferation assays, wound healing assays and beta-Galactosidase assays for cell senescence to characterize the effect of fetal secretomes (obtained from fetal chondrocytes and fetal MSCs) on adult injured chondrocytes (inflamed with 10ng IL1beta and TNFalpha per ml of medium). Secretomes of three fetal donors (for chondrocytes and MSCs) where pooled and tested on inflamed adult chondrocytes obtained from three different individuals.
We further compared the secretome composition and the response of the treated chondrocytes to key factors of fetal regeneration identified in previous studies. In these previous studies standardized cartilage lesions were surgically induced in adult (aged 2-4 years) and fetal sheep (80 days gestation). Time points for sampling were chosen according to the stages of healing (inflammatory phase, reparative phase, remodelling phase). Samples were compared for protein secretion and on the histologic level with special emphasis on extracellular matrix composition, collagen organization and collagen types, qualitative and quantitative composition of growth factors and cytokines, inflammatory response, chemotaxis, cell proliferation, MMPs and migration as well as senescence.
Tremendous differences between adult and fetal regeneration were observed with regard to inflammation-related processes and extracellular matrix remodelling.

INTRODUCTION: Human extracellular matrix (ECM) proteins are regarded as the perfect scaffold material for the manufacturing of medicinal products.[1] Numerous publications have shown that human ECM goes along with a better performance in cell culture and clinical applications when compared to animal ECM.[2] Human placenta is globally available and a constant source for industrial processing. The aim of this project was to establish a human ECM protein-based platform technology from placenta for cell culture applications.

MATERIAL/METHODS: Human ECM proteins were extracted using enzymatic or non-enzymatic strategies. Collagen-1 (COL1/3) was extracted using pepsin.[3] Laminin-111 (pLm111) and a basement-protein rich human placenta substrate (hpS) were extracted using Tris-NaCl buffers.[4,5] All extracted proteins were extensively characterized and used in different 2D or 3D in vitro experiments using HUVEC, hepatozytes, fibroblasts, or other cells.

RESULTS: Significant differences in cell viability, growth rate, or phenotype were observed between animal-based proteins and human-based proteins (COL1/3, pLm111, hpS), favoring the use of human-materials based for cell culture applications.

DISCUSSION/CONCLUSION: The source of biomaterials significantly influences the results of cell culture experiments. Human ECM proteins support the “3R” criteria in science and enable a better quality when compared to animal materials. Human ECM proteins could bring more precision into TERM, refine in vitro diagnostics or drug screening applications and by that reduce the drug development time in medicine. However, more experiments have to be performed, to assess the full potential of human ECM proteins for TERM.

TACKLING IMPLANT-ASSOCIATED INFECTIONS: TO PREVENT OR TO TREAT?

Rikke Meyer[P][1]

[1] *Interdisciplinary Nanoscience Center, Aarhus University*

Corresponding author's email: rikke.meyer@inano.au.dk

Implant-associated infections become chronic when bacteria form biofilms in which the bacteria exist are encased in a self-produced extracellular matrix that protects them from phagocytosis. Biofilms harbor persister-cells, which are dormant or slow-growing bacteria that tolerate extreme levels of antibiotics. These cells revive and cause the infection to relapse when antibiotic treatment is terminated. If the implant cannot be surgically replaced, the prognosis for some implant-associated infections is as poor as some of the worst cancers.

Faced with the failure of antibiotic treatment, decades of research has been devoted to understanding how bacteria attach to implants and form biofilms, and whether biofilm infections can be prevented by intercepting bacterial attachment. However, there is little evidence to suggest that the impressive results from anti-adhesive materials studied in the lab, will translate into lower infection rates in the clinic. Development of more effective treatments may therefore be more likely to succeed in tackling implant-associated infections. Such treatments rely on either high local doses of antibiotics, or development of entirely new drugs that effectively kill bacteria in a dormant state.

This keynote lecture gives an overview and discuss developments in anti-adhesive materials to prevent implant-associated infections, and the strategies for novel drugs or drug-delivery methods that eradicate the infection when prevention fails.

OSTEOCONDUCTION AND BONE AUGMENTATION: WHEN 3D-PRINTED DESIGNS MEET BONE BIOLOGY

Franz E Weber[P][1]

[1] *University of Zurich/Oral Biotechnology & Bioengineering*

Corresponding author's email: franz.weber@zzm.uzh.ch

In the last decades, advances in bone tissue engineering mainly based on osteoinduction and on stem cell research. Only recently, new efforts by others and us focused on the micro- and nanoarchitecture needed to improve and accelerate bone regeneration. By the use of additive manufacturing, libraries of diverse microarchitectures were produced and tested to identify the ideal pore size or rod distance for osteoconduction to occur. Presently, we try to elucidate the dependency of osteoconduction on microporosity and expand our view on micro- and nanoarchitecture of bone substitutes for optimal bone augmentation.

For the production of scaffolds, we applied for titanium-based scaffolds selective laser melting and for ceramics the CeraFab 7500 from Lithoz, a lithography-based additive manufacturing machine. As in vivo test model, we used a calvarial defect and a bone augmentation model in rabbits. The histomorphometric analysis showed that bone formation was significantly increased with pores between 0.7-1.2 mm in diameter. Moreover, microporosity appeared to be a strong driver of osteoconduction and influenced osteoclastic degradation. Best microarchitecture for osteoconduction and bone augmentation are not identical.

In essence, additive manufacturing enabled us to generate libraries of microarchitectures to search for the most osteoconductive microarchitecture and the ideal microarchitecture for bone augmentation purposes. Moreover, additive manufacturing appears as a promising tool for the production of personalized bone tissue engineering scaffolds to be used in cranio-maxillofacial surgery, dentistry, and orthopedics.

Decellularized tissue is an extracellular matrix obtained by removing cells from living tissue and is expected to be one of candidate biomaterials because of its high biocompatibility and high functionality. One of the problems is that the recellularization of a decellularized tissue is slow when used as a substitute tissue because infiltration of cells into the interior is extremely slow and difficult. Therefore, in this study, as one solution, a 3D tissue with cells was developed by re-cellularization and fabrication of the decellularized pericardium (d-pericardium). Porcine pericardium was treated with high hydrostatic pressure and then washed to remove cellular debris. The decellularization was confirmed by DNA quantification and HE staining. For SEM observation of the surface of d-pericardium, the wavy fibers with the diameter of about 0.5µm were observed and the fibers were aligned with same direction. Cells (C2C12 or hMSC) were seeded on the d-pericardium. Cells were adhered along with the direction of fibers on the d-pericardium and proliferated on the d-pericardium keeping the direction. The recellularized pericardium was cylindrically rolled so that the cell extending direction was parallel to the long axis direction of the cylinder and cultured for 3 days under static and flow conditions. The cells were still observed between the decellularized pericardium. The tensile strength of the 3D reconstructed tissue was similar to that of porcine anterior cruciate ligament. These results suggest that the ligament-like tissue was developed by the cylindrical formation of the recellularized d-pericardium.

DYNAMIC RECIPROCITY IN SUPRAMOLECULAR BIOMATERIALS: TOWARDS RESPONSIVE BIOMATERIALS

Joyce Brouns[P][1,2], Patricia Dankers[1,2]

[1] *Eindhoven University of Technology, Department of Biomedical Engineering*

[2] *Institute of Complex Molecular Systems (ICMS), Eindhoven University of Technology*

Dynamic reciprocity (DR) refers to the bidirectional interaction between cells and their extracellular matrix. One example of DR is the activity between matrix metalloproteinases (MMPs) and their inhibitors (TIMPs). In pathophysiological conditions, the balance between MMP and TIMP activity can be shifted, and excessive MMP activity can cause maladaptive changes to the tissues [1]. The aim of this project is the exploration of dynamic reciprocity in synthetic solid materials via feed-back controlled mechanisms.

We make use of supramolecular materials that are based on supramolecular motifs that allows polymers to self-assemble into supramolecular structures using hydrogen bonding [2]. These supramolecular motifs were coupled to MMP cleavable peptides and MMP inhibitor peptides and processed into a supramolecular scaffold. We showed that the MMP cleavable peptide can be cleaved both in solution and from surface. Moreover, the MMP inhibitor peptide could inhibit the MMP activity even when incorporated into a supramolecular surface. Next steps involve the incorporation of bioactive molecules in the system that can be cleaved from the surface upon different cellular cues. In this way, a biomaterial can be developed that respond to cellular cues (enzymes) by releasing molecules. This process can be inhibited by the release of inhibitor peptides. In this way, a biomaterial can be developed that shows a true interaction with the host tissue, being able de adapt and respond to cellular cues.

MODULAR HYDROGELS REVEAL THAT ILC1 DRIVE EPITHELIAL AND MATRIX REMODELLING IN HUMAN IPSC-DERIVED INTESTINAL ORGANOIDS

[1] *King's College London*

Corresponding author's email: eileen.gentleman@kcl.ac.uk

Type-1 innate lymphoid cells (ILC1) are enriched in patient mucosa with active inflammatory bowel disease (IBD), but the impact of this accumulation remains elusive. We established co-cultures of murine small intestinal organoids (SIO) with ILC1, and human iPSC-derived intestinal organoids (HIO) with patient ILC1. Transcriptomic analysis of SIO co-cultures revealed that IFNγ sensitises epithelial cells to Fas-mediated apoptosis. However, ILC1 also drive expansion of the epithelial stem cell crypt through p38γ phosphorylation and aberrant Cd44v6 expression, which is unexpectedly regulated by ILC1-derived TGFβ1, not IFNγ. We next established that human ILC1 also secrete TGFβ1, and drive CD44v6 expression in both HIO epithelium and the surrounding mesenchyme, though this phenotype is only recapitulated by ILC1 from patients with active gut inflammation. As TGFβ1 is a master regulator of fibrosis, we next characterised the ability of ILC1 to regulate matrix remodelling. We created modifiable PEG hydrogels that cross-link quickly but at low stiffnesses and harnessed this platform to perform microrheology and atomic force microscopy on encapsulated HIO. We show that ILC1 drive matrix stiffening and degradation, which we posit occurs through a balance of MMP9 degradation and TGFβ1-induced fibronectin deposition. Our synthetic organoid co-culture system enabled us to tease apart an important role for intestinal ILC1 in epithelial and matrix remodelling, which may drive either wound healing or fibrotic pathologies in IBD. Moreover, this controlled 3D microenvironment provides a broader platform for dissecting interactions between complex tissues and rare cell subtypes in development and disease.

Porous gradient structure is able to provide both mechanical strength and bone ingrowth of implant by adapting the porosity gradient. The aim of this study was to develop a general methodology for the design of customized gradient porous implant and to validate the osteointegration of a new type of porous structure. In macro level, the optimal distribution of mechanical properties of the implant was obtained in line with the design criterions of safety and stability, under the control of self-developed algorithms in FE model. In micro level, the relationship between geometric parameters and the equivalent mechanical properties of micro representative volume element (RVE) was investigated by finite element analysis and validated via mechanical tests. The osteointegration of a new kind of unit cell, body-centered cubic (BCC), was validated using animal experiments of rabbit model. The gradient porous implant was established by assembling all the RVEs automatically according to the functional relationship between elastic modulus and geometrical parameters. A hip implant was taken as an example. The gradient porous structure of a hip stem was automatic modelled with BCC unit based on optimized elastic modulus distribution. There were two aspects of contribution of this study: In micro level, the mechanical properties and osteointegration of micro porous unit cell were investigated. In macro level, a general methodology for the design and modelling of gradient porous implant was provided.

HIGH-DEFINITION BIOPRINTING ENABLED BY LIGHT

Aleksandr Ovsianikov[P][1,2]
[1] *3D Printing and Biofabrication Group, TU Wien (Vienna, Austria)*

Light is a powerful tool for pattering biomaterials and engineering complex 3D cell culture matrices. It is therefore not surprising, that lithography-based 3D printing methods and according materials are enjoying rapid adoption in the field of biofabrication and tissue engineering.
Multiphoton lithography (MPL) is relying on the nonlinear absorption of femtosecond laser pulses [1]. MPL is outstanding among light-based approaches since it can produce features much smaller than a single mammalian cell. Usually MPL is perceived as a method capable of high-resolution volumetric structuring via photopolymerization of the material. However, MPL can also be used to induce photodegradation or spatially resolved covalent binding of specific molecules in the volume of the sample [2]. Herewith, MPL is a versatile tool when it comes to precise engineering of 3D biomimetic cell culture matrices. Furthermore, we have recently demonstrated direct embedding of cells via MPL using specialized gelatin based bioink formulations, paving the way for High-Definition Bioprinting [3]. Our results demonstrate a wide range of exciting applications, from controlling morphology of stems cells in 3D to modelling barrier tissues in vitro and patterning of hierarchical vascular networks using co-culture of endothelial and stem cells.
In this talk, the recent progress on MPL development will be presented. Current state of the art, challenges and future perspectives will be discussed.

Invited talk at the "Smart biomaterials and dynamic biofabrication processes powered by light" Symposium, chaired by Riccardo Levato & Michiya Matsusaki.

Octacalcium phosphate and collagen composite (OCPcol) demonstrated superior bone regeneration with angiogenesis (1, 2), and have been commercialized recently in Japan (3). Teriparatide (TPTD) is a bioactive recombinant form of parathyroid hormone that is approved for osteoporosis treatment. And OCPcol with a local single administration of TPTD enhanced bone repair of a rodent critical-sized bone defect (4, 5). Because mandibular bone reconstruction after segmental resection is a key clinical problem, it was examined whether single-dose local administration of OCPcol with TPTD can affect recovery after this procedure. OCPcol was prepared, and a commercially available hydroxyapatite and collagen composite (HAPcol) was used as a control. A 15 mm length segmental bone defect was made in the mandibular region of male beagle dogs. The experimental animals were divided in four groups. OCPcol treated with TPTD (OCPcol+TPTD), OCPcol, HAPcol treated with TPTD (HAPcol+TPTD), or HAPcol was implanted into the defect. The radiopaque areas of the implanted site were measured and statistically analyzed, and histological examination was performed after 6 months. The value of radiopaque area in total region of OCPcol+TPTD was highest, followed in order by OCPcol, HAPcol+TPTD, and HAPcol, and that of OCPcol+TPTD was significantly higher than that of HAPcol+TPTD or HAPcol. All segmented mandibles of OCPcol+TPTD and a part of those of OCPcol were bridged with newly formed bone, whereas no bone bridges were observed in HAPcol+TPTD or HAPcol. These results suggested that OCPcol treated with TPTD enabled bone reconstruction after segmental mandibular resection more than other three groups.

REGENERATIVE MEDICINE APPROACHES TO INTERVERTEBRAL DISC, IMPORTANCE OF PATHOLOGY

Christine Le Maitre[P][1]
[1] *Sheffield Hallam University*
Corresponding author's email: c.lemaitre@shu.ac.uk

Low back pain is the leading cause of morbidity worldwide and yet most therapies fail to target the cause and are purely symptomatic or end stage surgical options. Intervertebral disc degeneration is associated with approximately 40% of low back pain cases and thus a target for potential regeneration. Intervertebral disc degeneration is a catabolic process caused by altered cell behaviour and tissue biomechanics, leading to a harsh environment for potential cell therapies. A viscous cycle of degeneration, whereby cellular changes impact on matrix composition and biomechanical environment interact, leading to acceleration of degeneration. Degeneration leads to ingrowth of nerves into the normally aneural disc and increased synthesis of pain sensitizers leads to increased pain formation. To generate a successful regeneration strategy for the intervertebral disc this harsh environment must be considered. Here, the pathogenesis of disc degeneration will be discussed to highlight the importance of understanding the disease processes prior to developing regenerative approaches. The potential influence of the pathogenic processes which lead to disc degeneration will be discussed in light of regenerative approaches under development. Cellular, gene and biomaterial approaches for regeneration will be highlighted and their potential to halt the viscous cycle of degeneration enabling regeneration.

INTRODUCTION: We have previously reported the development of an injectable hydrogel (NPgel), which has the potential to deliver patients own stem cells, via small bore needles, decreasing damage to the annulus fibrosus. NPgel drives stem cell differentiation to NP cells, and can inhibit the degenerate niche. However, clinical success of NPgel is dependent on the capacity to inject NPgel into naturally degenerate human discs, restore mechanical function to the IVD, and prevent extrusion during loading. Here, we investigated the injection of NPgel containing IOHEXOL to enable visualization during injection into human cadaveric discs and performed extrusion testing to determine whether NPgel was retained in the disc.
METHODS: Cadaveric discs were prepared with intact vertebral bone, X-ray images were captured from transverse and sagittal planes together to determine disc height. Discs were pre-warmed to 37ºC prior to mechanical analysis, discs were loaded under simulated walking conditions to calculate Moduli. Following initial testing discs were injected with NPgel containing IOHEXOL using fluoroscopy to visualize injection and disc height measured. Moduli measurements were determined post injection prior to ultimate strength testing to determine whether any NPgel extruded.
RESULTS: NPgel (600-1000µl) was easily injected into cadaveric discs where it filled cracks and fissures. NPgel injection resulted in significant increase in disc height and youngs moduli, furthermore NPgel was not extruded during failure testing.
CONCLUSIONS: These results support the use of NPgel as an injectable therapy for regeneration of disc degeneration.

Effective designing of rehabilitation apparatus with high comfort and functionality depends upon the accurate characterization of the shape of the residual limb as well as its volume and shape fluctuations. The active behavior of skeletal muscles, which plays an important role in the interfacial biomechanics of human-machine interaction, is not considered in the current design processes of the rehabilitation apparatus. In this study, a three-dimensional finite element (FE) model of the human thigh was proposed to simulate the soft tissue deformation caused by muscle contraction. In this model, the muscle model was composed of personalized muscle geometries and parametric muscle fibers. For obtaining the nearest computational deformation response to the real muscles, the model parameters of the muscle fibers were adjusted iteratively according to the differences between the deformation distributions obtained from the numerical calculation and the experimental measurements. The FE model with optimized parameters proved to be effective in accurately predicting the dynamic deformation responses of the soft tissue. The results demonstrated that the average errors for soft tissue deformation in the expanding and shrinking regions of the thigh were 1.34mm and 2.27mm, respectively. For different gaits, the average difference in the equivalent volume and cross-sectional area changes were less than 0.83% and 1.86%, respectively. The soft tissue deformation data can be used in data-driven computational algorithms for the design of prosthetic sockets or orthoses as well as other wearable technologies mechanically interfacing with the skin.

Introduction: Recent studies investigating the effects of extracorporeal shockwave therapy (ESWT) on peripheral nerve regeneration in the rat have shown proregenerative effects of this non-invasive treatment approach. However, results of ESWT treatment after conduit repair of peripheral nerve defects have remained unstudied yet. It was the aim of this study to investigate the effects of ESWT treatment on nerve regeneration following conduit repair of the rat median nerve.
Methods: In 123 male Lewis-rats a 7-mm segment of the right median nerve was removed and immediately reconstructed using either 1) an autologous nerve graft 2) a muscle-in-vein-conduit 3) a chitosan-conduit or 4) a silk fibroin-conduit. Half of the animals of each group (n= 10 - 16) were treated once with ESWT postoperatively. Functional recovery was evaluated until 12 weeks postoperative by means of the grasping test, computerized gait analysis and electrophysiological evaluations.
Results: Despite some positive trends, there were no significant effects of ESWT on grasping strength. Electrophysiological investigations revealed superior results of the autologous graft + ESWT group in comparison to both muscle-in-vein groups ($p<0.05$) and both silk fibroin groups ($p<0.05$). There were no significant effects of ESWT detectable via computerized gait analysis.
Conclusion: Despite partial positive effects of ESWT on electrophysiological properties we were unable to detect significant effects on functional recovery. This study's ambivalent results could on the one hand be related to the animal model used, on the other hand the mechanisms, optimal application form as well as application frequency of ESWT remain to be elucidated.

Regenerative therapies aim to enhance liver tissue repair and regeneration in different liver diseases. Hydrogels have been proposed to improve cell engraftment and survival. This study aims to evaluate the ability of biomimetic injectable hydrogels to promote liver functionality of encapsulated human hepatocytes and enhance in vivo outcomes in an animal model of acute liver failure.

Hydrogels of gelatin (GEL), hyaluronic acid (HA) and a GEL/HA mixture 20/80 were prepared by enzymatic crosslinking. GEL gelation is faster (6 min) than in HA (23 min) or in the mixture (13 min). The stiffer hydrogel was HA with a shear storage modulus of 509 ± 136 Pa, whereas GEL was very soft, 35 ± 7 Pa. GEL/HA had similar mechanical properties as HA, 459 ± 103 Pa. Ureogenesis, cytocrome P450 activity and albumin secretion of human hepatocytes encapsulated within GEL/HA hydrogel were enhanced, compared to monolayer cultures. Lyophilized sponges of GEL/HA seeded with human hepatocytes were implanted in mice with acute liver failure. The survival of animals implanted with sponges containing human hepatocytes was 100%, while in the non-transplanted animals it was 65%. Transaminases levels decreased significantly in transplanted animals compared to non-transplanted animals, indicating a positive effect of transplanted cells on recovery from injury.

GEL/HA hydrogel is a good candidate for liver regeneration.

HUMAN 3D ORGANOTYPIC CULTURE SYSTEMS TO MODEL TISSUE DEVELOPMENT, PHYSIOLOGICAL FUNCTION, PATHOLOGICAL CHANGES AND RESPONSE TO DRUGS

Ivan Martin$_P$[1]

[1] *Dept. of Biomedicine, University Hospital Basel*

Corresponding author's email: ivan.martin@usb.ch

Culture models based on human cells and capturing features of tissue physiology and pathology are key to advance fundamental understanding of development, to learn how to regulate homeostatic processes, and to test new therapies in degenerative or malignancy settings. This lecture will provide an overview of past and ongoing work of the group on the generation and use of 3D human organotypic bioreactor-based models. Following establishment of mesenchymal cell-based stromal tissues and embedding of vascular structures using perfusion flow, the miniaturization into microfluidic models will be introduced to increase throughput, include mechanical loading features and identify compounds regulating lineage commitment and rescuing from catabolic processes.Generated tissues will also be validated as stromal niches to sustain hematopoietic stem cells growth and differentiation, thus recapitulating in vitro the structure and function of bone marrow organs. Introduction in the system of malignant hematopoietic cells (e.g., from patients with myeloproliferative neoplasm or acute myeloid leukemia) will exemplify the possibility to model bone marrow pathologies in personalized settings.Finally, use of cancer cell lines and human primary tumor specimens will illustrate that the culture system allows to engineer tumor models and to generate patterns of response to drugs or immunotherapy strategies, which cannot be mimicked by 2D cultures or by more simple spheroids. Ongoing studies are targeting the connection of bone/bone marrow with tumor models to investigate metastatic processes of prostate and breast tumor cells.

It is estimated that 10% of the worldwide population suffers from chronic kidney disease (CKD) with a rising tendency. [1] Patients with CKD have limited treatment options and novel therapies that could halt or even reverse the progression of CKD are urgently needed. [1] Bioprinting is considered one of the most promising approaches to generate novel 3D in vitro models and organ-like constructs to investigate underlying pathomechanims of kidney diseases. [2-5].

This study aimed at establishing a method to isolate primary renal cells in an easy and reproducible way. These cells were used in a new bioprinting platform laying the foundation for the development of a 3D renal tubulointerstitium model for in vitro studies. Primary murine tubular (pmTECs), endothelial and fibroblast cells were successfully isolated, but further optimization is required for the culture and expansion of primary endothelial cells. Therefore, an endothelial cell line (HUVECs) and pmTECs were combined with polysaccharide biomaterial ink solutions and processed with a microfluidic 3D bioprinter, leading to high cell viability and metabolic activity. Core-shell bioprinted constructs with HUVECs and pmTECs were manufactured mimicking tubules. In conclusion, microfluidic bioprinting strategy could be used to build a novel 3D kidney in vitro model.

THE MORPHOLOGICAL WONDERLAND OF MELT ELECTROWRITING

Paul D. Dalton[P][1]

[1] *University of Oregon*

Corresponding author's email: pdalton@uoregon.edu

Melt electrowriting (MEW) uses an applied voltage to prevent a fluid jet from undergoing Plateau–Rayleigh instabilities, rather than initiate electrical instabilities (i.e. whipping), required for electrospinning (1). The result is well-positioned fibers in the low-micron scale that, when layered in 3D, result in a high porosity scaffolds or a reinforcing structure for matrices/bioinks. Since biofrabrication is focused on recapitulating hierarchical features of tissue, MEW is a high-resolution 3D printing tool that permits such design at the microscale. There have been several breakthroughs in MEW over the past few years including the use of dynamic electrical fields (2) and microscale-layer shifting (3) that increases the build height and geometric design options respectively. Subtle microscale shifts in layer by layer design can have substantial impacts in macroscopic mechanical properties. For the purpose of translating biomaterials to the clinic, the melt processing of medical-grade materials makes a compelling case (4), and many biomaterial polymers are processable with MEW. Most, if not all of the 3D printed implants used in the clinic to date are solvent-free and based on raw materials made under good manufacturing practice (GMP) - conditions. Furthermore, MEW partners well with digitization through online monitoring allowing validation of manufacture. After a decade of development with multiple biocompatible and biodegradable polymers, including as composite materials, MEW is poised to become a leading technology to produce advanced biomaterials with hierarchical structures.

Abstract **#60**

THE LONG AND WINDING ROAD TO CARDIAC REGENERATION

Thomas Eschenhagen[P][1]

[1] *University Medical Center Hamburg Eppendorf, Institute of Experimental Pharmacology and Toxicology, German Centre for Cardiovascular Research*

Corresponding author's email: t.eschenhagen@uke.de

Loss of cardiac muscle cells, e.g. by ischemia or overload, represents a key reason of heart failure with reduced ejection fraction, a leading cause of morbidity and mortality worldwide. In contrast to other organs, the postnatal heart possesses only minimal regenerative capacity. It lacks progenitor cells, and cardiomyocytes exit the cell cycle shortly after birth and do not re-enter after injury. Thus, any loss of cardiomyocytes is essentially irreversible, a conclusion already drawn >century ago. Experimental studies from the early 2000´s claiming the opposite and reporting the formation of new heart muscle from bone marrow cells led to the initiation of thousands of experimental and clinical cell therapy studies, but were eventually found to be fraudulent. It is now clear that injected or infused non-myocyte cells do not form new myocytes and that the beneficial effects consistently observed in preclinical animal models are the consequence of paracrine or immunological effects. True cardiac regeneration has thus remained an unfulfilled promise. Yet, through a clearer comprehension of signaling pathways that regulate the cardiomyocyte cell cycle and advances in pluripotent stem cell technology, strategies have evolved that demonstrate the potential to generate new myocytes and thereby fulfill an essential central criterion for heart repair. The three major strategies include in situ reprogramming on fibroblasts into myocytes, the induction of cardiomyocyte proliferation, and the transplantation of cardiomyocytes generated pluripotent stem cells either by direct injection or beating heart muscle patches, a technique the author´s group contributed to that will be discussed at more detail.

BIOMATERIAL-GUIDED GENE THERAPY FOR CARTILAGE REPAIR

Magali Cucchiarini[P][1]

[1] *Center of Experimental Orthopaedics, Saarland University Medical Center Kirrbergerstr. Bldg 37, D-66421, Homburg/Saar, Germany*

Corresponding author's email: mmcucchiarini@hotmail.com

Articular cartilage defects are highly prevalent problems in orthopaedics and may lead to osteoarthritis if left untreated in patients. While various options are available in the clinics, none can defintively and permanently restore an original, hyaline cartilage in its structure and mechanical functions in cartilage lesions. Gene therapy is a powerful tool to enhance the processes of cartilage repair over prolonged periods of time upon the delivery of chondroreparative gene sequences in sites of cartilage injury. Yet, such a strategy remains challenging and may be hindered in vivo by a number of obstacles to effective and durable gene transfer, including physical barriers (synovial fluid), biological barriers (pro-inflammatory mediators), neutralization (pre-existing humoral responses against viral gene vectors), and unwanted gene vector dissemination to non-target sites. The controlled delivery of gene vectors via highly compatible materials (biomaterial-guided gene therapy) is a promising approach to support the sustained and localized release of gene treatments in a spatiotemporally precise fashion, reducing vector dissemination and a loss of the therapeutic gene product, and to mask viral epitopes from possible neutralization (1). This strategy has a strong potential to improve cartilage repair in vivo and may be safely translated into clinical application in a near future.

INTRODUCTION: Tissue Engineering has enabled an accurate, reproducible low cost control of various features of the tumour microenvironment (TME), which is not possible with current preclinical models [1-6]. To that end, we have developed a poly urethane (PU) scaffold based model of pancreatic cancer which can be cultured for several weeks and is appropriate for therapeutic assessments [3,4]. Furthermore, we have recently advanced the model via incorporation of biological complexity. More specifically, we developed hybrid scaffolds with tailored extracellular matrix (ECM) for different cells (cancer, stellate, endothelial) of the TME [6]. This static model captures different levels of desmoplasia, i.e., a hallmark of pancreatic cancer, and is functional for several weeks without the need of re-suspension, unlike existing pancreatic cancer models.The aim of this work was to advance our multicellular hybrid static scaffold with interstitial flow. Vascularisation levels differ from patient to patient and can affect metastasis as well as the efficiency of drug delivery [1]. METHODS: Multicellular PU scaffolds [4,5,6] were placed in a bioreactor and perfusion cultures took place for more than 4 weeks. Various in situ assays for monitoring the cell viability, spatial organisation and ECM production were carried out at specific time points throughout the culture period.RESULTS: Addition of interstitial flow in our multicellular model resulted in discernible changes, in comparison to static scaffolds in terms of cellular growth, matrix production and cell migration. Our developed model is a novel, advanced, high throughput tool that can be used for personalized studies of pancreatic cancer.

Abstract #64

DESIGNING THE MICRO- TO MACRO-ENVIRONMENT OF CELLS FOR TISSUE ENGINEERING APPLICATIONS

João F. Mano$_P$[1]

[1] *University of Aveiro*

Corresponding author's email: jmano@ua.pt

Sophisticated strategies have been employed to encapsulate cells and bioactive molecules in micro-sized matrices using distinct biomaterials, to be explored in cell and tissue engineering. Hydrogels are adequate matrices for 3D culture of cells – examples of natural-based hydrogels with adequate mechanical and biological properties are shown. Using bioinspired strategies basic units of hydrogels can be processed in mild conditions, permitting the encapsulation of living cells and other biological cargo with high efficiency. By using spherical templates containing cells followed by adequate coating procedures it is possible to produce liquefied capsules that may entrap viable cells. The presence of solid microparticles with controlled mechanical properties inside such capsules offers adequate surface area for adherent cell attachment increasing the biological performance of these hierarchical systems, while maintain both permeability and injectability. The liquid environment allows for a free-organization in the space of the cells towards the formation of new microtissues. The basic hybrid elements may be assembled towards larger constructs, using, for example, bioprinting methodologies, permitting to engineering tissues in a bottom-up approach with a complete control of the biological cargo.

Thermoresponsive surfaces enable the detachment of cells or cell sheets by decreasing the temperature of the surface when harvesting the cells. However, human pluripotent stem cells (hPSCs), such as embryonic stem cells and induced pluripotent stem cells, cannot be directly cultured on a thermoresponsive surface; hPSCs need a specific extracellular matrix to bind to the integrin receptors on their surfaces [1-3]. We prepared a thermoresponsive surface by using poly(N-isopropylacrylamide-co-butylarylate), recombinant vitronectin and/or laminin-511 to provide an optimal coating concentration for hPSC culture. In particular, we developed a repeated and continuous cultivation method of hPSCs on the same thermoresponsive plates where hPSCs were partially released from the same thermoresponsive plates by lowering the temperature of the thermoresponsive plates below the LCST of the thermoresponsive copolymer. Subsequently, the residual cells on the thermoresponsive plates were repeatedly and continuously cultivated in fresh cultivation media, and the detached stem cells were continuously collected. These cultivation cycles (passages) of hESCs as well as hiPSCs were successively repeated for ten cycles in this investigation. The detached cells, even after continual culture for over ten passages, showed high pluripotency, the ability to differentiate into cells derived from the 3 germ layers in vitro (Embryoid body formation assay) and in vivo (teratoma formation assay) as well as the ability to undergo cardiac differentiation.

Abstract #66

FROM ORGAN-ON-A-CHIP TOOLS TOWARDS PATIENTS ON CHIPS – ENFORCING A PARADIGM SHIFT IN DRUG DEVELOPMENT

Uwe Marx[P][1]

[1] *TissUse GmbH, Germany*

Corresponding author's email: uwe.marx@tissuse.com

Microfluidic microphysiological systems (MPS) have proven to be a powerful tool for recreating human tissue- and organ-like functions at research level. This provides the basis for the establishment of qualified preclinical assays with improved predictive power. Industrial adoption of microphysiological systems and respective assays is progressing slowly due to their complexity. In the first part of the presentation status quo of MPS development and examples of industrial adoption of single-organ chip and two-organ chip solutions are highlighted. The underlying universal microfluidic Multi-Organ-Chip (MOC) platform of a size of a microscopic slide integrating an on-chip micro-pump and capable to interconnect different organ equivalents will be presented. Sixteen different single organ equivalents have been established on that platform and twelve organ combinations have been tested for stable long-term crosstalk yet. The second part of the presentation focusses on the challenges to translate a MOC-based combination of four human organ equivalents into a commercially useful tool for ADME profiling and toxicity testing of drug candidates. This four-organ tissue chip combines intestine, liver and kidney equivalents for adsorption, metabolism and excretion respectively. Furthermore, it provides an additional neuronal tissue culture compartment for extended toxicity testing. Issues to ensure long-term performance and industrial acceptance of such complex microphysiological systems, such as design criteria, tissue supply and on chip tissue homeostasis will be discussed. Finally, the presentation provides a roadmap towards on-chip patient models, which bear the potential of a paradigm shift in drug development.

Corresponding author's email: georg.duda@charite.de

Delayed or non-healing in bone is still a major clinical problem. Growing evidence shows that the specificity of inflammatory cells, the types of cytokines they secrete, and the timing of their appearance in the wound setting are essential for the healing cascade, revascularization and matrix formation. Understanding the local inflammatory response in healing is essential to control bone regeneration also in compromised settings.

We will present research showing that immune modulation can enhance bone regeneration. The complexity of the immune system and its numerous cell types offer several opportunities to employ immune modulation strategies: E.g. the induction of macrophage phenotype 2 over the inflammatory M1 phenotype or reduction of the number of pro-inflammatory CD8+ T cells in the wound bed. However, the optimal solution to stimulate healing by immune modulation is complicated to the tight interaction of the immune and skeletal system – influencing one without damaging the other.

Bringing basic understanding towards immune modulatory therapy is a challenge: Reducing negatively acting CD8+ effector T cells while simultaneously supporting beneficial regulatory T cells by raising the cAMP has been tested in vitro, in a pre-clinical experimental setting and will now be advanced towards a clinical trial. However, the immune composition changes with aging and differs individually. Thus, a careful stratification of patient is necessary in order to realize immune modulatory therapies. To realize translation of immune-modulatory strategies in regenerative medicine we need to broaden our basic understanding of the healing process and of the challenges that need to be overcome.

NEW ANIMAL MODELS TO INVESTIGATE MOLECULAR AND CELLULAR MECHANISMS OF CARDIOVASCULAR DISEASE AND PREMATURE AGING IN HUTCHINSON-GILDFORD PROGERIA SYNDROME

Vicente Andrés$_P$[1,2]

[1] *Centro Nacional de Investigaciones Cardiovasculares Carlos III (CNIC), Madrid, Spain*

2 CIBER de Enfermedades Cardiovasculares (CIBER-CV), Spain

Corresponding author's email: vandres@cnic.es

Hutchinson-Gilford progeria syndrome (HGPS) is a rare genetic disorder characterized by accelerated aging and death in adolescence mainly from cardiovascular disease (CVD). HGPS patients have a normal appearance at birth, and the disease is diagnosed during their first or second year of life after the development of clinical features. Most HGPS patients carry a heterozygous de novo synonymous point mutation in the LMNA gene (lamin A and C proteins). This mutation generates an aberrant LMNA splicing site that provokes the ubiquitous expression of progerin, a lamin A variant that induces multiple cellular alterations.

Mechanistic knowledge regarding how progerin accelerates CVD and aging has significantly increased in recent years. Using LmnaG609G knockin mice, we have identified mechanisms that contribute to vascular calcification, vessel stiffening, atherosclerotic disease, and cardiac repolarization defects in HGPS (1-6). We also demonstrated that restricting progerin expression to vascular smooth muscle cells (VSMCs) promotes endoplasmic reticulum stress/unfolded protein response, and is sufficient to accelerate vessel stiffness, contractile impairment and atherosclerosis, and reduces lifespan (2,3,7). We have generated new mouse models to address two questions that are relevant for translational and clinical HGPS research: 1) Can we prevent or slow down HGPS progression by ubiquitously suppressing progerin expression early after symptoms become apparent, and how late can we delay the initiation of treatment to achieve therapeutic benefit?; and 2) Can we prevent or slow down HGPS progression by suppressing progerin expression only in cardiovascular cells, major progerin targets? Some of our latest data will be presented.

STEM CELLS FOR ARTICULAR CARTIALGE ENGINEERING

Denis Evseenko[P][1]

[1] *University of Southern California*

Corresponding author's email: evseenko@usc.edu

Osteoarthritis (OA) impacts hundreds of millions of people worldwide, with those affected incurring significant physical and financial burdens. Injury to the articular surface is a major contributing risk factor for the development of OA. Current cartilage repair strategies are moderately effective at reducing pain but often replace damaged tissue with biomechanically inferior fibrocartilage. Here we describe the development, transcriptomic ontogenetic characterization and quality assessment at the single cell level, as well as the scaled manufacturing of an allogeneic pluripotent stem cell-derived articular chondrocyte formulation that exhibits long-term functional repair of porcine articular cartilage. We also provide some fundamental molecular differences between pluripotent stem cell and bone marrow stromal cell-derived chondrocytes. These results define a new potential clinical paradigm for articular cartilage repair and mitigation of the associated risk of OA.

INTRODUCTION: Epithelial ovarian cancer (EOC) is the 8th most common cause of cancer related deaths in women [1], due to its late diagnosis, therapeutic resistance and high recurrence rate. The need for robust experimental models to help understand the EOC's pathology and metastasis have led to the development of 3D models in the form of spheroids and hydrogels [2,3]. Spheroids are high-throughput, easy to use but lack structural complexity and are difficult to maintain long term. Hydrogels add more complexity and are also capable of maintaining long term culture. Most currently available hydrogels for EOC use animal derived biomaterials (collagen, Matrigel) and lack the ability for growth surface and stiffness customisation. The aim of our work is to develop an animal free customised 3D model of EOC based on synthetic peptides with customised growth surface & stiffness.METHODS: EOC 3D cultures were established & maintained (4 weeks) using peptide-based hydrogels of different stiffness and charge. In vitro chemotherapeutic assessment was carried out within the established 3D models. Various in situ assays for monitoring the cell viability, spatial organisation and ECM production were carried out at specific time points. RESULTS: We successfully established a synthetic hydrogel-based 3D model of EOC wherein we observed that stiffness and charge of the hydrogels affected cellular growth and morphology. Furthermore, variability in terms of cellular viability and spatial organisation was found for different patients. Our model can be used as a rapid tool for personalised treatment screening of ovarian cancer.

CLINICAL EXPERIENCE OF TISSUE ENGINEERED VASCULAR GRAFTS IN CHILDREN

Toshiharu Shinoka[P][1]

[1] *Nationwide Children's Hospital*

Corresponding author's email: toshiharu.shinoka@nationwidechildrens.org

We have applied new protocol to FDA for the second generation of TEVG, including a rapid cell seeding technique, administration of Losartan, and higher dose of cell seeding in 24 patients as Fontan conduits. The rational design of improved, second-generation TEVGs will be predicated on our understanding of the cellular and molecular mechanisms underlying the formation of TEVG stenosis. The feasibility of tissue engineering large caliber, autologous vascular conduits for use as venous interposition grafts for congenital heart surgery has been demonstrated in both large animal and in a human clinical trial. The carefully designed second clinical trial in USA under the supervision of the FDA will be started in 2020.

Millions of people suffer from loss and damage of organs and tissue every year due to accidents, birth defects, and disease. Human pluripotent stem cells (hPSCs) are a promising source of cells for tissue regeneration. However, histocompatibility of the transplanted cells remains a major challenge to their clinical application where human leukocyte antigen class (HLA) Ia (HLA-A, -B, -C) molecules are the primary mediators of immune reaction. We successfully generated universal induced pluripotent stem cells (hiPSCs) without gene editing, which were reprogrammed from human amniotic fluid stem cells with mixing two allogenic donors; these cells do not or less express human leukocyte antigen (HLA) class Ia (HLA-A, -B, and -C) and class II even after differentiation into cardiomyocytes, embryoid bodies (progenitor cells derived from three germ layers), and mesenchymal stem cells (universal hiPSCs). Cardiomyocytes differentiated from universal hiPSCs survived and continued beating even after treatment with allogenic mononuclear cells derived from different amniotic fluid (AF) donors. We speculate that the mechanism underlying the generation of universal hiPSCs is that fetal stem cells contain a specific group of cells that do not express HLA class Ia and class II but may express HLA-G, PD-L1 and/or CD47, which are expressed in baby tissue to avoid immune rejection with her mother, after the cells are reprogrammed into hiPSCs and subsequently differentiated into tissue cells.

WATERJET: A NOVEL TECHNOLOGY TO INJECT MYOBLASTS IN PREDETERMINED REGIONS OF THE URETHRAL SPHINCTER FOR IMPROVED CELL THERAPY OF URINARY INCONTINENCE

Ruizhi Geng[P1], Jasmin Knoll[1], Walter Linzenbold[2], Luise Jaeger[2], Markus Enderle[2], Tanja Abruzzese[1], Wilhelm K Aicher[1]

[1] *Dept. of Urology, UKT, Tuebingen, Germany*

[2] *ERBE Elektromedizin GmbH, Tuebingen, Germany*

Corresponding author's email: aicher@uni-tuebingen.de

Urinary incontinence is a significant medical challenge. Cell therapy may offer strategies to regenerate the sphincter function with high efficacy. Needle injection (NI) is the standard procedure but may misplace cells (1). We therefore developed a technology to inject cells by water jet (WJ) (2). We investigated if a) cells survive waterjet injections (WJI) with sufficient viability, b) the WJI inherits the risk of full tissue penetration of the urethra.

WJI were performed by a 2-phase injection as described (2). After WJI in capture fluid (n>5), cells were collected to determine the viability. For WJI in tissue, cells were labelled, injected (n>16), and either recovered and expanded in cultures or localized in cryosections by fluorescence microscopy.

WJI of myoblasts in capture fluid yielded mean viabilities of 88.3±3% or 87.9±2.1%. After injection in cadaveric samples followed by cell retrieval, differences in cell yield were not observed between WJI versus NI. However, NI in cadaveric samples analyzed in cryosections yielded more compact cell clusters compared to WJI. In WJI cells were distributed more precise and evenly. Injected cells presented with intact, round DAPI+ nuclei surrounded by Calcein+ cell somata indicating that myoblasts were intact after WJI.

We conclude that the novel WJT injects myoblasts precisely through the urothelial layer in the connective tissue of the urethra in a simple, fast, and precise way. Future studies will investigate the feasibility of the WJT in a living animal model and in a model of stress urinary incontinence (3).

Abstract #74

HARNESSING THE BIOMATERIAL-INFLAMMATORY CELL INTERACTIONS DURING THE DESIGN OF TISSUE ENGINEERED CONSTRUCTS

Donald O. Freytes[P][1,2]

[1] *Joint Department of Biomedical Engineering, NC State/UNC-CH, Raleigh, NC*

Corresponding author's email: dofreyte@ncsu.edu

One of the goals of tissue engineering and biomaterial design is to create functional and viable tissue replacements or to design in vitro platforms using tissue surrogates to further understand tissue repair. One important process during tissue repair is the inflammatory response and the direct and indirect interactions between cells and the components of the engineered construct. Understanding these interactions and harnessing them to better understand and guide tissue repair is a fundamental goal that could lead to better integration and function of engineered constructs. Examples will be provided on how the interactions between biomaterials, repair cells and inflammatory cells can be used to guide the design, manufacture and preparation process. Inflammatory cells such as monocytes, macrophages and mast cells can be used to improve decellularization protocols, improve the survival of repair cells (i.e. cardiomyocytes, MSCs, etc) and to optimize extracellular matrix hydrogel preparations targeted to specific tissues such as heart, skin and vocal folds.

Introduction:

Age-related macular degeneration (AMD), according to world health organization, ranks the third leading cause of vision impairment and further causes irreversible blindness. This AMD disease mainly results from the dysfunction of retinal pigmented epithelium (RPE). Fortunately, transplanting human pluripotent stem cells (hPSCs)-derived RPE can serve as regenerative approach to cure AMD disease. However, RPE derived from hPSCs usually suffers from insufficient purity, long culture period and low yield. Therefore, we compared different protocols and cell culture extracellular matrices (ECMs) to investigate which conditions would be the most suitable for hPSCs to differentiate into RPE progenitors.

Method:

We first selected and compared the protocols, (i) N2 protocol [1] and (ii) NIC+CTM protocol [2]. After we found the better protocol, we tried different substrates to culture and induce differentiation of hPSCs into RPEs. We evaluated neural marker of PAX6 expression by using immunostaining and flow cytometry assay to find the best condition for hPSCs to differentiate in to RPE progenitors.

Results and Discussion:

According to epidermal marker of PAX6 analysis from immunostaining and flow cytometry assay, we found NIC+CTM protocol showed the better performance of hPSC differentiation into RPEs compared to N2 protocol. Subsequently, we found the optimal xeno-free culturing surface that could be applied for massive production of high purity of RPE progenitors in NIC+CTM protocol. We are planning to use the same protocol to further investigate the most appropriate substrate for differentiation into mature RPEs, which can benefit AMD patients for clinical treatment.

The overall purpose of this work is to reproduce the morphology and composition of the pancreatic acino-ductal unit composed of specialized cells surrounded by stroma, a feature which is currently absent in 3D organoids modeling this functional unit1. This model serves as a powerful tool to investigate pathological processes such as pancreatic tumors (e.g. Pancreatic Ductal Adenocarcinoma, PDAC). The acino-ductal structure was reproduced through a 3D-bioprinting technology (ROKIT InVivo, Rokit, Seul) integrated with an atmospheric pressure plasma jet device (Stylus Plasma Noble, Nadir, Mestre). Specifically, the fabrication process was optimized to achieve high pore interconnectivity, accuracy in glandular geometry and precise control of pore size. 3D-printed structures morphology was characterized by optical and scanning electron microscopy (SEM). The images demonstrated the effectiveness of the optimization process which led to the formation of defect-free structures with interconnected pores. To introduce biomimetic cues within the polycaprolactone (PCL) structure, the plasma surface modification was implemented in a layer-by-layer and automatized manner in order to enhance the impregnation with a collagen solution. The collagen inside the pores allows cells to better colonize the structure and improves the adhesion, proliferation and growth of stromal cells inside the 3D structure as confirmed by morphological and cytochemical analysis. The cellularized final structure will provide a model of human PDAC at early stages which could be implemented in a microfluidic system. Advanced technologies which integrate optical components in microfluidic chips could be employed for the real-time monitoring of the tumor's evolution and for performing genomic analysis2.

The lung cancer, also known as lung carcinoma, is a malignant tumour characterized by uncontrolled cell growth in the specific tissue of respiratory system1. The lack of new therapies to treat lung carcinoma requires experimental models that can reproduce the behaviour of healthy and pathological tissues2. To overcome ethical, experimental and technological limitations of the traditional in vivo and in vitro models, we propose the implementation of a novel technological biomimetic platform to mimic the physiological condition by reproducing the basement membrane of alveolar wall and the physical stimuli characteristic of the blood-air barrier.

The basement membrane layer was reproduced through gelatin/polycaprolactone (GL/PCL) electrospun membrane obtained by mixing the two polymers (20:80 w/w) in a solution made of acetic and formic acid (1:1 v/v). A cold plasma treatment of the mats was carried out. The mechanical, physical and chemical properties of the mats were evaluated. A549 (lung epithelial cells, ATCC) and HULEC-5a (lung endothelial cells, ATCC) were cultured on the two side of electrospun membrane under static and dynamic conditions.

Scanning electron microscopy (SEM) images showed the nanofibers obtained after the electrospinning process. In vitro stability tests were performed to evaluate the degradation rate of the electrospun nanofibers. Cyclical traction tests were performed to assess the effect of the physiological breathing motion on membranes mechanical properties. The resazurin assay showed no significant reduction of cells viability after 7 days both in static and in dynamic condition.

The realized structures can be applied as ECM-mimic substrates for lung cells growth.

In the last two decades, piezoelectric nanomaterials have gained considerable attention in the biomedical community for their property to generate electrical activity in response to deformations and allow for the delivery of an electrical stimulus without the need of an external power source1. In tissue engineering applications, piezoelectric ceramic nanomaterial with perovskite-like structure have been widely combined with polymeric material, obtaining smart scaffold that promote the regeneration of electrically sensitive tissues such as bone 2 and nerve 3. In this work, we propose a method to fabricate extracellular matrix-like gelatin (GL) electrospun nanofibers with barium titanate nanoparticles (BTNPs)4.

Several GL (control) and GL/BTNPs solutions were prepared. Different concentrations of BTNPs were dispersed into the GL solutions (10% w/v to 30% w/v) and GA was added in order to improve the nanoparticles dispersion. The γ-glycidoxypropyltrimethoxysilane (GPTMS) agent was used to ensure the GL crosslinking. Nanofibrous mats were obtained after optimizing the electrospinning process parameters.

Scanning electron microscopy (SEM) images showed randomly-oriented nanofibers where BTNPs appeared uniformly distributed over the length of the composite fibres. Thermogravimetric analysis (TGA) confirmed the encapsulation of the nanoparticles into the fibres. The presence of BTNPs did not influence the viability of SaOS-2 cells. Therefore, an increase of calcium deposition was observed in MSCs cultured on piezoelectric substrate.

Electrospun composite nanofibers were successfully obtained and characterized demonstrating a strong potential as ECM-mimic substrates for tissue engineering application.

Cancer is one of the top 10 leading cause of death in world. Cancer stem cells (CSCs) are responsible for cancer proliferation and show stronger resistance than other cancer cells under conventional cancer therapy. Recent publication suggested the precision medicine shows positive effect for cancer patients treatment so isolation of patient specific primary cancer cell line is important. However, it is hard to distinguish CSCs from other cells in primary tissue. Thus, we have been developing a membrane filtration method to target CSCs.

This membrane filtration method was performed via Nylon mesh filter or poly(lactic-co-glycolic acid)-silk screen membranes. The primary colon cancer cells were isolated by several steps and the cancer cell solution was permeated through these membranes. CSCs and colon cancer cells were characterized using colony forming assay and expression of carcinoembryonic antigen (CEA) using ELISA assay. We also analyzed colon cancer cell lines using this method as a model of primary colon cancer tissue solution.

This purification method using membrane filtration method has been successfully verified using Lovo cancer cell line and the cells showing high level expression of CSCs marker (CD133, CD44) were isolated where CSC markers were analyzed using flow cytometry. We expect to establish patient specific colon cancer cell line by the membrane filtration method with different pore size, affinity and biocompatibility. This method is a promising approach, which can be applied for precision medicine screening in the future.

INTRODUCTION: Clinical trials are unable to pinpoint early onset of osteoarthritis (OA). Thus, we propose the superficial zone chondrocyte spatial organization (SCSO) for visualization and quantitative input for predictive modelling and user-independent diagnosis.

METHODS: Discs from human OA articular cartilage (AC) were fluoro-tagged and imaged with a fluorescence microscope and clinically available endomicroscope. Each SCSO was classified as chondrocyte string, double string, small cluster, big cluster, or diffuse organization. Multiple quantitative SCSO parameters were calculated for each disc through point pattern analysis and used for training a random forest model (RF).

RESULTS: We visualized all SCSO stages and quantified each stage using established spatial analysis parameters like the nearest neighbor cell-cell-distances (NNDs), cell intensity, the Clark-Evans-Aggregation-Index, the pair correlation function, and others. These were used for RF modelling. 50 different RFs were evaluated based on randomly sampling the input data. 22% of RFs classified the SCSO accurately in more than 90% of cases, and one model classified the SCSO accurately in 100% of cases with an excellent RF multiclass model performance measured via Matthews correlation coefficient (0.9229) and high reproducibility (100%). This selected RF model also demonstrated 100% accuracy in determining the SCSO stage of endomicroscopy-recorded SCSO stages.

DISCUSSION & CONCLUSIONS: We demonstrated that the SCSO, an experimental marker for early OA, can be visualized with currently available clinical technology. Moreover, quantitative data derived from the SCSO was suitable to train a RF model with 100% accuracy for correctly diagnosing early changes in SCSO, and thus early OA.

We previously showed that high hydrostatic pressure (HHP) treatment at 200 MPa for 10 min induced complete cell death in skin and skin tumors via necrosis. We used this technique to treat a giant congenital melanocytic nevus and reused the inactivated nevus tissue as a dermis autograft. However, skin inactivated by HHP promoted inflammation in a preclinical study using a porcine model. Therefore, in the present study, we explored the pressurization conditions that induce apoptosis of the skin, as apoptotic cells are not believed to promote inflammation, so the engraftment of inactivated skin should be improved. Using a human dermal fibroblast cell line in suspension culture, we found that HHP at 50 MPa for ≥36 h completely induced fibroblast cell death via apoptosis based on the morphological changes in transmission electron microscopy, reactive oxygen species elevation, caspase activation and phosphatidylserine membrane translocation. Furthermore, immunohistochemistry with terminal deoxynucleotidyl transferase dUTP nick-end labeling and cleaved caspase-3 showed most cells in the skin inactivated by pressurization to be apoptotic. Consequently, in vivo grafting of apoptosis-induced inactivated skin resulted in successful engraftment and greater dermal cellular density and macrophage infiltration than our existing method. Our finding supports an alternative approach to hydrostatic pressure application.

IL-17 CONTROL OF CHONDROCYTE NUCLEAR AND CELL SHAPE AND FUNCTION: POSSIBLE IMPACT ON CARTILAGE REPAIR MECHANISMS

Melanie L. Hart$_P$[1], Judith M. Horvath[1], Anna De Giuseppe[1], Eunjae Park[1], Ronja Sturm[1], Mischa Selig[1], Jasmin C. Lauer[1], Marita Völker[1], Bernd Rolauffs[1]

IL-17 has been implicated in cartilage degradation and inflammation. We aimed to understand how inflammation, cell morphology and cell function are linked. Articular cartilage superficial zone explants and chondrocytes from patients having different grades of macroscopic osteoarthritic (OA) degeneration were examined to determine a) whether there was a differential response of isolated chondrocytes to IL-1β vs. IL-17A and b) if OA cartilage explants responded similarly. Explants were exposed to injury and inflammatory cytokines, while chondrocytes were exposed to inflammatory cytokines. IL-1β caused a significant decrease in COL2A1 gene expression in both tissue explants and chondrocytes. IL-17A also resulted in a significant decrease in chondrocyte COL2A1 expression. In tissue explants, COL2A1 showed a decreasing trend in response to IL-17 and the decrease in expression was similar to IL-1β treatment. In contrast, in comparison to IL-1β, IL-17A resulted in a significantly decreased inflammatory response (IL-8 gene expression) in both chondrocytes (59-fold decrease, 24h; 10-fold decrease, day 7) and OA explants (32-fold decrease, 48h). Despite a decreased IL-8 mRNA expression response, IL-17A caused high secretion of soluble IL-8 from chondrocytes which correlated dose-dependently with nuclear size and shape. In chondrocytes, COL1A2 expression was not significantly altered by IL-17A, but its expression significantly correlated with cell aspect ratio, roundness, circularity, and solidity and nuclear aspect ratio and roundness. Importantly, IL-17A dose-dependently decreased COL2A1 expression which correlated with chondrocyte roundness and nuclear aspect ratio and roundness. Therefore, IL-17A is capable of controlling cell and nuclear shape and chondrogenic cell function which may impact cartilage repair.

Additive Manufacturing (AM) is a well known method to produce scaffolds with different geometrical patterns (grid, honeycomb, gyroid, etc.). These hierarchical porous structures can be designed ad hoc to enable specific mechanical properties and functionalities to provide cell viability and tissue regeneration. In particular, the AM technology based on material extrusion (MEX, commonly known as FDM) produces 3D porous structures processing several thermoplastic biopolymers. Nevertheless, the operational parameters and the characteristics of the deposition process generate a part in which real geometry is different from the theoretical one of the 3D model. This difference involves an additional problem for simulating the mechanical behaviour of the scaffold, for example by Finite Element Analysis (FEA). The paper presents two developed methods to predict the real geometry of scaffolds made by MEX and starting from G-code files. The first method is the "automated sweep CAD modeller of extrusion-based G-code (DECODE)" and the second the "volume conserving model for 3D printing (VOLCO)". DECODE reads the G-code and generates several scripts to automate the 3D CAD modelling (sweep features) to reproduce the extrusion paths. VOLCO builds a voxel-based model starting from the G-code and considering some features in the deposition process. Both methods were compared in terms of volume of the resulting geometry of the scaffolds, and the FEA simulation and testing of the stiffness. DECODE obtains more accuracy in volume (compared to the theoretical models) and can manage larger parts, while VOLCO, after a fitting process, is more accurate for mechanical prediction by FEM.

Abstract #85

SOLUTIONS FOR REPOPULATION OF DENSE CARTILAGE MATRIXES.

Sylvia Nürnberger[P][1,2,3]

1 Medical University of Vienna, Department of Orthopedics and Trauma-Surgery, Division of Trauma-Surgery

2 Ludwig Boltzmann Institute for Experimental and Clinical Traumatology, AUVA Trauma Research Center

3 Austrian Cluster for Tissue Regeneration

Corresponding author's email: sylvia.nuernberger@meduniwien.ac.at

Decellularised organs and tissues are promising scaffolds for tissue regeneration providing the accurate composition and architecture to support targeted tissue regeneration. In this process, repopulation of devitalized matrixes is the most critical and challenging step, especially in dense tissues such as cartilage. To overcome this difficulty, several chemical and mechanical strategies have been developed. Auricular cartilage can be enzymatically extracted from specific matrix components such as elastin, creating channels accessible for cells to grow into the dense matrix. However, for articular cartilage chemical treatment for selective removal of matrix components is not sufficient to achieve repopulation. As alternative, laser perforation has been developed allowing to engrave fine incisions of controlled and reproducible size by a high throughput process. Two of the most commonly used laser technologies used in the medical field, the CO2 and femtosecond laser, were applied to hyaline cartilage with very different structural effect. Within this talk, the structuralizing possibilities of laser and enzymatic treatments, the effect on the matrix and the general advantages and disadvantages for tissue engineering are discussed. We believe that the optimal combination of chemical and laser treatment have high potential for a new generation of biomaterials for tissue engineering.

Gelatine methacryloyl (GelMA) is a highly tunable, inexpensive hydrogel that can be loaded with adipose tissue-derived stromal cells (ASC) for therapeutic purposes. Information on the ASC remodelling of GelMA and its influence on mechanical properties is scarce. Yet, changes potentially affect the fate and function of GelMA-ASC constructs before patient implantation. Our study assessed if ASC modified the stiffness and viscoelasticity of GelMA hydrogels aimed for tissue engineering. Methods: Immortalised human ASC (iADSC13) were embedded in 5%, 10% and 15% (w/v) GelMA hydrogels. Cell-loaded and cell-free (control) hydrogels were photopolymerised. Viscoelastic changes in stiffness and the percentage of stress relaxation were measured by low-load compression testing at 20% strain s-1. Live and dead fluorescent staining assessed cell viability. Evaluation occurred at 0 h, 24 h, 7 d and 14 d. Results: GelMA hydrogels had a linear concentration-dependent increase in stiffness while cells caused a time-dependent decrease. In 5% GelMA, cells increased the percentage of stress relaxation, in 15% GelMA it decreased while in 10% GelMA decreased occurred only at 7 d. Initial cell viability was >90%, which prevailed in 5% GelMA over 14 d, while in 10% and 15% viability decreased. Conclusions: The data shows that the viscoelastic properties of GelMA hydrogels change due to cell-matrix interactions over time, but that stress relaxation changes occur independently of changes in the stiffness.

The extracellular matrix directs cell function through a complex choreography of biomacromolecular interactions in a tissue-dependent manner. Far from static, this hierarchical milieu of biochemical and biophysical cues presented within the native cellular niche is both spatially complex and ever changing. As these pericellular reconfigurations are vital for tissue morphogenesis, disease regulation, and healing, in vitro culture platforms that recapitulate such dynamic environmental phenomena would be invaluable for fundamental studies in cell biology, as well as in the eventual engineering of functional human tissue. In this talk, I will discuss some of our group's recent success in reversibly modifying both the chemical and physical aspects of synthetic cell culture platforms with user-defined spatiotemporal control. Innovating biomaterials sensitive to cytocompatible light, we exploit multiphoton laser-scanning lithographic strategies to create and photochemically modify biomaterials around living cells. Repurposing tools traditionally employed for biological imaging to directly manipulate biomaterials, we have gained the unique ability to modulate intricate cellular behavior including stem cell differentiation, protein secretion, and cell-cell interactions in 3D space and time (i.e., 4D).

DECELLULARIZED PORCINE NUCLEUS PULPOSUS TISSUE FOR INTERVERTEBRAL DISC REGENERATION

Tara C Schmitz$_P$[1], Marina van Doeselaar[1], Keita Ito[1]

[1] *Orthopaedic Biomechanics, Department of Biomedical Engineering, Eindhoven University of Technology, Eindhoven, the Netherlands*

Corresponding author's email: t.c.schmitz@tue.nl

Tissue-derived decellularized scaffolds are increasingly employed in tissue engineering for regenerative medicine. During decellularization cells within the extracellular matrix (ECM) are lysed using detergents/freeze-thaw cycles, frequently depleting essential matrix components like growth factors, collagen and glycosaminoglycans (GAGs).1–3 Porcine notochordal cell-derived matrix (NCM) has gained attention due to its beneficial effect on degenerated intervertebral discs. Notochordal cells secrete a set of soluble stimulating factors leading to increased ECM production by resident intervertebral disc cells.4–7 For its use as a therapeutic agent in human patients, porcine DNA must be removed from NCM to ensure safety regarding possible transmission of porcine endogenous retroviruses (PERVs) to the patient.8, 9 Here, we present a simple, detergent-free protocol for DNA digestion within NCM while maintaining its bioactive features. Cell lysis is achieved via tissue lyophilization, and >90% of porcine DNA is digested with high amounts of endonuclease while tissue dissociation is prevented by the low buffer volume used. No significant loss in GAG and collagen content was found, while >40% proteins remain. Endonuclease-remnants do not impair human fibroblast cell viability. Residual bioactivity is demonstrated by incubation of bovine NP cells with the decellularized NCM compared to non-processed NCM. We find that bioactivity is reduced after tissue processing, but still promotes NP cell-typical gene expression and matrix deposition, and decreases the inflammatory response. Further encapsulation of this decellularized NCM into a NP-like biomaterial may constitute a future regenerative treatment for degenerative disc disease providing biomechanical restoration of the disc in addition to its regenerative effect.

WIN, LOSE OR TIE: A COMPUTATIONAL MODEL OF THE COMPETITION AT THE CELL-ECM INTERFACE

Zeynep Z Karagöz[1], Thomas Geuens[1], Vanessa L.S. LaPointe[1], Martijn van Griensven[1], Aurélie Carlier[1]

The extracellular matrix (ECM) is a mesh of fibrous proteins that forms the basis of the tissue architecture and structurally supports the cells. Biophysical cues provided by the ECM are translated into biochemical signals by transmembrane integrin molecules. Understanding the interaction between the ECM and integrin molecules is particularly important when designing instructive biomaterials and organoid culture systems. Previous studies suggest that fine-tuning the ECM composition and mechanical properties can improve organoid development [1]–[3]. Towards the bigger goal of fully functional organoid development, we hypothesize that resolving the dynamics of ECM-integrin interactions will be highly instructive. To this end, we developed a mathematical model that enabled us to simulate three main interactions, namely integrin activation, ligand binding and integrin clustering. Different from previously published computational models, we account for the binding of more than one type of ligand to the same type of integrin. This competition between ligands defines the fate of the system. We have demonstrated that the ligand with higher binding rate occupies more integrins at the steady state than does the competing ligand. We have also demonstrated that an increase in the initial concentration of ligands does not ensure an increase in the steady state concentration of ligand-bound integrins. With cell type specific, quantitative input on integrin-ligand binding rates, this model can be used to develop instructive cell culture systems.

Keywords

integrin; extracellular matrix; reaction kinetics

KIDNEY-ON-A-CHIP PLATFORMS FOR DISEASE MODELING AND DRUG TESTING

Roos Masereeuw[P][1]

[1] *Utrecht Institute for Pharmaceutical Sciences, div. Pharmacology*

Corresponding author's email: r.masereeuw@uu.nl

The kidneys play an essential role in preserving homeostasis of the body's internal environment, including regulation of water and acid-base balances, waste removal, control of red blood cell production and blood pressure regulation. Impaired renal function is commonly observed in clinical practice and is often associated with use of drugs. Early prediction of those effects, which includes drug-drug interactions and renal toxicity, is crucial for the development of new and safe drugs by the pharmaceutical industry. Currently available in vitro assays do not accurately allow such prediction, predominantly due to inadequate preservation of the organs' microenvironment. The kidney epithelium is highly polarized, and the maintenance of this polarity is critical for optimal functioning and responsiveness to environmental signals influencing cell proliferation, migration and differentiation. This presentation will provide an overview of advances in 3D cultures of human kidney cells and organoids in microfluidics, and in particular kidney tubules, thereby improving physiological performance of the tissue. These kidney-on-a-chip platforms have great potential for disease modeling and drug screening, and provide novel alternative strategies for prediction of renal drug disposition and safety assessment in a human-specific context.

Organs-on-Chip (OoC) have recently emerged as innovative in vitro tools holding the potential to improve prediction over human drug responses. Here we present new beating OoC, advanced platforms integrating native-like 3D mechanical microenvironment with an unprecedented level of precision. This is achieved through uBeat®, an innovative technology(1) that allows to modulate mechanical deformation exerted on 3D microtissues in a controlled fashion. Two uBeat®-based models were developed: uHeart, a beating heart-on-chip integrating real-time electrophysiological measurements, and uKnee, the first in vitro model of human osteoarthritic (OA) cartilage-on-chip.

uHeart provides 3D human cardiac microtissues with a physiological cyclic uniaxial strain (10%, 1Hz). Cardiomyocytes from human induced pluripotent stem cells and human fibroblast embedded in fibrin hydrogel and cultured within uHeart developed in synchronously beating cardiac microtissues(2), as confirmed by on-chip electrophysiology studies. uKnee provides 3D cartilage-on-chip (CoC) with hyper-physiological (HP) compression (30%, 1 Hz), sufficient to elicit OA pathogenesis in vitro. Healthy CoC were generated from human articular chondrocytes embedded in poly(ethylene-glycol)-based hydrogel. HP stimulated CoC showed a shift in cartilage homeostasis towards catabolism, inflammation and hypertrophy, and acquisition of a gene profile compatible with OA clinical evidences(3). Both models were successfully exploited for testing the effect of well-known drugs and innovative compounds.

Integration of 3D mechanical microenvironment resulted in OoC models with enhanced functionality and resemblance to pathological states. uBeat® is highly versatile and applicable to any organ in which mechanical stimulation exerts a pathophysiological state. Beating OoC represent new powerful tools for in vitro drug screening and disease modelling.

INTRODUCTION

Tissue engineering to mimic in vivo milieus is fast advancing to support representative biophysical-chemical and mechanical tumour properties allowing realistic architecture, cell-matrix interactions and environmental gradients. Pancreatic ductal adenocarcinoma (PDAC) is a cancer of unmet needs with a notoriously unique and radio-resistant tumour microenvironment (TME). 3D re-modelling of the PDAC TME for radiation treatment screening is an understudied area of research. The BioProChem Group at the University of Surrey have previously fabricated a 3D porous polymeric scaffolding system to support long term PDAC cell growth and in vivo properties [1-3]. Utilising this system, we aim to replicate the PDAC TME incorporating long term hypoxic exposure to investigate hypoxia induced radio-resistance for the clinical application and optimisation of radiotherapy.

METHODS

Fabrication of polymeric 3D scaffolds employed the Thermally Induced Phase Separation method [1]. Scaffolds were coated in the extracellular matric protein fibronectin to aid cellular adhesion. PANC-1 cells were seeded at 0.5x106 and cultured for 3 weeks before being placed at 5% oxygen in a hypoxic chamber. Radiotherapy exposures were performed using an orthovoltage X-ray unit at the Royal Surrey County Hospital. Scanning electron microscopy and confocal laser Scanning microscopy (CLSM) enabled scaffold characterization, allowing analysis of cellular organisation and viability. More specifically, live/dead analysis and hypoxic biomarkers permit quantification of radio-resistance.

CONCLUSIONS

For the first time, this research develops a hypoxic PDAC 3D polymeric scaffold to support long-term cell culture. This platform allows hypoxia-associated radio-resistance profiling of PDAC towards radiation response screening for a cancer with such dismal prospects.

The challenge of Tissue Engineering hydrogel contraction during tissue maturation leads to a changed 3D geometry and thus dysfunction of the target tissue. To minimize contraction and enable biomimetic loadbearing of the engineered tissue we want to develop a textile-reinforced structure tailored to specific needs of an aortic valve.

In order to analyze tissue contraction we established a novel method based on the work by Truskey et. al to evaluate tissue contraction in static and dynamic cultivation. We performed multiple assays to evaluate tissue contraction and composition. Based on the results we developed a novel load specific textile scaffold for a tissue engineered aortic heart valve. In combination with a novel stent, we were able to measure good hemodynamics with a silicone heart valve under aortic conditions.

The hemodynamic tests showed results with in the ISO 8540 standard (a Total regurgitant fraction <20 % and an effective orifice area > 1.25mm² for a 23mm Valve). Preliminary tests in a low-pressure environment of a cell laden reinforced fibrin valve show good collagen production and cell mediated shrinkage is in an acceptable range.

Our biomimetic load specific scaffold can improve the in vitro results of heart valve conditioning in a low-pressure environment. The next step is to repeat the experiments in aortic conditions. This will be a major step towards a tissue engineered aortic heart valve.

EFFECTS OF SPACEFLIGHT ON HUMAN INDUCED PLURIPOTENT STEM CELL-DERIVED CARDIOMYOCYTE STRUCTURE AND FUNCTION

Arun Sharma[P][1]

[1] *Cedars-Sinai Medical Center*

Corresponding author's email: arun.sharma@cshs.org

With extended stays aboard the International Space Station (ISS) becoming commonplace, there is a need to better understand the effects of microgravity on cardiac function. We utilized human induced pluripotent stem cell-derived cardiomyocytes (hiPSC-CMs) to study the effects of microgravity on cell-level cardiac function and gene expression. The hiPSC-CMs were cultured aboard the ISS for 5.5 weeks and their gene expression, structure, and functions were compared to ground control hiPSC-CMs. Exposure to microgravity on the ISS caused alterations in hiPSC-CM calcium handling. RNA-sequencing analysis demonstrated 2,635 genes were differentially expressed among flight, post-flight, and ground control samples, including genes involved in mitochondrial metabolism. This study represents the first use of hiPSCs to model the effects of spaceflight on human cardiomyocyte structure and function.

Background and Aim:Biomimetic calcium phosphate (CaP) coatings have been developed for coating medical device as a slow and local drug delivery system.The aim of this study was to compare the osteoconductivity of the amorphous and crystalline coatings in the absence and presence of incorporated bovine serum albumin (BSA) in vitro and in vivo. Material and methods:Amorphous and crystalline coatings were prepared. Deposition and chemical property were examined by LSCM and FTIR respectively.Surfaces of implants were characterized by SEM.Loading and release of BSA were evaluated by ELISA. The activity of ALP were tested in vitro.6 different groups were used in vivo:no coating no BSA, no coating but with surface adsorption of BSA and incorporation of BSA in the biomimetic coating in the amorphous and crystalline coatings.Rats orthotopic model was used (n=6 rats per group).Time points are 3 days,1,2 and 4 weeks.Histological and histomorphormitrical ananlysis were done in order to determine bone to implant contact(BIC).Results:In vitro,the protein the morphology of BSA incorporated crystalline coating was changed into curly plates, and it shows slow-release profile.The BSA incorporated crystalline coating significantly decreased the activity of ALP.In vivo study, each group showed time-dependent increase in BIC.The incorporation of BSA had no significant effect on the percentage of BIC in no coating groups and crystalline coating groups,but resulted in lower BIC in amorphous coating groups.Conclusion: Biomimetic crystalline CaP coating can be an ideal carrier for protein or drugs;the amorphous biomimetic CaP coating promoted osteoconductivity and incorporation of BSA did not improve osteogenesis.

BIOFABRICATION OF A VASCULAR-LIKE STRUCTURE MIMICKING THE ARCHITECTURE AND CELL ALIGNMENT OF NATIVE BLOOD VESSELS

Cardiovascular diseases (CVD) are the main cause of worldwide death according to WHO (1), being the obstruction of vessels due to atherosclerosis the principal etiology. Up to now, the gold standard treatment has been blood vessel replacement from autologous source through bypass surgery. However, this is not always possible due to the inherent disease of the patient or previous harvest. Consequently, tissue engineered blood vessels (TEBV) have been considered as a promising alternative as a source graft (2). The aim of this study was to develop a mechanically stable dual-layered hydrogel hollowed structure where specific vascular cell types could be allocated, mimicking the microarchitecture of native blood vessels. Using a triple co-axial extrusion system, outer and inner layers were obtained, mainly composed of alginate and collagen, and hollow core was achieved using a sacrificial polymer. The TEBV presented homogeneous sizes, which could be controlled by changing the injection speed, and they were robust, allowing the perfusion of liquids. Human umbilical vein endothelial cells (HUVECs) and human aortic smooth muscle cells (HASMCs) were encapsulated in the inner and outer layer, respectively, presenting high survival rates (over 90%) after extrusion and after 20 days of culture. Moreover, both cell types could proliferate within the TEBV. Interestingly, HUVEC and HASMC could adopt the native alignment found in native vessels, being the concentric arrangement of HASMCs of special interest, as it facilitates the vasoconstriction. Further studies involving perfusion of these TEBV-like structures are required in order to induce maturation and a proper functionality.

Intervertebral disc (IVD) degeneration accompanying with lower back pain is a serious worldwide problem. Although, surgical treatments are available for pain relief, we need to establish enduring cell-based remedies. Notochordal (NC) cells, characterized by large vacuoles, as the ancestor of nucleus pulposus (NP) cells in human IVD, are a promising therapeutic target. Thus, we aimed to optimise the culture of NC cells in vitro without using Fetal Calf Serum (FCS) and investigate their morphology and gene expression in both 2D and 3D culture systems.

Porcine NC cells were extracted using pronase treatment followed by overnight collagenase II digestion. Extracted cells were culture in either 1.2% alginate beads (3D culture) with 21% or 5% oxygen or laminin-coated plates (2D culture) with 5% oxygen. Cells were harvested after 24 hours, 1 and 2 weeks for gene expression and immuno-staining analysis of NC and NP markers (CD24, KRT8, KRT18, KRT19, ACAN, COLII, PAX1, FOX-F1 and T).

A mixed phenotype of NC and NP cells was observed in alginate bead cultures. NCs were observed within all culture conditions with production of GAGs and maintenance of the vacuolated phenotype. In 21% O2 culture, a rim effect was observed with more NC cells toward the edges of the beads while in hypoxia, although a rim effect was observed, more NCs were located towards the centre of the beads.

Current investigations are completing these observations.

Optimising the culture of NC cells in vitro could further help us to expand these cells in larger scale for therapeutic purposes.

Once a lesion is present in the articular cartilage, the lesion is likely to deteriorate into whole joint osteoarthritis if not diagnosed timely. Tissue engineers have been designing scaffolds to regenerate osteochondral lesions at an early stage and minimize further degeneration of the joint. However, most constructs were designed under the assumption that the osteochondral tissue has a discontinuous stratified structure, whereas in reality the tissue gradually changes from cartilage into bone. Therefore, we hypothesized that for functional osteochondral regeneration a more biomimicking scaffold is needed, in which seeded cells smoothly differentiate from a chondrogenic towards an osteogenic phenotype across the construct. For this purpose, we developed 3D printed (3DP) scaffolds that contain a continuous gradient of chondro- or osteogenic inducing peptide on the fiber surface for gradual differentiation of human mesenchymal stromal cells (hMSCs). We used an in-house developed print head to extrude and mix two custom-made terminally functionalized polycaprolactone, onto which we specifically attached peptides or other biologically active molecules. Here, validation of the chemical system and fiber functionalization will be shown via different physico-chemical assays. Furthermore, we show with immunohistochemistry and biochemical assays that we exploit the gradient to manipulate hMSC behavior by attaching biological functionalities to the fibers such as (non-) cell adhesive or peptides. In a subcutaneous rat in-vivo study, we showed minimal toxicity towards our base materials and high cellular infiltration in the scaffolds. Finally, we implanted constructs in a rabbit osteochondral defect model and we aim to show histological results of this study.

AbstractCell-based tissue engineering therapies rely on the intrinsic capacity of cells to produce tissue-specific extracellular matrix (ECM) and create tissue-like surrogates in vitro. Although the efficiency and efficacy of cell-assembled tissue engineering therapies have been demonstrated clinically, only a handful of products have been commercialised. This limited technology transfer has been attributed to the prolonged ex vivo culture time required to develop a three-dimensional living substitute that is associated with phenotypic drift and very high manufacturing costs. Recent reports suggest that strategies that enhance and accelerate native ECM synthesis and deposition must be integrated into the developmental cycle of advanced therapy medicinal products to bridge the gap between positive therapeutic outcomes and market success. To this end, the concept of macromolecular crowding has been introduced that not only controls cell fate during ex vivo culture but also enhances (up to 120-fold) and accelerates (within 2-4 days) ECM deposition in permanently differentiated and stem cell cultures. This talk will provide an overview of the fundamentals of macromolecular crowding in eukaryotic cell culture for the accelerated development of functional and truly three-dimensional ECM-rich tissue like surrogates in vitro.References1. Satyam et al. Macromolecular crowding meets tissue engineering by self-assembly: A paradigm shift in regenerative medicine. BIOPRINTING: ADVANCES, CHALLENGES, AND PERSPECTIVES ON CLINICAL TRANSLATION

James Yoo[P][1]

[1] *Wake Forest Institute for Regenerative Medicine*

Corresponding author's email: jyoo@wakehealth.edu

Over the years, various engineering strategies have been developed and applied for building functional tissues and organs for clinical applications. While techniques developed for tissue engineering and regenerative medicine applications have had initial successes in building a number of tissues clinically, challenges still exist in developing complex tissue systems. In recent years, 3D bioprinting has emerged as an innovative tool that enables rapid construction of complex 3D tissue structures with precision and reproducibility. This rapidly developing field promises to revolutionize the field of medicine addressing the dire need for tissues and organs suitable for surgical reconstruction. In this session novel and versatile approaches to building tissue structures using 3D bioprinting technology will be discussed. Clinical perspectives unique to 3D printed structures will also be discussed.

Abstract #105

CELL-FREE TISSUE REGENERATION

James Yoo[P][1]

[1] *Wake Forest Institute for Regenerative Medicine*

Corresponding author's email: jyoo@wakehealth.edu

Cell-based approaches have offered new opportunities for repairing various tissue pathologies. While the concept of using cells and scaffolds to develop functional tissues has remained as a viable strategy to bring new therapies to the clinic, this approach usually requires a donor tissue biopsy and extensive cell manipulation ex vivo prior to application in vivo. Simplifying these processes would provide a more efficient means of developing biological substitutes for functional tissue restoration. It has been demonstrated that almost every tissue in the body contains some type of stem or progenitor cells. These cells are believed to be part of underlying regenerative machinery that is responsible for daily maintenance and repair of injured tissue. The presence of an underlying regenerative mechanism in the form of tissue-specific stem and progenitor cells suggests that there may be a potential opportunity to bias the host response towards repair and replacement of tissue defects. This may be achieved by maneuvering host stem and progenitor cells using target-specific scaffolds. This emerging concept of in situ tissue regeneration using the body's own biological resources has gained increasing attention recently. In this session, translational tissue applications using this concept will be discussed.

PRODUCTION, STERILIZATION AND IMPLANTATION OF HUMAN TISSUE-ENGINEERED BLOOD VESSELS PRODUCED BY WEAVING THREADS OF CELL-ASSEMBLED EXTRACELLULAR MATRIX.

Potart Diane$_P$[1]

[1] *INSERM*

Corresponding author's email: diane.potart@inserm.fr

To meet the clinical need for small vascular graft, we propose a new human and textile-based Tissue-Engineered Blood Vessel (TEBV). Vessels were produced by weaving yarn of Cell-Assembled extracellular Matrix (CAM) synthetized in vitro by skin fibroblasts. Study objectives were to 1) find the best sterilization method to simplify TEBVs production while preserving its biomechanical and biological properties, and 2) assess the human TEBV functionality in an immunodeficient rat model.
Well-organized human CAM sheets were produced in vitro after two months of culture with 20% bovine serum and 500 mM ascorbate. Sheets were cut into 5 mm wide ribbons that were sterilized using gamma irradiation (dry or wet, with high or low dose rates), electron beam irradiation, ethylene oxide (EtO), or supercritical carbon dioxide (scCO2). Ribbons (16 cm long, n=8/condition) were implanted subcutaneously in immunodeficient rats (4/rat) and tensile tests were performed after 2, 4, 12, and 24 weeks. TEBVs (8 mm long, 1.6 mm inner diameter) were woven from 2 mm-wide ribbons and implanted in abdominal aortas of immunodeficient rats.
Before implantation, the strength of the gamma-wet group was significantly lower than control (sterile production group) by 34%, while the EtO group was stronger (+20% of control). After five months, the gamma-wet group remained the weakest, while scCO2 group seemed to be stronger than other conditions. Preliminary surgeries in rat abdominal aortas demonstrated graft implantability and the absence of transmural leakage.
In conclusion, ribbons can be sterilized while preserving satisfying mechanical properties, and be assembled into promising grafts.

Human pluripotent stem cells (hPSCs) have become an alternative model for recapitulating key milestones of human embryogenesis such as tissue development, which is an important and highly regulated process, yet poorly understood1. Currently, creating an in vitro model that provides the appropriate microenvironmental cues in a spatiotemporal manner to enable hPSCs to differentiate into complex 3D tissue structures remains a challenge2,3. Our initial studies have shown that mature tissue-like structures derived from three germ layers can be generated in vitro using a combination of murine embryoid bodies (mEBs) followed by their prolonged maintenance and differentiation on a porous scaffold. This approach extends EB viability by flattening the shape of the EB resulting in reduced diffusion distances and increased cell viability that subsequently permits long-termer cultures, increased cell differentiation and the formation of high order structures. Current work involving size controlled human embryoid bodies (hEBs) has revealed the ability of the system to maintain and form complex tissue structures with features of various human embryonic tissues. We hypothesize that through the development and application of new in vitro technologies, it is feasible to extend the growth and maturation of differentiating tissues derived from hPSCs. Furthermore, the manipulation of physical and chemical factors within the microenvironment will enable the ability to direct tissue development in specific ways. In conclusion, we anticipate that this novel approach will provide an opportunity to study early stages of tissue development and deliver an animal free alternative to assess the pluripotency of hPSCs.

Regenerative Rehabilitation is an emerging area that aims to enhance regenerative medicine. One definition is "Regenerative rehabilitation integrates regenerative technologies with rehabilitation clinical practices to restitute function and quality of life in individuals with disabilities due to otherwise irreparable tissues or organs damaged by disease or trauma".[1]It is well established that musculoskeletal system healing is highly regulated by the mechanical environment experienced after injury. Thus offering an ideal opportunity to enhance tissue regeneration. The AO Foundation is a nonprofit organization dedicated to improving the care of people with musculoskeletal injuries through research, development, education and quality assurance in the principles, practice, and result of fracture treatment. Since 1958 early mobilization has been a central tenant of AO principles of patient treatment. More recently, the underlying cellular mechanisms are being increasingly understood, allowing for optimization of rehabilitation protocols. Within this presentation applied methods will be discussed at the protein and at the tissue level, where mechanical load is demonstrably the main driver of bone healing. Localized cellular responses can be driven at the protein level by changes in expression due to the mechanical forces applied. Additionally, it has been shown that physical stimulation is able to activate latent TGF-β by way of mechanical load alone. Once the underlying process is understood, the translation from defined preclinical environment to a less defined clinical environment remains a challenge. Therefore, how this information can be used to inform development of clinical devices will be discussed, with an example provided.

MULTIPLE TRAITS OF HUMAN NASAL SEPTUM-DERIVED CHONDROCYTES ENCAPSULATED IN COLLAGEN AS INJECTABLE THERAPEUTIC AGENT FOR CARTILAGE DEFECT REPAIR

SeHwan Hwang$_P$[1]

[1] *The catholic university of Korea*

Corresponding author's email: yellobird@catholic.ac.kr

Implantation of chondrocytes is a promising therapeutic strategy for the treatment of cartilage repair. However, articular cartilage injury has poor repair ability and has limited regeneration capacity by therapy based on implantation of articular chondrocytes. Human chondrocytes from nasal septal cartilage (hNCs) are an excellent alternative source of articular chondrocytes for cartilage tissue regeneration because hNCs can be obtained easily by minimally invasive collection procedures and chondrogenic properties of hNCs are maintained after extensive culture expansion, which are demonstrated by immunostaining and expression of cartilage-specific protein. In this study, we fabricated hNCs by encapsulating them in hydrogel, type I collagen, to transplant into injured articular cartilage tissue, and we evaluated their characteristics. Cell moving after encapsulation was detected by microscopy and hNCs were uniformly distributed throughout the collagen. hNCs encapsulated in collagen (hNCs-collagen) showed higher viability than 80% and remain at this levels for 12 hr at 4°C incubation. Fluorescence staining of hNCs-collagen showed great expression levels of chondrocyte-specific protein, Type II collagen, Sox9 and Aggrecan in clinically applicable condition of 24 hr. Notably, in osteochondral defect model, implantation of hNCs-collagen led to greater chondrogenic repair into focal cartilage defect in rats. Moreover, at 8 weeks after implantation, many of human cells were detected around cartilage defect, which is expected to potential and benefits for cartilage regeneration. hNCs-collagen would be a valuable therapeutic agent for implantation into injured cartilage tissue and can be used clinically for repair of cartilage defect in the knee.

INTRODUCTION: Bone healing can be augmented by preconditioning MSCs (pMSCs) with inflammatory cytokines. Another approach is timely resolution of inflammation using immunomodulatory cytokines. We investigated the efficacy of pMSC and genetically modified MSCs that over-express IL-4 (IL4-MSCs) on early stage steroid-associated osteonecrosis of the femoral head (ONFH) in rabbits.METHODS: 36 male mature NZW rabbits received methylprednisolone acetate (20mg/kgIM) 4 weeks before surgery. There were 6 groups: 1. Core Decompress (CD) alone – a 3 mm drill hole+ injection of:2. hydrogel (HG) - 200 µl of hydrogel carrier3. MSCs–1 million rabbit MSCs4. pMSC - LPS (20 µg/ml) + TNFα (20 ng/ml) preconditioned MSCs 5. IL4-MSCs – rabbit IL-4 over-expressing MSCs 6. IL4-pMSCs – preconditioned IL-4 over-expressing MSCsEight weeks after surgery, femurs were evaluated by microCT, biomechanical, and histological analyses.RESULTS: Bone mineral density (BMD) and bone volume fraction (BVF) increased outside the CD in the pMSC group compared to the CD and MSC groups ($p < 0.05$). IL4-pMSC group was increased compared to the CD group ($p < 0.05$). The percentage of empty lacunae in the IL4-MSC group was significantly less than other groups outside the CD ($p < 0.05$); however, IL4-MSC group had less trabecular bone formation inside the CD. DISCUSSION: pMSC increased new bone formation after CD in ONFH; IL4-MSCs decreased the number of empty lacunae. Immunomodulation of bone healing has the potential to improve bone healing after CD for early stage ONFH; these interventions must be applied in a temporally sensitive fashion.

APPLICATION OF SECRETOME FROM HYPOXIA-PRECONDITIONED MESENCHYMAL STEM CELLS ON CARTILAGE REGENERATION

Yanmeng Yang[P][1], Yingnan Wu[1]

[1] *Department of Orthopaedic Surgery, Yong Loo Lin School of Medicine, National University of Singapore*

Corresponding author's email: e0338264@u.nus.edu

Mesenchymal stem cell (MSC) secretome-based therapy is regarded as a promising treatment for cartilage lesions due to the action of MSC secretory factors. Hypoxia, as the physiological condition of MSCs, increases its proliferation, survival and paracrine activity, and has been shown to enhance angiogenesis, migration and suppress inflammation in various disease models. In this study, we investigate the effect of conditioned medium (CM) generated from hypoxia-preconditioned human bone marrow MSCs on cartilage regeneration. MSCs were subjected to normoxic (20% O2) or hypoxic (1% O2) conditions to generate CM. Treatment with hypoxic CM enhanced the proliferation and migration of both MSCs and chondrocytes. Hypoxic CM exerted a superior effect over normoxic CM in the relief of IL-1β induced up-regulation of pro-inflammatory genes (COX2, IL-6) and hypertrophic marker, COLX in chondrocytes exposed to IL-1β. In addition, extracellular matrix degrading enzyme, ADAMTS5 was significantly suppressed by hypoxic CM, resulting in the rescue of IL-1β induced degradation of extracellular matrix. Furthermore, protein array analysis revealed increased production of chemokine (SDF1), anti-inflammatory factors (IL1-ra and GDF15) and growth factors (VEGF, HGF and FGF2) in hypoxic CM relative to normoxic CM, correlating to the functional augmentation of hypoxic CM. Taken together, the results demonstrate that hypoxic condition was able to significantly potentiate the migration and proliferation capability, as well as the chondro-protective and anti-inflammatory paracrine function of MSC secretome. Hypoxia could be a more efficient culture platform to improve the repertoire of MSC secretome for cartilage regeneration.

BIOMECHANICS OF BONE TISSUE REGENERATION IN 3D POROUS STRUCTURES: A MECHANO-DRIVEN APPROACH

Maria Angeles Perez$_P$[1], Gabriele Nasello[1], Simone Russo[1], Jose Manuel García-Aznar[1]

[1] *University of Zaragoza*

Corresponding author's email: angeles@unizar.es

Large bone defects represent a clinical challenge for which regenerative therapies and tissue engineering strategies aim at offering treatment alternative to conventional replacement approaches by metallic implants (1). Materials currently used for bone tissue scaffold fabrication are inorganic materials (magnesium, titanium, ceramics) and natural or synthetic polymers (write examples of both polymers, e.g. PCL). Some of them possess an interesting characteristic, that is degradability. Additionally, 3D printing technologies provide porous scaffolds with designed shape, controlled chemistry and interconnected porosity, where bone will regenerate (2).

In the last decades a strong effort has been made to optimize scaffold designs by means of computational tools. because the final aim is to promote bone regeneration with mechanobiologically optimized scaffolds. In fact, computer techniques and mathematically based models are becoming very useful tools for material engineers and biologists to advance the understanding of the scaffold behaviour under different environments (3). Regeneration algorithms elucidated the relationship between the tissue being formed within the pores and the loading environment, as well as the mechanical benefits of a degrading scaffold during bone formation (4).

In this work, a mechano-driven model is presented which recapitulates the mechanics of 3D printed porous scaffolds (non-degradable and degradable) and predicts short- and long-term bone regeneration. The scaffold regenerative potential based on the biomechanical contributions of both the host and the scaffold itself is also evaluated. Using this computational model, we demonstrated that the mechanical stimulus is intrinsically associated with the regenerative response to bone scaffolds in terms of bone formation.

Myocardial infarction (MI) irreversibly destroys millions of cardiomyocytes in the ventricle, making it the leading cause of heart failure worldwide. Current therapies are unable to replace the lost cardiac tissue, thereby not preventing progression towards heart failure. As a novel regenerative therapy, a new cardiac stem cell type with high cardiomyogenic differentiation capacity, the cardiac atrial appendage stem cell (CASC), was identified. Although CASCs can improve cardiac function after MI, the application potential of CASCs is limited by the low cell engraftment and survival upon transplantation, largely due to their limited angiogenic properties. Since dental pulp stem cells (DPSCs) are highly angiogenic but lack cardiomyogenic properties, they can be used as a priming strategy to improve the efficacy of regenerative CASC therapy. This study investigated whether DPSCs are able to enhance CASCs properties in vitro by examining the effect on CASCs proliferation, viability, migration and angiogenesis. Rat CASCs were either cultured in conditioned medium of rat DPSCs or indirectly co-cultured with rat DPSCs. The effect of DPSCs on CASCs proliferation and viability was assessed by a propidium iodide assay in presence of 2% serum or serum-free medium respectively. Migration of CASCs was examined using a transwell migration assay. To investigate the effect on CASCs paracrine angiogenic properties, conditioned medium of treated and untreated CASCs was collected for in vitro functional assays using a human umbilical vein endothelial cell line (HUVEC). Endothelial cell proliferation, migration and tube formation were assessed. In ovo angiogenesis was examined using the chorioallantoic membrane assay.

TARGETING EARLY HEALING PHASE WITH TITANIA NANOTUBE ARRAYS ON TUNABLE DIAMETERS TO ACCELERATE BONE REGENERATION AND OSSEOINTEGRATION

Yin Xiao[P][1]

[1] *Queensland University of Technology*

Corresponding author's email: yin.xiao@qut.edu.au

Blood coagulation and inflammation are the earliest biological responses to implant surfaces. It is well known that implant nano-surfaces can significantly impact the osteogenesis and osseointegration, which is most likely through the influence on the early phase of bone regeneration. However, the interplay between blood clot property and inflammatory reaction on nanosurfaces is less understood. This study investigated the influence of distinct surface properties of titanium on blood clot features, and whether the adaptable clot features are capable of steering osteoimmunomodulation targeting osteointegration. Titania nanotube arrays (TNAs) with different diameter were fabricated and in vitro evaluation with the whole blood indicated that TNA with a diameter of 15 nm (TNA-15) enabled noteworthy platelet activation resulting in distinct clot features compared with that of pure Ti and TNA with a diameter of 120 nm (TNA-120). The co-culture of macrophages (MΦs) with the clot showed that the clot on TNA-15 downregulated the inflammation and manipulated a favorable osteoimmunomodulatory environment for osteogenesis. In the animal model, TNA-15 downregulated inflammation-related markers (IL-1β, TNF, and IL8), while upregulated growth metabolism-related gene expression (BMP-2, WNT5A, and ITG-β1) in early healing hematoma identified by RNA sequencing. Eight weeks post-implantation in rabbit model TNA-15 promoted the de novo bone formation with improved extending of osteocyte dendrites, demonstrating the desired osseointegration. The results indicate that surface nano-dimensions can significantly influence blood clot formation, which manipulates a favorable osteoimmunomodulatory environment for bone regeneration and osseointegration.

Epithelial organoids cultured in appropriate 3D conditions typically develop a micro-scaled, cystic structure lined with a polarized epithelium. Despite their great potential in research and therapy, epithelial organoids grow in heterogeneous sizes, and are too small to display physiologically relevant performance and applications. Here, we show guided assembly of mouse tracheal basal stem cell organoids towards geometrically-defined, lumenized constructs. The observed shape stability of organoid assembly is confirmed by theoretical modelling based on organoid morphology and the physical forces involved in fusion. We provide hypothesis on how epithelial organoid assembly can be achieved in a more efficient and predictable manner, of which principles could be extended to other organoid types developed form epithelial stem cells. The guided self-assembly strategy presented here opens up the possibility for biofabricating size-relevant, geometrically defined epithelial structures towards broad applications in biomimetic organoid-on-a-chip, and tissue engineering.

Cell seeding process influence the final tissue formation [1,2]. Preceding all other steps of tissue engineering, better cell adhesion and even spatial distribution are associated with improved culture results [3]. For understanding cell seeding process deeply, two geometry scaffold were designed to investigate the cell attachment process through experiment and simulation analysis, including a cubic design and a truncated octahedron design . A novel numerical model is developed by coupling the volume of fluid (VOF), discrete phase model (DPM) and cell impingement model (CIM) for predicting cell distribution after cell seeding. This methodology could help to predict initial stage of cell attachment clinical test more accuracy and also reduce a number of in vivo experiments.This method is able to predict the cell distribution and assessing the scaffold design. Truncated octahedron scaffold showed a more even distribution than cubic design in vitro cell seeding. Truncated octahedron scaffold with spatial distribution beams could provide a more suitble environment for nurtients transport and cell movement and distribution.

Accelerating the rate of nerve regeneration can result in a better functional outcome for the denervated tissue. One of the potential methods for improving nerve regeneration and the restoration of function is electrical stimulation (ES). This inspires to exploit electrically conductive neural scaffold to promote neurite outgrowth. We have developed biocompatible and biodegradable 3D aligned electroconductive scaffolds with minimal immune response for possible use as smart nerve guidance channels (NGCs). The proposed smart NGCs were fabricated using natural fibroin protein of B. mori and A. assama silk (endemic to North-East India). To confer speedy axonal growth, we introduced electrically conducting polymer, polypyrrole (PPy), in the scaffold. The hypothesis of speedy axonal growth in primary dorsal root ganglions (DRGs) and enhanced neural differentiation of adipose derived mesenchymal stem cells (ADMSCs) was tested under pulsed ES using a function generator at amplitude 0, 50, 100, 200, and 300 mV/cm (500 Hz) for 2h/day (3 days). Current-voltage and CV analysis demonstrated their voltage dependent conductive behaviour and redox stability in neutral electrolyte, including cell culture media. The ES test showed multiple fold increase in axonal growth in DRGs and enhanced neural differentiation of ADMSCs. The materials showed minimal immune response when evaluated with murine macrophage cells for release of IL1-beta and nitric oxide. With the higher redox stability cell culture media and faster axonal growth as well as improved neural differentiation, our findings could be considered as a proof-of-concept for a new NGC for faster nerve repairing.

Global demand for corneal tissue was 12.7 million patients in 2016 with approximately 185,000 corneal transplants performed annually in 116 countries, leaving over 12 million corneal-blind cases worldwide untreated [1]. One limitation is access to quality donor tissue due to inadequate eye donation services and infrastructure in some less-economically developed countries. This is compounded by the fact that there are no long-term storage solutions for effectively preserving spare donor corneas collected in countries with a surplus. We have developed a low temperature vacuum evaporation preservation technique that can dehydrate human corneas to enable ambient storage of corneas for over 2 years and allows for global ambient shipping. Dried corneas are comparable to non-dried in all aspects (weight, thickness, ECM content and structure), other than a loss of cellular viability during drying, rendering the preserved corneas as devitalised. When implanted subcutaneously in rats, the dried corneas were well tolerated, with cellular migration into the matrix and no visible immune rejection. We spoke to 12 corneal consultants, at 7 different hospitals, all gave positive feedback regarding future use and suitable clinical indications of tectonic support and deep anterior lamellar keratoplasty were identified. Our preservation technique provides a non-viable, dehydrated, cornea alternative, suitable for a range of clinical indications and tectonic support in emergency situations. It can be stored on the shelf in hospitals for over 2 years and can be shipped at ambient temperatures worldwide, relieving the global shortage of corneal tissue.

Severe vocal fold (VF) defects significantly impact patients' communication and swallowing functions.[1] Existing injectable biomaterials can temporarily augment the defected VF. However, they are absorbed into surrounding tissue over time without repairing the defect, leading to a need for re-injection. Hydrogels produced from decellularized extracellular matrices (dECM) such as porcine small intestinal submucosa (SIS) have been shown to provide cues that aid in wound healing but degrade rapidly and possess low mechanical integrity.[2, 3] To address these challenges, we used click chemistry to develop a SIS-alginate composite hydrogel that possesses greater stability than SIS alone, without a deleterious impact on cells.[4] We first used carbodiimide crosslinking to functionalize the SIS with norbornene and alginate with methyltetrazine and achieved a degree of substitution of approximately 5% in both cases. Gelatin was used as a control for SIS. When mixed, the functionalized SIS and alginate underwent a click reaction, tetrazine ligation, and formed a gel within one hour. Through gene ontology of SIS proteomics, we found that the hydrogel contains proteins involved in cellular adhesion as well as the reconstruction of the extracellular matrix (ECM), key processes in VF regeneration. Specifically, these proteins promote pathways in fibroblast-mediated ECM remodeling, breaking down damaged or scarred ECM and replacing it with healthy neo-ECM. Our results indicate that the click SIS-alginate hydrogel provides cues that could aid in stimulating complete tissue regeneration, thereby reducing the medical burden of biomaterial rejection in the treatment of VF defects.

IN VITRO MODEL OF THE IMMUNOMODULATORY EFFECT OF WHARTON'S JELLY DERIVED MESENCHYMAL STEM CELLS (WJ-MSCS) IN PULMONARY FIBROBLASTS SPHEROIDS INFECTED WITH HUMAN CORONAVIRUS 229E (HCV 229E).

Patients infected with the SARS-Cov2 virus have been severely affected [1]. The high rate damaged reported by the effects of this virus is due mainly to a storm pro-inflammatory cytokines production that is triggered by immune response overexpression [2]. Thus, research on this virus has become a high priority for public health [3]. However, biosafety regulations hinder rapid advancements on this research line. Therefore, it is essential to find an in vitro model that provides a close approximation to the actual SARS-Cov2 infection.

The developed model is based on the detection of anti-inflammatory cytokines produced by Wharton's jelly derived mesenchymal stem cells (WJ-MSCs) as a response of HCV-229E infection at a lung spheroid. For this purpose, a co-culture of lung fibroblast spheroid (MRC-5) constituted in human collagen type 1, infected with HCV-229E, and human peripheral blood leukocytes were grown for 3 days, pursuing the generation of the pro-inflammatory signaling cascade. Subsequently, WJ-MSCs were co-cultured within the previous described environment.

As a result, it was demonstrated that WJ-MSCs play an immunomodulatory role against HCV-229E infection. After 72 h of WJ-MSCs exposure a significant decrease in pro-inflammatory cytokines IL(1,2,6,7) and TNF α was observed. Additionally, a very marked increase in anti-inflammatory cytokines such as IL(4,10,11,13) and TGF-β was detected. We conclude that this model could be used for COVID-19 research and other similar respiratory syndromes without the manipulation of the actual virulent strand, this would aid in the understanding of mechanism behind the disease and the use WJ-MSCS such as therapy.

Treating of full-thickness wounds has long been considered by researchers. Full-thickness wounds require medical attention to prevent infections and scarring. In such group of skin injuries, trying to increase the epithelialization rate and wound closure is paramount importance. Tissue engineering has provided various strategies to repair such skin damages. One of the possible strategies is recruiting immune system to accelerate the healing process. Type 2 immune response consists of different cells and growth factors that help wounds to be healed faster by increasing parameters that support wound healing, such as increasing angiogenesis and wound contraction. Cytokines including IL-10, IL-4, IL-5, and TGF-B are the main cytokines in this type of immune. The interaction of these factors together causes the macrophages to polarize towards type 2 macrophages, and these cells increase epithelialization and wound closure by secreting different repairing factors such as VEGF, ARG-1, and TGF-B. So far, various substances have been identified with the ability to induce type 2 immune response. Oligosaccharides derived from parasitic antigens and human milk have the property of inducing a type 2 immune response. The use of these materials in skin substitutes in addition to reduce the inflammation of the damaged area, accelerates healing by shifting immune response toward the type 2 immunity.

Background: Acellular-matrix based microvascular prostheses have potential as an alternative to autologous-venous grafts utilized in 2–30% of free flaps and replantation surgeries, but methods are required to improve their blood interfaces. Here, the applicability of a decellularized microvascular graft modified with the integrin α4β1 ligand, REDV, for arterial and venous reconstruction was evaluated in a rat-tail replantation model.

Methods: Male-ACI-rat tail arteries (inner diameter: 0.6 mm) were decellularized via ultra-high-hydrostatic pressure treatment, and modified with REDV to induce antithrombogenic interfaces and promote endothelialization post-implantation [1]. Grafts were implanted into the tail artery and vein to re-establish blood circulation in amputated Lewis-rat tails (n =12). The primary endpoint was the survival rate of replants, analyzed by laser-speckle imaging. Secondary endpoints were graft patency, remodeling, and regeneration for 6 months.

Results: Three cases of technical errors or postoperative self-mutilation were excluded. All remaining nine tails survived without partial necrosis. Six-month Kaplan-Meier patency was 100% for arterial grafts and 62% for venous grafts. Two venous grafts were occluded for 3 weeks but displayed no sign of tail-venous congestion, suggesting that the implants remained patent until the regeneration of collateral veins. At 6 months, the neo-tunica media was regenerated inside the neo-intima. One arterial graft extracted at 6 months displayed drug-induced smooth muscle contraction in vitro.

Conclusions: Rat-tails were successfully replanted using allogenic REDV-conjugated microvascular grafts as both arterial and venous substitutes. Further investigations using larger animal models are required.

Keywords

decellularized; microvascular graft

INTRODUCTION: Current clinical treatment for spinal instability requires invasive IVD fusion with a lumbar cage and pedicle screw instrumentation. We previously reported a novel injectable hydrogel (Bgel), which supports the delivery and differentiation of mesenchymal stem cells (MSCs) to bone forming cells(1) and supports bone formation in vivo(2). Here, we tested the application of this gel which contains hydroxyapatite nanoparticles and investigated its bone forming capacity. METHODS: Laponite crosslinked pNIPAM-co-DMAc incorporated with hydroxyapatite nanoparticles (Bgel), was injected into lumbar cages and bovine and human IVD tissue explants, with and without MSCs. Human IVD samples from discectomy patients were obtained from Sheffield Teaching Hospitals. All samples were cultured for 4 weeks. Tissue samples were cultured under hypoxia (5%) in standard culture media. Micro-CT scans were analyzed to determine mineralization within the lumbar cages. All samples were embedded to wax for histological and immunohistochemical analysis. RESULTS: Bgel seeded with MSCs showed mineralization within the lumbar cages. Increased collagen deposition was seen in tissue explants injected with Bgel, with evidence of elevated native cell migration towards the hydrogel. Increased collagen staining was seen in explants injected with MSC-incorporated Bgel. Calcium deposition was increased in Bgel-treated samples, compared to controls. Phenotypic markers; runx2, collagen type X, osteopontin and osteocalcin were assessed to determine the bone synthesizing response within the explant cultures. DISCUSSION: We have developed an injectable hydrogel system which shows potential to support spinal fusion either via directing bone growth through the center of bone cages, or via direct injection into the disc.

RECYCLING CULTURE MEDIUM FOR ENHANCED CELLULAR INTERACTIONS IN IN VITRO BONE MODELS

Michelle A.M. Vis[P][1], Keita Ito[1], Sandra Hofmann[1]

[1] Orthopaedic Biomechanics, Department of Biomedical Engineering and Institute for Complex Molecular Systems, Eindhoven University of Technology, PO Box 513, 5600 MB, Eindhoven, the Netherlands

Corresponding author's email: m.a.m.vis@tue.nl

In a standard cell culture, medium is exchanged. By doing so, important soluble factors for auto- and paracrine signaling are lost and the cells must make a new effort to restore their communication through soluble factors [1]. This effort could considerably influence the cell's behavior. However, renewal of the medium is necessary to prevent waste product accumulation, which in turn inhibits cell growth [2].

To overcome the waste accumulation problem, cell culture systems were developed in which culture medium was filtered or dialyzed to remove waste products. At the moment, dialysis for the re-use of culture medium is not frequently reported and mainly used for culturing of human induced pluripotent stem cells [3-5], which require the use of expensive macro-molecules. Recycling medium enabled the reduction of these costly macro-molecules [5].

This study investigates whether dialysis could be used to improve an osteogenic differentiation culture. A custom-made simple dialysis culture system with a cellulose dialysis membrane is used. It is hypothesized that recycling of culture medium contributes to a more efficient and more physiological environment for cell proliferation and differentiation, leading to faster osteogenic differentiation as auto- and paracrine factors are not removed from the culture. Results show significantly higher ALP/DNA in the dialysis group compared to the control after 3 weeks, which indicates a faster differentiation in the dialysis group. This is confirmed by a higher osteopontin expression after 4 weeks. Overall, the dialysis system shows promising potential as a tool for faster and more physiological osteogenic differentiation.

LOSARTAN SUPPRESSES TNF-ALPHA INDUCED INFLAMMATORY RESPONSE AND DEGENERATION OF HUMAN NUCLEUS PULPOSUS CELLS

Babak Saravi[1,2], Judith Pfannkuche[1,2], Sonja Häckel[3], Mauro Alini[1], Sibylle Grad[1], Norbert Südkamp[2], Hagen Schmal[2], David Kubosch[2], Zhen Li[1], Gernot Lang[2]

INTRODUCTION: Low back pain (LBP) is the main reason for disability worldwide, leading to an immense socioeconomic burden for the affected individuals and healthcare systems. Degeneration of the intervertebral disc (IVD) is known to be a major cause of LBP. We recently showed that effector molecules of the tissue renin-angiotensin system (tRAS) were expressed in the human IVD and that their expression correlated with the extent of inflammatory responses and tissue degeneration[1]. We, therefore, sought to investigate the impact of the angiotensin II type 1 receptor blocker (AGTR1) Losartan on TNF-alpha induced inflammation and degeneration of the human nucleus pulposus (NP) cells.METHODS: Human NP tissue was obtained from male trauma patients (n=4). NP cells were isolated and expanded. TNF-alpha (10ng/ml) was used to induce degeneration and inflammation. Losartan (1mM) was added, and gene expression of tRAS molecules and inflammatory markers were measured. T0070907, a PPARγ antagonist, was applied to the NP cells to investigate the regulatory pathway of Losartan.RESULTS: Losartan significantly suppressed TNF-alpha induced expression of inflammatory mediators (Nitric oxide, TNF-alpha), tRAS related molecules (Angiotensinogen, Angiotensin-Converting-Enzyme, Cathepsin D), and catabolic enzymes (MMP-1, MMP-3). These inhibitions of TNF-alpha induced proinflammatory and degenerative processes were counteracted by T0070907, indicating Losartan attenuates TNF-alpha induced inflammation and degeneration acting in part as a PPARγ agonist.CONCLUSIONS: Collectively, these data illustrate that Losartan, an AGTR1 inhibitor, suppresses TNF-alpha induced inflammation and degradation in human NP cells. Furthermore, our findings reveal that Losartan unfolds this effect, at least in part, through the PPARγ pathway.

Spinal cord injury (SCI) is a debilitating disorder that often results in the loss of motor and sensory function of the patient, as well as paralysis at or below the injury site. Currently, there is no effective treatment for SCI, with most of the clinical endeavors focusing on rehabilitation of the patient [1]. In the past, biomedical engineering strategies for SCI repair focused on the utilization of neural stem cells and biomolecules, though a new tissue engineering strategy is currently emerging in the form of electroconductive materials, which often deliver more optimal results when equated to their non-conductive counterparts. In developing such a material, critical requirements must be met; including excellent biocompatibility, biodegradability, and suitability for cell/bioactive factor incorporation, whilst allowing multiple pathways for conducive facilitation of neuronal or axonal tract regeneration in the spine. In the present work, biomaterials with all the above features are developed and characterized for suitability as an electroconductive biomaterial. We established a novel synthesis method to produce Poly(3,4-ethylenedioxythiophene) (PEDOT) electroconductive nanoparticles based on the mini-emulsion method, which possess the potential to produce nanoparticles with a myriad of functionalities. Further incorporation of PEDOT nanoparticles with bioactive components allowed for the development of a novel electroconductive biomaterial. The physicochemical characterization of this biomaterial includes morphology, degradation profiles, compression tests, electroconductivity, rheology, and biocompatibility studies. In-vitro cytocompatibility studies include Alamar Blue assay and Immuno-fluorescence staining of protein markers on neural stem cells.

The nascent field of cultured meat, as a proposed low value, high throughput product, requires the implementation of large-scale tissue engineering to take advantage of economies of scale and meet potential product demands. Limitations to scale exist for the adherent culture of skeletal muscle cells in bioreactors on microcarriers as a result of the inherent shear forces imposed.[1–2] An alternative, high cell density perfusion bioreactor option that decouples the cells from the shear force of liquid flow was investigated in the form of hollow fibre bioreactors, by assessing the methods for scaling up and optimising the flow conditions for nutrient supply.

Porous polystyrene hollow fibres were fabricated in-house by dry-wet spinning and used as scaffolds in custom hollow fibre bioreactors to expand C2C12 cells with lumen media flow (DMEM + 10% FBS). Monitoring was performed via discrete dissolved oxygen measurement with in-line sensors and off-line media sample analysis. Cell number and viability was quantified and used to analyse expansion, cell density, growth kinetics and metabolite kinetics.

Variation of inlet flow conditions enabled the effect of flow regimes and mass transfer on cell growth, metabolite utilization and final cell density to be assessed. Different methods of scaling hollow fibre bioreactors were investigated. i) Scaling by increasing bioreactor size, performed via in situ cell dissociation and seeding in larger bioreactors. ii) Numbering up (scale-out), verified by the operation of multiple bioreactors in parallel. iii) Process intensification, by decreasing the size of the hollow fibres to increase the maximum cell density attainable.

Trauma and burn wounds have a bad prognostic nature. Hydrogels are the best candidates for dressing such wounds. Exosomes are extracellular vesicles responsible for generating intercellular signaling pathways and cell growth stimulation. Sildenafil citrate has been reported to be effective in angiogenesis. Accordingly, the purpose of this study was to make a novel hydrogel wound dressing following the integration of various findings on wound healing and the use of regenerative medicine.

Materials and methods: Various compounds were fabricated by chitosan/polyvinyl alcohol and then characterized to obtain the optimal composition using several techniques, including a water vapor passage test, antibacterial test, TEM, SEM, water absorption, tensile strength, biodegradability, and FTIR. Then, the synthesized silver nanoparticles (AgNPs) were added to the compound. Exosomes from hADSCs were characterized. Sildenafil citrate reached 5% by weight suspension. Dressings with different compounds were applied to four Wistar rat groups. Hematoxylin and eosin (H&E), silver, and Mallory's trichrome staining methods were used to examine the tissue samples.

Results: The findings revealed the optimal dressing ratio. Better antibacterial activity was found for the AgNPs dressing. The tissue-extracted cells were confirmed to be stem cells using real-time PCR for oct4 and Nanog genes. The presence of exosomal markers was verified by a Western blot test. A novel approach for preparing an exosome for TEM imaging has been developed, and acceptable recovery was observed for the rats. A significant improvement was found for the dressing group within two weeks.

Conclusion: Our new fabricated dressing exhibited satisfactory scarless wound healing properties.

Macrophages play key roles in wound healing process(1). In response to different stimuli, macrophages can adopt the polarization into pro-inflammatory (M1) and anti-inflammatory (M2) phenotypes. Non-healing chronic wounds, such as diabetic ulcers, indefinitely arrest in the inflammation stage of wound healing. Due to the presence of inflammatory cytokines, local macrophages remain in the M1 phenotype and the normal phases of healing do not make any progress(2). While various therapeutic strategies are used to accelerate wound healing, recent studies target the microenvironmental signals and molecular mechanisms that mediate macrophage polarization(3).

In this study, using the native macrophage intracellular signaling pathways and regulators, we investigated the effect of SOCS protein family on macrophage polarization. We designed antisense oligodeoxynucleotide (ASO) sequences against SOCS3 to induce sequence-specific gene silencing by targeting SOCS3 mRNA(4). Mannosylated chitosan (MCH) was prepared as a carrier to delivery SOCS3 ASO(5). The cellular uptake, transfection efficiency, and repolarization capability of RAW 264.7 macrophages were assessed. Transfection of MCH/SOCS3 ASO decreased SOCS3 gene expression and also increased M2 phenotype gene expression in RAW264.7 macrophages, which could reprogram the macrophages from M1 to M2 phenotype.

We investigated the effect of ASO on macrophages phenotype in the impaired wound healing in diabetic mice. Based on histological and immunohistochemical studies it accelerated wound closure, decreased collagen deposition and increased the M2 phenotype levels, compared to the untreated group. Overall,our results demonstrated that MCH/ASO led macrophage functional polarity from M1 toward an anti-inflammatory M2 phenotype, which could be a promising platform for chronic wound healing.

Polyhydroxyalkanoates (PHAs), a family of bioresorbable and biocompatible polymers, are known to be particularly cardio-regenerative in nature(1,2,3). Myocardial infarction results in the generation of scar tissue with limited regeneration due to the modest nature of intrinsic myocardial regenerative capability. The concept of a cardiac patch is tailored to meet the unmet medical need of cardiac regeneration where a biomaterial-based patch would be used to induce efficient cardiac regeneration. Medium chain length PHAs (MCL-PHAs) are highly elastomeric in nature and have been shown to be excellent substrates for the growth and function of neonatal cardiomyocytes(3). This work describes an in-depth study of the potential of MCL-PHAs for the development of functional cardiac patches laden with human pluripotent stem cell derived cardiomyocytes (hiPSC-CMs) and human embryonic stem cell derived endothelial cells (hESC-ECs), providing mechanical support, vascularisation and cell-based therapy.The hiPSC-CMs attach and grow well on MCL-PHA scaffolds, with growth and beat rates comparable to that on gelatin. Immunohistochemical analysis has shown that the hiPSC-CMs exhibit all expected phenotypic characteristics of mature, adult cardiomyocytes when grown on the PHA scaffolds, with the required sarcomere length. Calcium transients, the main functional assay of the hiPSC-CMs are within required values, confirming that the MCL-PHAs support calcium exchange and promote contractions. Similar results were observed on melt electrowritten 3D substrates using hiPSC-CMs and hESC-ECs. Recently, 3D-printed MCL-PHA based multi-material structures have been created and found to be equally functionally efficient. Overall, this work established the highly cardio-regenerative nature of MCL-PHAs, natural materials of bacterial origin.

Nanoneedles are a successful and attractive alternative for gene delivery, without eliciting cell and tissue toxicity [1, 2]. Although nanoneedles offer exceptional localized tissue specificity, control over dosing and release kinetics is poor, as mediated only by surface adsorption. To overcome these limitations, ultrathin coatings were developed using multilayer film deposition of chitosan and polysaccharide-based polyanions onto the surface of silicon nanoneedles. A pCAG-GFP gene plasmid was loaded into pABOL polyplexes and incorporated within the coating multilayers, containing one or more polyplex layers. Confocal microscopy, SEM and XPS surface analyses revealed that all coating components, including polyplexes were uniformly distributed on the surface of nanoneedles, preserving the architecture of nanoneedles. Degradation of the coating and polyplexes over time was monitored with AFM. Release assays showed that an increased number of layers containing polyplexes provided an increased amount and length of pCAG-GFP release. In vitro testing on COS-7 cells seeded on coated nanoneedles showed improved cell viability (close to 100%) compared to non-coated nanoneedles. Transfection efficiency on COS-7 cells was studied via fluorescence microscopy and flow cytometry using increasing layers of polyplexes and multiple nanoneedle patterns. Results 24-hour post-transfection revealed increased transfection efficiency when increasing number of layers. Interestingly, distinct transfection efficiencies where observed with different nanoneedle patterns. These results suggest that transfection efficiency is mostly dependent on the surface area available for interaction with cells, rather than nanoneedle-mediated puncture of cell membrane. Regardless of the mechanisms mediating transfection, these coated nanoneedle-based platforms represent a promising alternative for controlled gene delivery.

A 3D PRINTED MICROFLUIDIC BIOCHIP FOR RAPID DRUG SCREENING

Yi-Chen Li$_P$[1]

[1] *Department of Chemical Engineering, Feng Chia University*

Corresponding author's email: ycli0212@gmail.com

Microfluidic devices offer a relatively rapid, compact and low-cost alternative for mimicking the physiological environment and can test various drug samples with extremely small reagent volumes. Therefore, the development of high-throughput microfluidic chip for culturing cells that can accurately and efficiently predict overall efficacy of drugs. However, traditional lithography methods including stencil-assisted patterning, microfluidic patterning and others exist limitations such as complex manufacturing procedures, limited patternable flexibility, vulnerability of patterning equipment, etc. that are difficult to provide a process to fabricate a high-throughput chip on the substrates with various surface properties which are suitable for culturing cells. Here we propose a concept to fabricate a 3D tree-shape like microfluidic biochip on the substrates with various surface properties (i.e., hydrophilic and hydrophobic) by using a 3D printing technology. We hypothesized that this 3D bioprinted microfluidic chip could provide a rapid easy process to fabricate a microfluidic chip on different substrates and offers a concentration gradient for high-throughput screening drug effects on cells.

REDUCED GRAPHENE OXIDE: POTENTIAL FOR CARDIAC TISSUE ENGINEERING

Nafiseh Baheiraei[P][1]

[1] *Tissue Engineering and Applied Cell Sciences Division, Department of Hematology, Faculty of Medical Sciences, Tarbiat Modares University, Tehran, Iran*

Corresponding author's email: n.baheiraei@modares.ac.ir

Graphene based nanomaterials ,with unique electrical and mechanical properties, are encouraging candidates to support the electrical conductivity of cell-seeded scaffolds for cardiac tissue engineering.

This research was designed to investigate the physicochemical and biological effects of an electroactive cardiac patch of collagen (Col) being coated covalently by different concentrations of graphene oxide (GO). Some samples were also reduced to rGO by a reduction agent to restore the high conductivity of GO. The expression profiles of the cardiac markers were analyzed using quantitative real-time PCR. Vascularization potential of the prepared scaffolds was investigated through subcutaneous implantation of the scaffolds in mice. Also, the antibacterial properties of reduced scaffolds against Escherichia coli, Staphylococcus aureus and Streptococcus pyogenes were confirmed by culture and Field Emission Scanning Electron Microscope (FESEM) observation.

By increasing GO concentration, both mechanical properties and Electrical conductivity of the scaffolds were increased. No toxic effects were observed against human umbilical vein endothelial cells (HUVECs) using MTT assay. Compared with the Col counterpart, electroactive containing rGO scaffolds upregulated cardiac genes, including Cx43, Actin4, and Trpt-2.The obtained results also confirmed the angiogenic and antibacterial properties of reduced Go-containing scaffolds for cardiovascular applications.

Taken together, our results showed that rGO coating provides promising properties to Col scaffolds presenting a desirable micro environment for cardiomyocytes coupling and gene upregulation as well as angiogenic and antibacterial activities for cardiac patch application.

MODEL-FREE ASSESSMENT OF BIOMECHANICAL PROPERTIES FOR PERSONALIZED MEDICAL DEVICES

Michael Gasik[P][1]

[1] *Aalto University Foundation*

Corresponding author's email: michael.gasik@aalto.fi

Biomaterials along with engineered tissues and implants are essential part of any operations for tissue repair and regeneration. Mechanical signal transduction is one of the fundamental modes of cells and materials surfaces interaction but it has so far received insufficient attention. This is also critical for personalized implants (such as 3D fabricated with a complex geometry) and for the regulatory approval. Existing different methods of biomechanical testing give rather different outcomes, and it is not easy to obtain realistic, true properties, evaluated in a correct and physiologically relevant way.

For the risk assessment and regulatory compliance with MDR 2017/745 it is important to deploy methods which provide model-free, invariant and robust estimation of the factors and properties equally useful for medical engineers as well as clinical applications. Here we present an overview of new methodology with examples, compliant to MDR Annex I, enabling robust design and tailoring implants for musculo-skeletal applications.

A part of this work has received funding from the EU Horizon 2020 research and innovation programme under grant No 760921 "PANBIORA".

Artificial vertebral implant with a lateral or posterior screw-rod fixation system are usually employed to rebuild the lumbar spine after spinal resection. This study aims to evaluate the influence of different surgical fixation strategies on the biomechanical performance of a reconstructed lumbar spine system. Two typical lumbar spine reconstruction case that correspond to lateral or posterior fixation systems were selected. Finite element analyses were performed, and comparisons were made between the two models in terms of the safety and stability under various normal daily activities. The load from the upper vertebral body can be effectively transmitted onto the lower vertebral body with the lateral fixation system; which was favorable for bone growth. However, significantly high stresses were concentrated around the interaction region between the screws and bone, owing to the uneven lateral fixation structure; this may increase the risk of bone fractures and screw loosening. For the posterior fixation case, stably posterior fixation structure was favorable to maintain stability for the reconstructed lumbar spine. However, owing to the stress shielding effect, the load was mainly transmitted via the posterior fixation rod rather than the vertebral implant. Therefore, the predicted strain on the endplate were insufficient for bone ingrowth under most of the spinal activates, which could cause bone loss and prosthesis loosening. The results of this study will have a clear impact in understanding the biomechanics of the lumbar spine with different fixation strategies and providing necessary instructions to the design and application of the lumbar spinal fixation system.

CADAVERIC CELLS AS BUILDING BLOCKS FOR TISSUE ENGINEERING: SPINAL CORD NEURONAL PROGENITORS.

Andrey Mikhailov$_P$[1], Yoshiyuki Sankai[1]

[1] *University of Tsukuba*

Corresponding author's email: mikhailov.andrey.fp@u.tsukuba.ac.jp

Until recently, neuronal tissue was not considered for donations from adults, other than for research purposes. Most of the published works utilized one of two main sources of neuronal stem cells (NSCs) for interventions: established cell lines and iPSC-derived NSCs. Cadaver derived live cells should be able to reproduce all the “bystander” neurodegenerative effects, and, in principle, give advantages of better immune matching, highest available cell number, and lower costs associated with in-laboratory cell propagation at required scale.

We studied distribution of apoptotic cells in goat spinal cord at different (0-56hr) intervals postmortem. Number of TUNEL-positive cells found in histological samples and amount of activated Caspase 3 fragment measured by Western Blot gradually increased over time, however, were much lower that in brain of the same animals. Distribution of GD2-positive cells (neuronal progenitors, NSCs) was the densest in the anterior horns of the spinal cord grey matter. NSCs were separated by magnetic force from homogenised and enzymatically processed spinal cord with antibodies against GD2, while the mature neurones with antibodies against CD24. Separated cells were placed on multielectrode arrays and their electrical activity measured before and after enforced differentiation. Cells differentiated from NSCs displayed close spontaneous activity pattern as the matured neurones and displayed similar response to GABA stimulation with bicuculline. We conclude that NSCs can be successfully harvested from post mortal spinal cord material and can be differentiated into electrically active functional neurones.

Ischemia impacts multiple organ systems and is the major cause of morbidity and mortality in the developed world. Ischemia disrupts tissue homeostasis, driving cell death and damaging tissue structure integrity. Strategies to heal organs, like the infarcted heart, or to replace cells, as done in pancreatic islet β-cell transplantations, are often hindered by ischemic conditions. Here, we discover that the basement membrane glycoprotein nidogen-1 attenuates the apoptotic effect of hypoxia in cardiomyocytes and pancreatic β-cells via the αvβ3 integrin and promotes a regenerative immune response. We show that nidogen-1 significantly increases heart function and angiogenesis, while reducing fibrosis, in a mouse post-myocardial infarction model. These results demonstrate the protective and regenerative potential of nidogen-1 in ischemic conditions.

Modern 3D printing of implantable devices provides an important opportunity for the development of personalized implants with good anatomical fit. 3D printing of silicone has been challenging and recently is possible via extrusion. Potential impacts of the 3D printing process of silicone on its biomechanical and biological properties has not been yet studied so in this study we compare 3D printed and molded silicone for their cytotoxicity, surface roughness, biomechanical properties and in vivo tissue reaction. The 3D printing process found to increase nanoscale roughness and microscale topography. Neither the presence of these features nor the differences in processes were found to result in an increase in cytotoxicity or tissue reaction for 3D printed structures, exhibiting limited inflammatory reaction and cell viability above the threshold values. On the contrary, the biomechanical properties have demonstrated significant differences in static and dynamic conditions, and also in thermal expansion. Our results demonstrate that 3D printing can be used for establishing a better biomechanical microenvironment for the surrounding tissue of the implant particularly for fragile soft tissue like epithelial mucosa without having any negative effect on the cytotoxicity or in vivo reaction to silicone. For engineering of the implants, however, one must take into account the differences in mechanical properties to result in correct and personalized geometry and proper physical interaction with tissues.

This work has received funding from the EU Horizon 2020 research and innovation programme under grant No 760921 "PANBIORA".

We hypothesized that the implantation of mesenchymal stem cells (MSCs) aggregates with gelatin hydrogel microspheres (GMS) enhances the efficacy of cell therapy for equine superficial digital flexor tendon (SDFT) injury. We evaluated the residual period of the administered MSC and their therapeutic effect in vivo.

1. Labelled MSC were used to produce aggregates with GMS or monolayer-cultured MSCs. Each of them was injected into a contralateral injured SDFT for six horses. The fluorescent intensity was measured after 10 days. 2. After the injections performed in the same manner for another six horses, ultrasonography examinations were performed to evaluate healing of the lesion over time.

As a results, 1. The fluorescence intensity obtained from aggregates-administered tendons was significantly higher than that from tendons treated with the monolayer-cultured cells ($p<0.05$). 2. Compared to tendons treated with the monolayer-cultured cells, the aggregates-administered tendons had an early decrease in the ratio of hypoechogenic area to the cross-sectional tendon area, an early increase in the strain ratio of sonoelastography (each $p<0.01$) and an earlier disappearance of new blood vessels ($p<0.05$).

Our results suggest the aggregates with GMS are effective to prolong the residual period of MSCs in injured tendons. The findings of the ultrasonography examinations suggest an early recovery of tissue stiffness and early progression of the inflammatory process in the lesion. Although further research is necessary to establish a mechanism to improve the repair of injured tendon, aggregates with GMS would be effective to enhance the efficacy of cell therapy.

CRISPR-MEDIATED EPIGENETIC MODIFICATION RESCUES OSTEOPOROTIC ASC CHONDROGENIC DEFICIENCY AND PROMOTES CALVARIAL BONE HEALING IN OSTEOPOROTIC RAT

Anh Vu Truongp[1], Ya-Hui Lin[1], Thi Kieu Nuong Nguyen[1], Mu-Nung Hsu[1], Yu-Chen Hu[1,2]

Corresponding author's email: av.chemist@gmail.com

Calvarial bone regeneration poses a tremendous challenge in clinical settings due to poor spontaneous healing. Previous studies reported that chondrogenic induction of ASC was able to boost the healing progress via the non-native endochondral ossification pathway. Non-osteoporotic and osteoporotic ASC (OVX-ASC) are inferior in osteogenesis capacity and predisposed to adipogenic commitment, while OVX-ASC chondrogenic tendency remains elusive. CRISPR-mediated epigenetic manipulation has emerged as a robust approach for targeted gene activation/silencing. To activate chondrogenesis, we constructed a baculovirus encoding dSpCas9 fused with the histone acetylation domain p300core with (Bac-p300-VPR) or without (Bac-p300) an extra recruitable MCP-VPR activation fusion targeting the chondrogenic Sox trio (Sox5, Sox6, Sox9). To suppress adipogenesis, we generated a baculovirus encoding dSaCas9 fused with the DNA methyltransferase 3A (Bac-DNMT3A) targeting adipogenic regulators (C/ebpa, Pparg). Bac-p300-VPR conveyed more efficient gene activation than Bac-p300 while Bac-DNMT3A exerted considerable gene knockdown. Bac-p300-VPR-transduced ASC displayed a profound promotion of chondrogenic phenotype as judged by abundant presence of glycosaminoglycan (GAG), while OVX-ASC remained resistant to chondrogenic differentiation albeit the Sox trio activation. Strikingly, co-transduction of OVX-ASC with Bac-p300-VPR/Bac-DNMT3A substantially drove the cells towards chondrogenic lineage. 3D construct culture of the co-transduced OVX-ASC gave rise to significant amount of GAG and collagen type II over the mock-transduced construct. Ultimately, implantation of the transduced construct accelerated and enhanced calvarial defect regeneration in osteoporotic rats. Collectively, our results demonstrated the feasibility of CRISPR-based epigenetic alteration for orthogonal regulation of gene expression in stem cells for regenerative medicine.

Fetal bovine serum (FBS) is a common supplement in cell culture providing cells with nutrients but is controversial due to its unknown batch-dependent composition that could lead to significant differences in experimental outcomes1. For example, FBS has been shown to influence the formation of mineral precipitation and osteogenic differentiation of cells. It was hypothesized that alkaline phosphatase (ALP) could be a serum component which would affect the mineralization process2. Hence, this study focused on how the ALP activity of different FBS types influences in vitro bone-like tissue formation. Acellular and human bone marrow mesenchymal stromal cell-seeded silk fibroin scaffolds were cultured in medium containing four different FBS types under static and dynamic conditions (stirring-induced wall shear stress). Acellular constructs under static condition showed higher calcium phosphate content in the medium with higher serum ALP activity. Mineral deposition on acellular constructs were greatly influenced by dynamic conditions compared to static ones. The cell-seeded constructs were also influenced by the FBS type. In the statically cultured cell-seeded constructs, medium ALP activity had more impact on mineral precipitation than cell ALP activity; while, in the dynamic cultures cell ALP activity had larger contribution on mineral deposition. This study highlights that the ALP activity inherent to different FBS brands could be one of the driving components having an impact on the mineralization process and should be determined in batch testing. For future studies, conventional FBS should be replaced by defined or serum-free medium to increase the reproducibility of studies and comparability of obtained outcomes.

The current innovation on rapid prototyping has increased the demand for customized bioinks with tunable properties for different biomedical applications. In this work, thermo-sensitive and photo-curable bioinks were developed, using an amphiphilic Poloxamer 407-based polyurethane (PEU) entrapped into a photo-crosslinked poly(ethylene glycol) diacrylate (PEGDA) mesh. PEU concentration within the bioink was optimized (12%w/v) to observe gelation around 37°C within few minutes. PEGDA was produced at two molecular weights (3350 and 6000Da) and blended with PEU at different ratios. Circular-shaped samples (10mm diameter, 2mm thickness) were then photo-crosslinked using UV light (365nm, 10mW/cm2, photo-initiator: lithium phenyl-2,4,6-trimethylbenzoylphosphinate, 0.05%w/v). In simulated physiological environment, PEGDA3350-containing systems dissolved after 1-2 weeks, while PEGDA6000-based gels were still present after two months. Rheological and photo-rheological characterization evidenced the possibility to finely tune gel mechanical properties working on PEU/PEGDA ratio and PEGDA molecular weight (storage modulus within the range 5-100kPa upon photo-curing). Bone marrow-derived mesenchymal stem cells were embedded into the formulations and 3D bioprinted (up to 8 layers) at high resolution (approx. 30 µm) exploiting bioink thermo-sensitivity to provide primary stability and then photo-crosslinked layer-by-layer to further stabilize the structures. Each step of the printing process (i.e., cell embedding, printing, photo-curing) was biologically optimized to minimize cell suffering. Viability tests suggested that the whole scaffold fabrication process did not induce cell death and cells exhibited prolonged viability and homogeneous distribution. The here designed thermosensitive and photocurable hydrogels thus represent a promising platform of bioinks with tunable physico-mechanical properties for driving stem cell differentiation towards the desired phenotype.

Tympanic membrane perforation (TMP) is a common condition in ENT clinics and is generally attributed to trauma, chronic otitis media (COM) or ventilation tubes placement [1]. Although most TMP cases heal spontaneously in a few weeks, chronic perforations can cause permanent alterations in the middle ear or hearing impairment [2]. The current TMP treatment involves the placement of a paper patch upon the perforation, or a surgical procedure (tympanoplasty) whereby a material, such as an autologous tissue (fascia or cartilage) is grafted [3,4]. We produced a human collagen membrane for eardrum regeneration (HCM-E) that reduces the amount of collagen needed, without resorting to more expensive methods. HCM-E is an allogenic graft for TMP treatment, an alternative that will be cost-efficient and will obviate the immunological risks and invasive procedures. The HCM-E is constituted of type I collagen and has a porosity of 83.81 ± 7.09 %. Crosslinking of the graft resulted in improvement of the mechanical properties, and a degradation time of 3.72 ± 0.48 h assessed by an in vitro collagenase digestibility assay. Furthermore, the crosslinking process did not affect the HCM-E's cytocompatibility, as shown by the residual formaldehyde content that was below 0.001% (v/v) [5]. This was later confirmed by seeding human primary fibroblast from skin onto the HCM-E and stained by DAPI and Phalloidine after 10 days in culture. Finally, we observed that the HCM-E supported and promoted cell growth and migration and could be a possible scaffold for eadrum regeneration.

THE SHAPE-EFFECT OF CALCIUM PHOSPHATE NANOPARTICLES ON THEIR OSTEOGENIC PROPERTIES.

Pichaporn Sutthavas$_P$[1], Pamela Habibovic[1], Sabine Van Rijt[1]

[1] *MERLN, Maastricht University*

Corresponding author's email: p.sutthavas@maastrichtuniversity.nl

Calcium phosphates in the form of hydroxyapatite (HA) have been extensively studied in the context of bone regeneration due to their chemical similarity to natural bone mineral. While HA is known to promote osteogenic differentiation, the structural properties of the ceramic have been shown to affect the extent of this effect; several studies have suggested that nanostructured HA can improve the bioactivity. However, the role shape plays in the osteogenic potential is more elusive. Here we studied the effect of HA nanoparticle shape on the ability to induce osteogenesis in human mesenchymal stromal cells (hMSCs) by developing nanoparticle films using three different nanoparticle-size HA. We showed that the HA films made from all three shapes of nanoparticles induced increased levels of osteogenic markers on protein and gene level in comparison to hMSCs cultured on cover glass slides. However, their expression levels and profiles differed significantly as a function of nanoparticle shape. In addition, we showed that nanoparticle films were more efficient in inducing osteogenic gene expression in hMSCs compared to adding nanoparticles to hMSCs in culture media. Finally, we demonstrated that hMSC morphology upon adhesion to the HA nanoparticle films is dependent on nanoparticle shape. Our data suggests that HA nanoparticle films are efficient in inducing hMSC osteogenesis in basic cell culture conditions and that nanoparticle shape plays a vital role in cell adhesion and morphology and extent of induction of osteogenic differentiation.

Background: Spermatogonial stem cell (SSC) loss due to cancer treatment, developmental disorder, or genetic abnormality may cause permanent infertility. Tissue and cell culture, 3D scaffolds, and adding of supplements recently have created a new perspective for the differentiation of stem cells in vitro. Therefore, the purpose of this study was to use sheep testicular extracellular matrix (T-ECM) as a biological material for the culture of mouse SSCs in vitro.Materials and Methods: The extracted T-ECM (with different percentages of 0, 1.5, 3, 5%) was used to print the hydrogel scaffold with alginate-gelatin. After cross-linking using aqueous CaCl2 + glutaraldehyde solution, mechanical tests were performed to evaluate the compressive strength and FTIR, degradability, and swelling tests to evaluate the structural and biological properties of the scaffolds. The surface morphology of the scaffold was examined using SEM. Non-toxicity and scaffolds cell adhesion for SSCs was studied using MTT assay and SEM. Result: Results of our study showed that increasing the concentration of ECM in printed scaffolds could increase the hydrophilicity of the scaffold and subsequently enhance the swelling properties that in the printed scaffolds with 5% ECM was acceptable. Also, the results of SEM and MTT assay demonstrated that the printed scaffolds with 5% ECM had proper surface properties, cell adhesion, and good biocompatibility than other groups. Conclusion: In general, our study suggested that T-ECM can be used as a bio-ink for design a functional bioartificial testis in vitro that would offer new fertility restoration options.

Myocardial infarction causes cardiomyocytes loss, and extracellular matrix (ECM) remodelling, resulting in the progressive formation of stiff dysfunctional fibrotic tissue mainly populated by cardiac fibroblasts1. In vitro disease models of human cardiac tissue reproducing post-infarct microenvironment at different stages could improve preclinical validation of new therapies for heart regeneration, in agreement with the 3Rs principle.

Adult human cardiac fibroblasts (AHCFs) were cultured on 3D polycaprolactone (PCL) scaffolds fabricated by melt-extrusion additive manufacturing and surface grafted with type A gelatin (G), to engineer in vitro early and late stage cardiac fibrosis, depending on scaffold architecture. Early stage fibrosis was reproduced on scaffolds with square grid-shaped meshes and different pore sizes (150 µm; 350 µm), while late-stage fibrosis was reproduced on scaffolds with rectangular grid-shaped meshes (300x150 µm2 pore area). G was efficiently grafted through polyDOPA pre-coating as confirmed by QCM-D (performed both on bare and PCL coated gold sensor), ATR-FTIR, AFM, XPS, static contact angle analysis and profilometry. G coating stability was demonstrated by sample incubation in physiological-like conditions. After culturing AHCFs for 3 weeks and subsequent decellularisation, ECM decorated scaffolds were analysed by immunostaining and Western Blot. Activation of AHCFs was studied based on α-smooth muscle actinin (α-SMA) expression.

As a conclusion, long-term AHCFs cultures on bioartificial scaffolds allowed reproducing the progression of human cardiac fibrosis depending on scaffold architectures (orientation and pore size).

This research was supported by BIORECAR project funded from European Research Council (ERC) under EU's Horizon 2020 programme (grant agreement No 772168).

For successful 3D bioprinting, it is well known that bioink rheological properties namely viscosity, yield stress and shear-thinning have to be considered as they can all affect the printing quality and cell viability.
Here we investigated an aspect which has not been considered so far, namely the micro-heterogeneity of the bioink and we established effects of hydrogel structural micro-heterogeneities on the macroelasticity as well as on printing quality and cell viability. Classical rotational rheometry and multiple particle tracking (MPT) based microrheology have been used to characterize macro- as well as micromechanical and -structural properties, respectively. Bioinks of different composition have been investigated: pure alginate and gelatine solutions; alginate (pre-) crosslinked with calcium salts; mixtures of alginate/poly(vinyl alcohol) (PVA), gelatine/PVA and gelatine/nanosilicate clay (Laponite). Pure polymer solutions show a homogeneous microstructure independent of the solvent used. In contrast, for (pre-) crosslinked gels and mixtures, measurements reveal a heterogeneous structure on the micrometer-scale with formation of viscous inclusions within a highly elastic matrix in both water and in cell culture medium. Viscosity, size and spatial distribution of these inclusions have been characterized. Additionally, we observed that gels with the higher degree of heterogeneity exhibit a higher macro elasticity. Finally, hydrogels have been 3D-printed and a correlation between microheterogeneities, cell viability and printing quality has been established. These results will help to better understand the relationship between the bioink´s microstructure before printing and cell viability after printing, as well as feature size and shape fidelity of 3D printed objects.

OSTEOGENIC ACTIVITY OF ACTIFUSE™ IS NOT ENHANCED BY PRE-ADSORBED BMP2

Jasmin Kohnken-Sawall$_P$[1], Simon C. F. Rawlinson[2], Karin A. Hing[1]

[1] *School of Engineering and Materials Science, Queen Mary University of London, London, United Kingdom*

BMP2 has a greater affinity for silicate-substituted hydroxyapatite (SiHA) than stoichiometric HA [1], leading to the hypothesis that the enhanced osteoinductivity of SiHA bone graft substitutes (BGS) is associated with surface enrichment of BMP2. We assessed the proliferation and osteogenic differentiation of human mesenchymal stem cells (hMSCs) on SiHA-BGS with and without BMP2.

hMSC were cultured on 80% porous 0.8wt% SiHA-BGS granules (Actifuse™, Baxter Inc, AF) with pre-adsorbed BMP2 (AF+BMP2) or without (AF) for up to 21 days. hMSCs were cultured on plastic in the absence of both AF and BMP2 (control) or in the presence of 300ng BMP2 (control+BMP2). Osteogenic differentiation was assessed by real-time RT-qPCR of bone markers, analysis of ALP activity, and procollagen-1 production.

From Days 3-21, DNA was significantly higher on AF than on AF+BMP2. Control+BMP2 promoted similar specific ALP activities compared with control, whereas AF+BMP2 resulted in higher specific ALP activity over 21 days. hMSCs on AF demonstrated significantly greater specific ALP activity compared to all samples. AF and AF+BMP2 significantly stimulated procollagen production from Days 7-21 compared to control and control+BMP2. control+BMP2 generated the highest osterix expression, suggesting a stronger osteogenic effect of BMP2 in solution. The opposite was found for endogenous BMP2 expression: AF+BMP2 promoted the significantly highest expression from Days 1-21.

Incubation on AF supported osteogenic differentiation of hMSCs compared with control. AF+BMP2 and control+BMP2 significantly stimulated early osteogenic gene expression, but it did not translate into increased osteogenic behaviour. Enhanced SiHA-BGS osteoinductivity might not be linked to surface enrichment of BMP2.

THE ETHICAL IMPLICATIONS OF TISSUE ENGINEERING FOR REGENERATIVE PURPOSES: A SYSTEMATIC REVIEW

Anne-Floor de Kanter[P][1], Karin Jongsma[1], Annelien Bredenoord[1]
[1] *Department of Medical Humanities, Julius Center, University Medical Center Utrecht, Utrecht, The Netherlands*
Corresponding author's email: a.j.dekanter@umcutrecht.nl

It has been argued that tissue engineering (TE) is a paradigm-changing and potentially disruptive technology (1,2). The ethical and societal implications of TE therefore need to be mapped out and evaluated in parallel to its development (3). To this end, we have systematically reviewed the ethical implications of the development and application of tissue engineering for regenerative purposes, as mentioned in the academic literature. Our review includes over 200 articles published in the period 2008-2020. The major results of this review will be presented in this paper.

A number of recurring themes emerge from our review. These include the need to balance hype and hope in media representations of TE and Regenerative Medicine (RM), the question of when a TE technology is safe enough to enter clinical translation, and the challenge of reducing, replacing and refining animal experimentation during TE development. In this paper we will highlight which ethical aspects of TE have received remarkably little attention to date. Notably, this includes ethical questions related both to the earliest and the latest phases of technology development, i.e. research preceding the involvement of animal and human subjects, and future outlooks on the (societal) implications of TE on the long term.

Overall, through our systematic review, we hope to provide insight into the ethical and societal implications of TE, to serve as a practical guide to researchers working in this field, and as a starting point for further exploration of as yet underexplored ethical implications of TE.

The fine-tuning of cytoskeleton dynamics is crucial for a number of cellular processes, including migration, division and differentiation and is guided by a complex interplay between biochemical and mechanical cues arising from the extracellular matrix (ECM) or provided by the neighbouring cells. YAP-TEAD respond to cell-cell interaction and to substrate mechanics and, among their downstream effects, prompt focal adhesion (FA) gene transcription, thus contributing to FA-cytoskeleton stability. This activity is key to the definition of adult cell mechanical properties and function. The mechanobiology of pluripotent stem cells (PSCs) is still poorly understood.

Here we provide evidence that human PSCs display a sustained basal YAP-driven transcriptional activity despite they grow in very dense colonies, indicating these cells are insensitive to contact inhibition. PSC inability to perceive cell-cell interactions can be restored by tampering with Tankyrase enzyme, thus favouring AMOT inhibition of YAP function. YAP-TEAD complex is promptly inactivated when germ layers are specified, and this event is needed to adjust PSC mechanical properties in response to physiological substrate stiffness. By providing evidence that the mechanical activation of YAP-TEAD1 complex affects the expression of a handful of genes encoding for proteins involved in cytoskeleton dynamics, we suggest that substrate mechanics can direct PSC specification by influencing cytoskeleton arrangement and intracellular tension. We propose an aberrant activation of YAP-TEAD1 axis alters PSC potency by inhibiting cytoskeleton dynamics, thus paralyzing the changes in shape requested for the acquisition of the given phenotype.

Myocardial infarction causes a deep remodelling of cardiac ECM and progressive formation of stiff fibrotic tissue, populated by cardiac fibroblasts[1]. In vitro models of post-infarct microenvironment are required for preclinical validation of new therapies for myocardial regeneration. However, cardiac fibrotic tissue is characterised by high variability in terms of composition, size, stiffness and structure, depending on location and time from heart attack. The aim of this work was to design a platform of 2D and 3D "bioartificial" scaffolds, based on polycaprolactone (PCL) and gelatin (G), fabricated by different techniques (electrospinning and melt-extrusion additive manufacturing) with tuned architectures to mimic the variety and progression of cardiac fibrosis.

Adult human cardiac fibroblasts from both healthy and pathological human ventricle (HCFs) were cultured on scaffolds for 3 weeks. Upon scaffold decellularization, deposition of the typical cardiac ECM proteins by cells was evaluated by immunofluorescence, immunoblot and proteomics analyses as a function of scaffold architecture and healthy and pathological HCFs. Scaffold architecture affected stiffness and porosity, which in turn influenced the type of cell-secreted proteins, their distribution and orientation. Comparisons of engineered constructs with human infarcted samples are in progress to validate the engineered "bioartificial" tissues as platforms for in vitro modelling of cardiac fibrosis progression, tuned by scaffold architecture. Results will be beneficial for the preclinical investigation of new therapies and the study of different degrees of cardiac fibrosis.

This project has received funding from the European Research Council (ERC) under the European Union's Horizon 2020 research and innovation programme grant agreement No-772168.

3D ACTIVE BONE FORMING MODEL TO STUDY AMELOBLASTOMA

Deniz Bakkalci[P][1]

[1] *Researcher*

Corresponding author's email: deniz.bakkalci.16@ucl.ac.uk

Ameloblastoma is a locally aggressive tumour of the jawbones and associated with disruption of bone homeostasis, which is the balance between the removal of mineral and organic constituents of the bone matrix by osteoclasts and the new bone formation by osteoblasts. The precise molecular mechanisms regulating the cross-talking between ameloblastoma tumour cells and the surrounding osteoclasts and osteoblasts remain unknown. We have been working on the development of a biomimetic 3D model of ameloblastoma and its relevant tumour microenvironment, in order to investigate the cellular mechanisms and molecular pathways behind the bone resorption of ameloblastoma. Here, we have managed to establish 3D tumoroid models for two different histological subtypes of ameloblastoma; plexiform and follicular. The models are composed of an artificial cancer mass-composed of either AM-1 cells (plexiform ameloblastoma cell line) or AM-3 (follicular ameloblastoma cell line) and a surrounding bone-like stroma with active bone-forming osteoblasts. The surrounding stroma was developed by incorporating primary osteoblasts from the calvaria of neonatal rats. All cell types were grown in 2D to be used as controls. Our findings show that the tumoroid models present histological features similar to those of classical ameloblastoma from patient samples. We managed to form ~7 times more bone nodules at an earlier day in our 3D active bone forming models compared to 2D control (*$p<0.05$). We also demonstrated that ameloblastoma cells inhibited bone formation in all of our tumoroid models (n=9). Our data first to indicate that, ameloblastoma cells inhibit osteoblast-driven bone nodule formation.

3D PRINTED CELL-LADEN CONSTRUCTS FOR SKELETAL MUSCLE REGENERATION

Sahar Salehi[P][1], Mairon Trujillo-Miranda[2], Claudia Müller[1]

[1] *Department of Biomaterials, Univerisity of Bayreuth*

Corresponding author's email: sahar.salehi@bm.uni-bayreuth.de

Highly aligned and dense microbundles composed of fibers are the major portion of the muscles. Nevertheless, the primary source of such hierarchical structure is specialized cells called myoblasts which are able to differentiate and form multinuclear myotubes and finally myofibers [1]. Alignment and direction that such fused cells adopt within the natural constructs are critical for the vitality of the muscle and its proper function [2]. In this study, we aim to study the fabrication of 3D construct for skeletal muscle tissue regeneration and the effect of external stimuli on the formation of muscle fibers from encapsulated muscle cells.

Therefore, we attempt to evaluate a printable bioink comprising of a methacrylated gelatin (GelMA) and photoinitiators with various concentrations and different crosslinking times which can undergo cyclic stretching (Scheme 1). Moreover, this appropriate bioink must support the cell growth, proliferation and differentiation to form organized muscle fibers. Therefore, the rheological behavior of the bioink and mechanical properties of the hydrogels were measured using rheometer and compression test, respectively. Swelling degree was monitored after 24 hr and at last, 3D printed construct was stretched mechanically under various cycles.

It was shown that pre-incubation at 4°C increased the mechanical stability of GelMA hydrogels, and additional photocrosslinking using VA-086 as a photoinitiator, led to production of porous and flexible hydrogels with high compressive modulus and crosslinking density. After 7 days of differentiation encapsulated mouse myoblasts cells (C2C12) in the ink showed significant differences in formation of myofibers with and without mechanical loading.

Recent advances in 3D microfluidic based bioprinting have enabled manufacturing of complex structures with controlled architectures and tunable properties. Coupling 3D bioprinting with cells derived from human induced pluripotent stem cells (iPSCs), represents a unique opportunity towards modeling complex tissues in an effort to de-risk preclinical drug discovery pipelines. In this study, we use a novel multi-layered flow focusing printhead and validated bioinks compatible with bioprinting iPSC-derived brain endothelial cells (iBECs) to bioprint multi-cellular in vitro perfusable blood vessel models, consisting of a continuous iBECs surrounded by i-neurons and i-astrocytes that make up the neurovascular unit. For each cell type, the effects of different bioink composition, composed of alginate functionalized with gelatin, collagen, fibronectin and laminin as well as extracellular matrix (ECM) remodeling will be investigated and correlated to material biocompatibility by evaluating cell attachment, viability, growth and collagen deposition. The 3D bioprinted construct will be incorporated into a microfluidic device platform to facilitate perfusion and cell maturation while enabling controlled dosing and sampling of test compounds to assess drug efficacy. The ability to print iPSC cells and perfusable blood vessels within 3D bioprinted tissue constructs holds great potential for the creation of more physiologically relevant in vitro models suitable especially as platforms for the pre-screening of drugs, such as the blood brain barrier.

OSTEOINDUCTIVE AND ROS SCAVENGING EXTRACELLULAR MATRIX MIMETIC MINERAL FIBERS FOR BONE REGENERATION

Hayeon Byun[P][1], Heungsoo Shin[1]

[1] *Hanyang University*

Corresponding author's email: leodenter@hanyang.ac.kr

Biomineralization in body is essential in bone regeneration due to its osteoinductive and osteoconductive properties. Thus, there have been several methods to induce biomineral formation on the surface of biomaterials with mimicking its structure and composition. Among them, simulated body fluid (SBF) has been used as a method performed under physiologically relevant temperature. However, this process still has several limitations including long processing time and poor mineralization on unpolarized material surface. Additionally, generation of reactive oxygen species (ROS) and induction of pro-inflammatory genes by the synthetic biominerals have been reported. In this study, we developed a method for multi-functional mineralization method using extracellular matrix (ECM) like synthetic fibers with osteoinductivity and ROS scavenging ability by employing epigallocatechin gallate (EGCG), a polyphenol potentially forming biominerals in SBF via phenol metal network and ROS. We success fully controlled mineralization on the fibers and confirmed hydroxyapatite-like chemical structure of the mineral. To investigate the effect of the biomineralized nanofibers, human adipose-derived stem cells (ADSCs) were assembled with the prepared nanofibers as spheroids, as a module for in vitro analysis and in vivo transplantation. The composite spheroids showed ROS scavenging effect under oxidative stress condition and in vitro osteoinductive activity of ADSCs. Furthermore, transplanted composite spheroids enhanced in vivo bone regeneration in mouse calvarial defect model. In conclusion, we verified rapid and controlled mineralization via our system and multi-functionality related to bone regeneration. Therefore, this novel biomineralization method and advanced spheroid fabrication system could be utilized for bone tissue engineering.

A NOVEL HYDROGEL-BASED TREATMENT FOR COMPLETE TRANSECTION SPINAL CORD INJURY REPAIR IS DRIVEN BY MICROGLIA/MACROPHAGES REPOPULATION

He Shen[P][1]

[1] *Suzhou Institute of Nano-Tech and Nano-Bionics, Chinese Academy of Sciences*

Corresponding author's email: clover_4_hope@sina.com

Microglia/macrophage mediated-inflammation, a main contributor to the microenvironment after spinal cord injury (SCI), persists for a long period of time and inhibits SCI repair. However, the effects of microglia/macrophage mediated-inflammation on neurogenic differentiation of endogenous neural stem/progenitor cells (NSPCs) are not well understood. In this study, to attenuate activated microglia/macrophage mediated-inflammation in the spinal cord of complete transection SCI mice, a combination of photo-crosslinked hydrogel transplantation and CSF1R inhibitor (PLX3397) treatment was used to replace the prolonged, activated microglia/macrophages via cell depletion and repopulation. This combined treatment in SCI mice produced a significant reduction in CD68-positive reactive microglia/macrophages and mRNA levels of pro-inflammatory factors, and a substantial increase in the number of Tuj1-positive neurons in the lesion area compared with single treatment methods. Moreover, most of the newborn Tuj1-positive neurons were confirmed to be generated from endogenous NSPCs using a genetic fate mapping mouse line (Nestin-CreERT2;LSL-tdTomato) that can label and trace NSPC marker-nestin expressing cells and their progenies. Collectively, our findings show that the combined treatment method for inhibiting microglia/macrophage mediated-inflammation promotes endogenous NSPC neurogenesis and improves functional recovery, which provides a promising therapeutic strategy for complete transection SCI.

REGENERATIVE MEDICINE AND ENGINEERING – A NEW BACHELOR PROGRAM

Jurica Bauer$_P$[1], Guy Bendermacher[1], Vanessa LaPointe[1], Pamela Habibović[1]

[1] *Maastricht University*

Corresponding author's email: j.bauer@maastrichtuniversity.nl

Regenerative Medicine is a relatively new field at the intersection of science, engineering and medicine. Traditionally, researchers in this field are biologists, chemists, materials scientists, data scientists, engineers or physicians who have acquired skills and knowledge beyond their basic training and stepped into the multidisciplinary world of regenerative medicine. Many of them, however, still approach their research questions largely from the perspective of their own discipline and find it difficult to step outside that domain. Having recognized the need for a new multidisciplinary researcher profile that would receive basic training in all the required disciplines to easily enter the aforementioned field, we have taken the initiative of designing an undergraduate program focusing on Regenerative Medicine and Engineering. Within this program we aim to educate a new generation of researchers that will swiftly adapt to any area of regenerative medicine and develop medical therapies and products for research and clinical use. Applying the principles of problem- and research-based learning, our program will offer a solid STEM foundation, which will be strongly integrated with medicine. An example of this is a real-world student research project defined by clinicians within the academic hospital. In addition, special attention will be paid to the development of the translational scientific skills necessary to bring new therapies and products onto the market.

Alongside discussing our progress in this endeavor, in this interactive session anyone with an interest in education will be most welcome to share their own vision and experiences relating to education in regenerative medicine.

Compromised arteries such as those suffering from severe atherosclerosis can lead to myocardial infarction, which is the leading cause of death worldwide. Autologous or commercially available synthetic grafts can be used as artery replacement, but these often fail to provide long-term patency and display limited regeneration. There is a high demand for alternative grafts that can develop into neovessels, yet do not rupture or occlude after surgery. Towards this goal, we have fabricated vascular grafts from a combination of tropoelastin (TE), the soluble precursor to elastin, and polyglycerol sebacate (PGS), a highly elastic degradable biomaterial.

Scaffolds were fabricated into a spectrum of microstructures from TE fiber-reinforced PGS matrix to pervasive TE-PGS fiber-networks, resulting in scaffolds with mechanical properties comparable to the human coronary artery. The addition of TE promoted the attachment and proliferation of organized vascular endothelial and smooth muscle cells. Vascular endothelial cells formed a monolayer in vitro and expressed functional markers of endothelium including VE-Cad, eNOS, and vWF. Vascular smooth muscle cells changed from rhomboid to spindle shapes on scaffolds and expressed contractile phenotype markers such as alpha-SMA and MHC II, which have been shown to contribute to reducing the risk of hyperplasia. Implantation in mice aorta showed the compliance of the patent TE-PGS vascular grafts continued to increase in 6 weeks. Hematoxylin and eosin stain showed the graft is being degraded by immune cells. Verhoeff-Van Gieson stain showed de novo regeneration of elastic fibers and their organization into long and continuous elastin similar to native elastic laminae.

This report describes activity in Europe for the years 2016 and 2017 in the area of cellular and tissue-engineered therapies, excluding hematopoietic stem cell treatments for the reconstitution of hematopoiesis. It is the eighth of its kind and is supported by five established scientific organizations amongst them TERMIS-EU. In 2016 and 2017, a combined 234 teams from 29 countries responded to the survey; 227 teams reported treating 8236 patients in these two years. Indications were categorized in hematology/oncology (40%; predominantly prevention or treatment of graft versus host disease and hematopoietic graft enhancement), musculoskeletal/rheumatological disorders (29%), cardiovascular disorders (6%), neurological disorders (4%), gastrointestinal disorders (<1%), as well as miscellaneous disorders (20%), which were not assigned to the previous indications. The predominantly used cells were autologous (61%). The majority of autologous cells were used to treat musculoskeletal/rheumatological (44%) disorders, whereas allogeneic cells were mainly used for hematology/oncology (78%). The reported cell types were mesenchymal stem/stromal cells (MSCs) (56%), hematopoietic cells (21%), keratinocytes (7%), chondrocytes (6%) dermal fibroblasts (4%), dendritic cells (2%), and other cell types (4%). Cells were expanded in vitro in 62% of the treatments, sorted in 11% of the cases, and rarely transduced (2%). The processing of cells was out-sourced to external facilities in 30% of the cases. Cells were delivered predominantly intravenously or intra-arterially [47%], as suspension [36%], or using a membrane/scaffold (16%). The surveying of cell and tissue-engineered therapies is a relevant instrument to capture developing trends and monitor advances in the field, based on effective treatments performed.

IMPROVING THE MIGRATION OF INTRAVENOUSLY INJECTED MESENCHYMAL STEM CELLS TO INFLAMMATION SITES BY CELL SURFACE ENGINEERING WITH POLYETHYLENE GLYCOL

Yukiya Takayama[P][1], Kosuke Kusamori[1], Makiya Nishikawa[1]

Corresponding author's email: 3a17702@ed.tus.ac.jp

Mesenchymal stem cells (MSCs) have some notable functions such as homing to inflammation sites, tissue repair, and immune regulation. However, the homing rate of intravenously injected MSCs to inflammation sites is as low as less than 1% due mainly to their entrapment in the lung vasculature. We previously reported that cell surface modification using the avidin-biotin complex (ABC) method was useful to stably modify MSCs with various biotinylated compounds.1 In this study, we attempted to modify the surface of MSCs with polyethylene glycol (PEG), a biocompatible polymer, using the ABC method to avoid the lung entrapment after intravenous injection through inhibition of the intercellular adhesion between MSCs and vascular endothelial cells in the lung. PEG-modified MSCs were prepared by sequentially reacting MSCs with sulfo-NHS-LC-biotin, streptavidin and PEG-biotin. PEG-modified MSCs were then seeded onto the confluent monolayered mouse aortic endothelial cells (MAECs). The number of PEG-modified MSCs adhering to MAECs was significantly lower than that of unmodified MSCs. Then, PEG-modified MSCs were intravenously injected to the tail veins of carbon tetrachloride-induced acute liver failure model mice. At 1 h after injection, the number of PEG-modified MSCs in the lung was significantly lower than that of unmodified MSCs. Moreover, significantly more PEG-modified MSCs were observed in the liver than unmodified MSCs at 24 h after injection. Taken together, these results indicate that PEG modification to the surface of MSCs by the ABC method reduces the lung entrapment of MSCs and improves their migration to the inflammation sites after intravenous injection.

Injectable hydrogels are emerging biomaterials because they provide new avenues to reduce healing time and decrease risks of post-operative infections. Here, we report development of a new generation of injectable, tunable, hydrogels based on cellulose nanofibrils (TUNICELL) isolated from tunicates grown in Norwegian fjords. Tuning is achieved through mechanical and chemical modifications. Processing in a GMP compliant clean room resulted in pure (99% purity), highly crystalline (89%) cellulose fibrils <10 nm in diameter, with tunable lengths. TUNICELL is sterilized, and has endotoxin levels below 0.5 EU/g, meeting medical requirements. Cellulose nanofibril dispersions in water, adjusted from 2 to 4% dry matter, showed very good shear thinning properties as determined by rheological evaluation. Mechanical treatment by passing dispersions through a microfluidizer, allowed control of both fibril lengths (hundreds of nm to several μm), and fibril length distributions, as determined by AFM. We studied injectability using simulated tissues of various stiffness. Shorter fibrils with broader fibril length distributions, and increased concentration of fibrils, improved injectability. Chemical modification to generate carboxymethylated cellulose nanofibrils, which could be crosslinked with calcium ions, resulted in hydrogels with higher shear modulus than crosslinked alginate with the same polymer content. Tunicate nanocellulose hydrogels of varying compositions were evaluated for controlled rates of hemoglobin delivery for wound healing applications, as well as stem cell delivery for cartilage repair.

Bioprinting is one of the most advance technology in tissue engineering and regenerative medicine. Trough LDM (liquid deposition modelling) and ink-jet technics, biomaterials including cells are used to produce tissues with cell density and shape recapitulating human tissue behaviours. However, these processes present limitations such as cells viability, due to a high shear stress value inside the dispensing system. In this study, we evaluated the shear stress impact on the quantification (lysis) and qualification (necrosis, apoptosis) of cells to ensure the production of organoids. Our approach was based on the relation between biomaterial viscoelastic properties, sizing of deposition system and cells viability. To access the shear stress map inside the bioprinting system, a specific algorithm was developed based on Poiseuille tube flow of a pseudoplastic power law fluid. Different kind of cells were used to understand the capacity of them to withstand stress. Living and labelled necrotic or apoptotic cells were counted before and post-printing process to evaluated cell viability and total cell recovery in various conditions. In view of results, the shear stress gradient can be controlled through biomaterial rheological behaviour and sizing of dispensing system. Cells viability seems to be depend on shear stress value but also duration. In future, the recording of data in a library will allow biomaterial engineers to use algorithm in reverse engineering mode, to tailored bioprinting system and/or biomaterials properties in function of the kind of cells. A disruptive innovation could be applied in autograft technique to ensure the success of surgical intervention.

There is often a trade-off between mechanical properties and degradation rate of biodegradable materials for in vivo applications; hence, finding the right balance in properties for biomedical applications is challenging. In this study, we hypothesise that blending semicrystalline poly (p-dioxanone) (PDO) and poly (lactide-co-caprolactone) (LCL) in a specific composition will improve the toughness while also enabling tailored degradation rate. Hence, blends of semicrystalline PDO and poly (lactide-co-caprolactone) (LCL) were prepared in varying concentrations and formed into films by solvent casting. A range of experimental methods were used to characterize the properties of the blends during hydrolytic degradation in neutral phosphate-buffered saline (PBS) solution at 37 °C for up to 24 weeks. Cellular performance was determined by seeding mouse fibroblasts onto the samples and culturing for 72 hours, before using proliferation assays and confocal imaging. All blends exhibited good cell viability. However, an increase in LCL content causes a reduction in hydrolytic degradation, indicated by weight loss, induced crystallinity, surface and bulk erosions, and tensile properties. A blend of 30% PDO and 70% LCL (PDO3LCL7) resulted in small PDO droplets uniformly dispersed within the LCL matrix and showed toughening behaviour with a notable strain-hardening effect reaching 320% elongation at failure; over 3 times the final elongation of neat LCL, and has an ultimate tensile strength (18.9 MPa) comparable to neat PDO (20.5 MPa). This work highlights that the combination of elastomeric behaviour capable of high deformation, together with moderate degradation rates, particularly suit tissue engineering applications in tendon tissue repair.

Current additive manufacturing (AM) methods such as fused deposition modeling and bioprinting follow a certain tool pathway to deposit material, often referred to G-code. G-code is based on an arranged list of X, Y and Z coordinates that are followed by the printhead to deposit material and is generated from a 3D CAD model into layers. Each layer can have a specific pattern for the print head to follow. However, most automated pattern generation software have limited line patterns that run parallel or circumferential to each other resulting in woodpile structures. Here, we present an automated method for producing a variety of patterns based on fractals. These unexplored patterns have a different mechanical behavior than conventional patterns, such as negative Poisson's ratios or multiple linear elastic regions. In addition, the mechanical stimulation of the fractal scaffolds on induced pluripotent stem cells (iPSCs) pluripotency was assessed.

Scripts were written in Rhino 6 Grasshopper to generate fractal patterns into G-code compatible for AM (Bioscaffolder SYSENG) using Polycaprolactone. The resulting scaffolds were mechanically tested (TA Electroforce 3200). A finite-element model of the scaffolds was used (COMSOL multiphysics) to simulate the stress and displacement. A bioreactor was developed to mechanical stimulate the scaffolds during culture with iPSCs.

The scripts successfully generated different fractal patterns. Compared to a woodpile structure, certain fractals showed multiple linear elastic regions during compression tests or a negative Poisson's ratio during tensile tests. Initial cell culture in static conditions showed that iPSCs did not lose pluripotency on the fabricated scaffolds.

MEDICAL ELECTROSPINNING; CHALLENGES AND SOLUTIONS TO BRING FIBER BASED PRODUCTS TO THE MARKET

Judith Heikoop[P][1], Marc Simonet[1], Kikki de Laat[P]

[1] *IME Medical Electrospinning*

Corresponding author's email: m.simonet@ime-electrospinning.com

Fiber-based scaffolds can be a powerful tool to engineer living tissue replacements by providing mechanical, structural and organizational support to guide the development of well-organized and functional extracellular matrices (ECM). In the regenerative medicine field, electrospinning is often the preferred scaffold production technique due to its capability to produce 3-dimensional fibrous ECM-lookalike scaffolds with similar nanometer to micrometer length scales utilizing an extensive range of natural and synthetic polymers. The electrospinning process is highly versatile, allowing to tailor scaffold properties to fit the regenerative demands of various tissues to be engineered.

Controlling all these parameters, defining this method's versatility, has proven to be a challenge, leading to production inconsistencies, batch-to-batch variability and reproducibility issues. Hence, it's of outmost importance to tightly control and log all relevant parameters. For example, the humidity affects the structural properties of the scaffold on the macro and micro level. These structural changes can have a large effect on the mechanical and biological properties of the scaffolds.

Keeping a tight control of the entire production process, combined with real time scaffold thickness monitoring, is an innovative approach to drastically reduce variability of fiber-based scaffolds between and within batches. This also minimizes waste during the production and is therefore a prerequisite for scaling a research process to an economically viable manufacturing process.

Tightly controlled Medical Electrospinning will allow the translation of promising research outcomes into the design and development of scaffolds to promote regeneration of the natural structures of the extracellular matrix in a variety of tissues.

NEW IMMUNE-MODULATORY SURFACES BASED ON COATINGS WITH GLYCOSAMINOGLYCANS

Thomas Groth[P][1]

[1] *Department Biomedical Materials, Institute of Pharmacy, Martin Luther University Halle-Wittenberg*

Corresponding author's email: thomas.groth@pharmazie.uni-halle.de

Implantation of biomaterials triggers inflammation that can be transient defeating infections and promoting healing, or longer lasting undesired chronic, with foreign body response and fibrous encapsulation. Hence, design of biomaterials that control inflammation is desirable. Macrophages represent key players at the implantation site that secrete cytokines and other mediators of inflammation, which synthesis is regulated by nuclear transcription factor-κB (NF-κB) signaling pathways. Glycosaminoglycans (GAG) like heparin (Hep) and hyaluronic acid (HA) were studied here as biomaterial coatings to control inflammation by their effects on human macrophages in vitro and after subcutaneous implantation in mice. GAG were either covalently immobilized or physically adsorbed as multilayers (in combination with chitosan) on model substrata or biphasic calcium phosphate (BCP) particles. In vitro studies on model surfaces could demonstrate reduction in macrophage adhesion, formation of multinucleated giant cells and interleukin-I secretion after immobilization of HA and Hep with heparin being more effective. These effects were strongly related to suppression of NF-kB signaling as studied by immunofluorescence and immunoblotting and related to association and uptake of GAG by macrophages. In vivo studies with mice revealed that coating of BCP particles with HA suppressed the inflammatory response together with formation of new bone-like tissue, while the presence of Hep delayed the onset of inflammation permitting osteogenesis in this subcutaneous bone-forming model. Results of this study may also pave the way to reduction of inflammation after implantation of sensors, soft and hard tissue implants and other medical devices.

CHONDROPROTECTIVE AND ANTI-INFLAMMATORY EFFECTS MEDIATED BY EXTRACELLULAR VESICLES FROM PLASMA- AND SERUM-BASED BLOOD-DERIVED PRODUCTS FOR OSTEOARTHRITIS THERAPY

Alexander Otahal[P1], Karina Kramer[1], Olga Kuten-Pella[1,2], Christoph Stotter[1], Zsombor Lacza[2], Stefan Nehrer[1], Andrea De Luna[1]

Blood-derived products gain increasing interest in the field of regenerative medicine as well as in orthopaedics, aesthetic surgery and cosmetics. Currently, citrate-anti-coagulated platelet-rich plasma (CPRP) preparations are often applied in osteoarthritis (OA), but more physiological and cell-free alternatives such as hyperacute serum (hypACT) are under development. Beside growth factors, blood products also bring along extracellular vesicles (EVs) packed with signal molecules which opens up a new level of complexity at evaluating the functional spectrum of blood products. To attribute potential chondroprotective and anti-inflammatory effects elicited by blood products to EVs, they were enriched from blood products via ultracentrifugation and depletion of frequently co-isolated components such as lipoproteins was verified via Western Blot. EV treatment of primary chondrocytes isolated from OA cartilage enhanced the expression of anabolic markers type II collagen (COL2A1), SRY-box transcription factor 9 (SOX9) and aggrecan (ACAN) compared to full blood products, but also the catabolic marker and tissue remodeling factor matrix metalloproteinase 3 (MMP3), while hypACT EVs prevented increased type I collagen (COL1A1) expression compared to CPRP EVs. CPRP blood product increased SOX9 protein expression, in contrast to hypACT blood product. However, hypACT EVs induced SOX9 protein expression while preventing IL6 secretion. These results indicate that blood EVs are sufficient to induce chondrogenic gene expression changes in OA chondrocytes, while preventing pro-inflammatory cytokine release compared to full blood product. This highlights the potential of blood-derived EVs as regulators of cartilage extracellular matrix metabolism and inflammation as well as candidates for new cell-free therapeutic approaches for OA.

BEYOND THE LIMITS OF DIFFUSION - DEVELOPING NEW HUMANIZED TOOLS TO MODEL DISEASE

Kristina Haase[P][1]

[1] *European Molecular Biology Laboratory*

Corresponding author's email: kristina.haase@embl.es

Complex in vitro models are expected to leap from the bench to the bedside. However, there has been a lack of adoption thus far, resulting from the inability of these models to accurately predict clinical outcomes. Despite advances in patient-specific iPSC and gene-editing technologies, the lack of functional vasculature is hypothesized as a key factor in the limited predictability of current systems. Given its role in regulating oxygen tension, nutrient delivery and immune cell interactions, functional vasculature is required for the development and long-term maintenance of normal tissue physiology. To overcome the limitations of current systems, we develop disease-specific models integrating tissue-specific microvasculature. This talk will provide an overview of several human vascularized models being developed in our lab (placental, ischemic, and tumor). These tools allow us to exploit the self-assembly process of endothelial cells, while tuning the microenvironment to allow for insight into complex tissue biology and pathologic development. These perfusable microvessels enable us to investigate specific cell-cell interactions through live imaging techniques and to understand the effects of mechanical cues, such as luminal flow, on the regulation of microvessel morphology and permeability. In addition, drug dissemination studies can be performed and examined in the context of perfused vascularized tissues. This will lead to further insight into the human response to treatment, and aims to reduce unintended side-effects not seen in animal models. These physiologically relevant microsystems hold significant promise for development into more accurate preclinical models – a major aim of our lab.

Ischemic stroke is one of the most frequent causes of death and disability globally. Novel therapeutic strategies for enhancing the repair of neural structures and the recovery of functions are urgently warranted. In this work, we aim to employ a stem cell-based approach for treating ischemic stroke. Three-dimensional (3D) spheroids composed of human mesenchymal stem cells (MSCs), which are capable of secreting neuroprotective agents and inducing therapeutic angiogenesis, and human umbilical vein endothelial cells are constructed using a methylcellulose hydrogel system. Our in vitro results demonstrate that the fabricated 3D stem cell spheroids can protect neurons that are under oxygen glucose deprivation. Additionally, the neurite outgrowth from neurons and tubular network formation by vascular endothelial cells are significantly enhanced. Intracerebral transplantation of 3D stem cell spheroids into the mouse model of middle cerebral artery occlusion effectively reduce lesion area, maintain cerebral structural integrity, and improve post-stroke motor function. In summary, the developed 3D stem cell spheroids possess significant neuroprotective and pro-angiogenic potential, thus holding a great promise to be employed as an effective therapeutic agent for treating ischemic stroke.

Vascularisation of implanted engineered tissues is essential to ensure sufficient nutrients to support therapeutic cells once implanted in vivo [1]. Prevascularisation by the inclusion of endothelial cells (ECs), which form capillary-like structures in vitro and anastomose with host vasculature, is one such method [1].

We demonstrate a flexible mathematical model of vascular network formation in a 3D hydrogel, integrating global features such as construct geometry, environmental conditions, and interstitial flow, with key chemical and mechanical cell mechanisms that lead to network formation [2]. Based on a multiphase model framework [3], a set of coupled partial differential equations (PDEs) describe the temporal and spatial evolution of the EC density, extracellular matrix density, oxygen and VEGF concentrations. We explore the impact of key mechanisms including autologous chemotaxis, oxygen-dependent VEGF production, and cell-matrix interactions mediated by traction and matrix stiffness.

Combining data from literature, sensitivity analysis, and parameter optimisation methods, we identify parameter sets under which capillary-like structures form. Using metrics such as vessel length, area, and network complexity, we validate our computational model against in vitro data at the UCL Centre for Nerve Engineering.

Further refinement of the PDE model alongside relevant in vitro experiments will allow us to optimise culture conditions, and elucidate the benefits of interstitial flow towards creating functional prevascularised engineered tissues. The model, implemented and solved in Python, will remain adaptable to hydrogel properties, cell types and culture conditions, with the aim to make the software open for use within other tissue engineering groups.

Keywords

Prevascularisation; Hydrogel; Multiphase model

PROMOTING SMOOTH MUSCLE CELL MIGRATION IN ELECTROSPUN VASCULAR SCAFFOLDS

Lauren West-Livingston[1,2], Young Min Ju[2], Anthony Atala[2], Sang Jin Lee[2]

Objective: This study sought to utilize growth factors to promote the migration of smooth muscle cells (SMC) into an electrospun vascular scaffold. The hypothesis was that the use of growth factors would allow for acellular tissue-engineered vascular grafts that are capable of recruiting smooth muscle cellular proliferation and infiltration in situ.

Methods: Scaffolds electrospun with poly(ε-caprolactone) (PCL)/collagen polymers were surface modified through the passive adsorption of platelet-derived growth factor with two beta subunits (PDGF-BB) and stromal derived growth factor 1α (SDF-1α) at various concentrations, individually and together. Single-factor studies investigated each factor at concentrations of 100 ng/mL, 250 ng/mL, and 500 ng/mL. Dual-factor studies investigated the combined effects of 100 ng/mL PDGF-BB and 500 ng/mL of SDF-1α.

Results: Compared to unmodified controls, scaffolds modified with growth factors showed higher rates of smooth muscle cell proliferation. Notably, scaffolds bioconjugated with a concentration of 100 ng/mL PDGF-BB alone and a concentration of 500 ng/mL SDF-1α alone demonstrated the greatest degree of smooth muscle cell proliferation compared to other single-factor concentrations, which confirmed ideal concentrations reported by other studies. A novel finding was that the combination of these growth factors at the aforementioned concentrations showed synergy in the ability to increase the degree of SMC migration into the depth of the electrospun scaffold.

Conclusion: This series of experiments verifies that growth factors promote proliferation of SMCs on an electrospun scaffold, and that combining multiple factors can optimize migration of SMCs farther into the thickness of electrospun scaffolds in an in vitro setting.

ADIPOSE TISSUE-DERIVED STROMAL VASCULAR FRACTION SHOWS SUPERIOR OSTEOGENIC DIFFERENTIATION COMPARED TO DONOR-MATCHED MESENCHYMAL STROMAL CELLS

Johanna Husch[P][1], Charlotte Woud[1], Jurriaan Vossen[1], Jeroen van den Beucken[1]

[1] Regenerative Biomaterials - Dentistry, Radboud Institute for Molecular Life Sciences, Radboudumc, Nijmegen, The Netherlands

Stromal vascular fraction (SVF) is the primary isolate obtained after enzymatic digestion of adipose tissue that contains various cell types (1). Its successful application for cell-based construct preparation in an intra-operative setting for clinical bone augmentation (2) and regeneration (3) has previously been reported. However, the performance of SVF-based constructs compared to traditional ex vivo expanded adipose tissue-derived MSCs (ATMSCs) remains unclear and direct comparative analyses are scarce (4). Consequently, we here aimed to compare the osteogenic differentiation capacity of donor-matched SVF and ATMSCs. Human adipose tissue from 4 different donors was used to isolate SVF, which was further purified using adherent cell culture to obtain donor-matched ATMSCs. The cell populations were characterized for MSC, endothelial and hematopoietic markers by flow cytometry and immunocytochemistry. For normalized seeding densities of donor-matched cell populations, the plastic adherent fraction within SVF and ATMSCs was determined. Thereafter, SVF and ATMSCs were seeded and cultured in osteogenic differentiation medium for 28 days. Proliferation and mineralization were analyzed during the culture period. ATMSCs showed to be a homogenous cell population, while SVF consisted of different cell lineages. Plastic adherence revealed to be significantly lower for SVF compared to donor-matched ATMSCs. Remarkably, all donor-matched comparisons showed either accelerated or more robust mineralization for SVF which could relate to endothelial cells found present during early osteogenic culture. Our data demonstrate superior osteogenic differentiation capacity of SVF over donor-matched ATMSCs. Further preclinical bone defect studies will explore whether this effect also extends to their performance in bone regenerative applications.

The decellularization of homografts is a process where cells and their waste are removed (>99%) without affecting the extracellular matrix (ECM) while keeping growth factors for cell signalling1. Different methods such as chemical, enzymatic, physical or a combination of them have been reported. The most common involve the use of detergents for solubilization of the cytoplasmic membrane and dissociation of proteins along with the use of nucleases for removal of cellular material. However, these methods may result in an incomplete decellularization, denaturalization of proteins and damage to the ECM1,2.

The aim of this research is to propose and validate a novel process of tissue decellularization that diminishes the damage to the ECM while improving process time and cost. For this, we developed a reactor for using on an aorta and pulmonary artery of a donor, simultaneously. The process consisted of pumping hypotonic solutions in four steps (NaCl ranging from 40 to 0 mM at different time points) for controlling the diffusion and achieving cell lysis with minimal damage to the ECM, digestion with nucleases to remove residual nucleic acids and rinsing with an isotonic solution for remnants removal.

As a result, low amount of residual DNA (< 50 ng of double stranded DNA)2 and not visible nuclear material in histologic analysis with HE staining2 were observed. Cytocompatibility was assessed by exposing the acellular tissue to human fibroblast and adipose derivate human stem cells. We conclude that this could be a potential solution for decellularizing homografts for treating heart congenital defects.

BIOMATERIAL SURFACE FUNCTIONALIZATION FOR SUSTAINED DELIVERY OF NGF AND BDNF TO STIMULATE NEURITE GROWTH

Ana Sandoval-Castellanos[P][1], John Haycock[1], Frederik Claeyssens[1]

[1] *The University of Sheffield*

Corresponding author's email: amsandovalcastellanos1@sheffield.ac.uk

Peripheral nerve injury is a major cause of disability [1-2]. The clinical standard is the use of autografts; however, their performance is limited. Nerve guide conduits (NGCs) could be used as an alternative. The addition of neurotrophins has been studied to improve the performance of NGCs, however, neurite outgrowth has not been stimulated significantly [3-4]. It is paramount to design a platform for the sustained delivery of neurotrophins [5]. The aim of this study was to fabricate bioactive surfaces, which would stimulate neurite outgrowth, by using heparin to bind to amine groups. Then, NGF or BDNF were bound electrostatically, or immobilized, to heparin. To characterize the bioactive surface, water contact angle (WCA), XPS analysis, and ELISA assay were performed. To study the effect of the bioactive surface, chick embryo dorsal root ganglia (DRGs) were seeded on bioactive surfaces, and neurite outgrowth was measured [6]. The bioactive surface was successfully fabricated, confirmed by WCA and XPS analysis. ELISA assay revealed that surfaces with immobilized NGF 1 ng/mL showed no neurotrophin release until 168 h, where 1% of NGF was detected. DRGs cultured on immobilized NGF 1 ng/mL developed neurites significantly longer in comparison to control and other test surfaces, possibly due to a low initial burst release, and for the sustained activation of a non-internalized NGF-TrkA complex [6]. In conclusion, locally delivered NGF and BDNF, at relatively low concentrations, is a promising and scalable approach to support sufficient neurite outgrowth for modifying medical implantable devices for nerve regeneration.

TOPOGRAPHICALLY CONTROLLED NANOFIBROUS MEMBRANES TO MIMIC THE EPIDERMAL STEM CELL MICROENVIROMENT OF THE RETE RIDGES

David Hiram Ramos$_P$[1], Sheila MacNeil[1], Frederik Claeyssens[1], Ilida Ortega Asencio[1]

[1] *The University of Sheffield*

Corresponding author's email: dhramosrodriguez1@sheffield.ac.uk

Adult stem cells reside on specific microenvironments at the interface between the epidermal and dermal layers of the skin called rete ridges. These microenvironments control stem cell quiescence via cell-cell interactions and soluble factors [1]. Although current approaches replicate one or more components of the rete ridges, the design of a biomedical device that mimics the micro and nanostructure of the stem cell microenvironment is yet to be explored in vitro [2] [3]. The aim of this project is to study the regenerative capabilities of topographically controlled electrospun scaffolds (TCESs) using an in vitro tissue-engineered skin model.

Polycaprolactone TCES were electrospun using poly(methyl methacrylate) patterned collectors. Skin models were prepared using human dermal fibroblasts and keratinocytes onto de-epidermised acellular human dermis. Additionally, control models without the scaffold were burned at day 7 followed by implantation of the TCES. H&E histology and ICC were used to evaluate tissue structure.

Histology sections showed cell infiltration from the TCES towards the dermal component. The microfeatures formed, although wider, showed similar depths. Topographical cues proved to be a key factor for tissue integration, with low cell attachment and no infiltration for conventional plain scaffolds. When burned at day 7, control skin models were not able to repopulate the damaged areas, whereas TCES controls showed improvements in the regeneration of the epidermal component and formation of basic microenvironments. This work demonstrates that the inclusion of topographical cues within scaffold design is a promising approach to recreate to a degree the morphology of the Rete Ridges.

Eight patients die daily awaiting liver transplant. Although there is donor liver scarcity, thousands of livers are discarded due to conditions such as advanced age. To ameliorate donor scarcity, we aim repurposing discarded human donor livers through whole liver decellularization and subsequent recellularization with patient-specific cells. The purpose of this study is to assess the effect of advanced donor age on ECM composition and structural organization as the variation in quality and age will affect translating this approach to clinical settings. To achieve this, we have decellularized 3 young (<44 years old) and 6 aged (>44 years old) whole human livers through a 4 day-long protocol of perfusion with sodium dodecyl sulfate through portal vein and hepatic artery. Total DNA, collagen, and glycosaminoglycan contents were assessed, and mass spectrometry and histology were used to examine age-related changes in structural composition and organization of the liver matrix. Our results showed that more than 90% of DNA removal from all livers. Aged livers had a less homogenous decellularization and higher collagen and glycosaminoglycan content. Histology analysis showed that the structural integrity was preserved in livers regardless of age while aged livers had higher remaining fat content and a denser collagen network. Overall, our results indicate that there are age-related changes in liver ECM composition and structure. Through further characterization of livers from different aged donors, the widely varying discarded donor livers can be classified, thus be used effectively as decellularized scaffolds to develop human liver substitutes with high functionality and regenerative capacity.

Biological treatment using engineered osteochondral composites with the dynamic microenvironment has received growing attention. In this study, a bone-derived scaffold with good biocompatibility and osteoinductive capability was constructed. Porcine femur in distal metaphysis was treated by chemical decellularization, deproteinization, decalcification, and degreasing to obtain the bone-derived scaffold. It was found that bone-derived scaffold was eluted and had good biocompatibility which can serve as a suitable material to support bone tissue. We also designed a spinner bioreactor for the in vitro modeling of the microenvironment which can promote adipose mesenchymal stem cell (ADSCs) recruitment from the simulated bone marrow compartment into the bone-derived scaffold under physiological flow conditions. Results demonstrated that at the end of 14 days in dynamic microenvironment culture, the ADSCs had achieved 1.73-fold expansions than in the static culture. And the ADSCs-bone derived scaffold composites had better proliferation and differentiation under dynamic microenvironment via spinner flask than static culture, and were able to differentiate into osteoblasts better with extensive mineralized nodules forming the bone aggregates over 3 weeks postosteogenic induction. The electromagnetic field (EMF) stimulation of ADSCs was evaluated in vitro. The results showed that 75Hz/1mT EMF fields stimulated ADSCs could enhance osteogenic proliferation and differentiation. Results also shown that the numbers of ADSCs expanded under 1mT EMFculture were 1.55 times in DMEM and 1.64 times in OM more than EMF-free culture. In conclusion, the designed EMF-stimulated dynamic microenvironment can served as an suitable investigational tool for the screening of other biomaterial-based tissue engineering strategies.

Traditional Chinese medicine therapy, which can serve as adjuvant therapy for cancer treatment, has no obvious side effects on the human body. Geniposide (GEN), one of the main iridoid glycosides in gardenia fruit, has been widely reported to have anti-cancer effects. In this study, we aimed to inspect whether GEN could inhibit proliferation and promote the apoptosis of human breast cancer cells (MCF-7). In order to better predict the efficacy of GEN, we have prepared the Cs/Gel composite scaffolds by 3D printing technology to mimic the MCF-7 cell growth microenvironment. The prepared Cs/Gel scaffold has good mechanical properties and biocompatibility, which can provide a more accurate platform for drug screening. The semi-inhibitory concentration (IC50) evaluated by CCK-8 assay was 16.06 mg/mL (24 h), 14.85 mg/mL (48 h), and 13.14 mg/mL (72 h). After exposed to GEN for 48h, the cancer cell survival rate reduced from 69.15 ± 2.86% (13 mg/mL) to 20.97 ± 3.24% (16 mg/mL). Although the inhibitory effect was weaker in the 3D culture system, it also managed to inhibit cell proliferation and induce cell apoptosis. Besides, Live/Dead staining, Hematoxylin-Eosin (H&E) staining and SEM evaluation were also conducted to estimate the anti-cancer effect of GEN in 2D and 3D cultures. The results indicate that GEN has an anti-cancer effect based on a time- and dose-dependent manner.

Triply Periodic Minimal Surfaces (TPMS) based porous scaffolds are expected to provide better strength, stiffness, and microarchitecture for cell proliferation to repair bone fractures [1-2]. Here, we describe an effective method to generate and test the biocompatibility of EOS stainless steel 316 based TPMS scaffolds using additive manufacturing technology. Five different types of porous TPMS scaffolds: cubic (control), gyrosheets, IWP, diamond, and gyrosolids were designed, 3D printed, and tested for its structure, mechanical properties and biocompatibility. Though the designed porosity of the scaffolds was 50%, the actual porosity of the 3D printed scaffolds showed slight variations ranging from 4 to15%. SEM image analysis of the scaffold surface pore sizes showed a range of 150 – 800 µm, well suited to facilitate the cell proliferation and vascularization. In compression tests, all five types of scaffolds showed Young's modulus similar to native bone tissue, ranging from 2.3 - 4.8GPa, while the toughness of the scaffolds was in the rage of 40-120 MJ/M3, suitable to resist bone fractures. The plateau stress assessment of the TPMS scaffolds revealed a stiffness ranging from 95 - 112.59 MPa, which denotes superior load-bearing ability of these structures. The cell toxicity (live-dead count) and the cell proliferation assays (MTT assay) using MEF cell culture in the scaffolds showed that the scaffolds were non-toxic, biocompatible and favor cell growth. With a porous structure, reduced weight, and enhanced cell proliferation, our results indicate that the 3D printed SS-based TPMS scaffolds have high potential to be used as permanent bone implants.

POTENTIAL OF BIOINSPIRED POLYPHENOLIC SURFACE MODIFICATIONS FOR ANTI-INFLAMMATORY AND ANTIMICROBIAL TI DENTAL IMPLANTS

Florian Weber[P][1], Alejandro Barrantes[2], Hanna Tiainen[1]

Biofilm-film associated infections around dental implants lead to chronic inflammatory response that results in significant tissue destruction and reduced wound healing capacity even after the biofilm has been removed.1 In the quest for the future generation of implant surfaces, continuous efforts are made studying plant polyphenolic molecules due to their combined antioxidant and antimicrobial properties. A variety of these molecules have been shown to mediate inflammatory conditions by scavenging reactive radical species and reducing the expression of pro-inflammatory cytokines.2, 3 Further, their interaction with microbial cell walls, and inhibition of essential enzymes and signaling pathways results in antimicrobial properties.4

While these effects have been mainly studied in vitro using dissolved polyphenolic molecules, our aim is to functionalize implant surfaces with these molecules. Therefore, we investigated the oxidative polymerization of pyrogallol and created novel silica-phenolic networks using tannic acid. The use of silica-TA networks allowed us to lower the reaction pH and thereby avoid oxidation and polymerization processes, which led to an increased deposition efficacy. As a result of the reduced pH, the antioxidant capacity of TA coating was increased.

Utilizing this continuous, surface independent deposition process of TA and PG, a local reservoir of active molecules can be built. The subsequent release of active molecules was shown to be more sensitive to acidic environment for silica-TA networks compared to PG coatings. Since antimicrobial and anti-inflammatory properties of polyphenolic coatings have been related to released molecules,5 increased layer thicknesses have a higher potential to reduce bacterial colonization and relieve inflammatory conditions.

Tumors contain a small population of cancer stem cells (CSCs), which express stem cell properties, and possess a self-renewing capacity and differentiation abilities. CSCs that exist as a different population to cancer cells are responsible for tumor generation and also result in relapse and metastasis that gives rise to new tumors. However, CSCs only comprise 1%–5% of the total tumor cell population. Therefore, finding the optimal environment for CSCs to proliferate is extremely important. We investigated patient-specific cancer cell line to target the CSCs for future application of chemotherapy drug selection for each specific colon cancer patient.

We evaluated the effect of cancer stem cells through culturing with different extracellular matrix (ECM) and different seeding density. Different ECM have specific physical and biochemical properties that provide structural support of cells and play important roles in cell survival, migration, and differentiation. Single cancer cell can secrete paracrine by itself, which facilitates the growth; hence, we want to observe if the ECM-coated dish could enhance the cancer cell proliferation. We analyzed the cell attachment ratio on different ECM-coated surface and found Matrigel was the best ECM for establishment and proliferation of cancer cell colonies. Furthermore, we discovered the seeding density, 100 cells/well, has the greatest expansion fold and shorter doubling time on each ECM-coated surface. Consequently, we continue operating flow cytometry (CD44, CD133) to verify CSC expression and ultimately find the optimal environment for CSC proliferation and establishment.

Cartilage wear is a common joint disease, which may lead to osteoarthritis, and may even damage the subchondral bone as it progresses. Research related to bioceramics have its own values in tissue engineering, especially, calcium silicate-based materials are attractive due to their unique osteoinductivity. Three-dimensional (3D) printing technology has the advantages of fast, accurate and controllable manufacturing process, and has been widely used in cartilage tissue engineering. In this study, we fabricate the lithum-doped calcium silicate porous scaffold by 3D printing technology for the repairing of subchondral defects. The experimental results found that the scaffold have a mechanical structure with sufficient strength, as well as accelerated proliferation and differentiation of Wharton's jelly mesenchymal stromal cells. The animal model with subchondral defects also shown that the lithium-doped calcium silicate scaffold has the better ability to enhance new osteochondral regeneration in vivo. In summary, litium-doped bioceramic porous scaffolds could be a promising biomaterial for the osteochondral regeneration.

Cardiovascular diseases represent a significant socio-economic burden. For instance, following losing cardiac cells after an infarct, substantial work has been invested in optimizing and advancing cell transplantation strategies to restore heart function. A particular concern is that the implantation of cells using a non-electroconductive matrix potentially induces arrhythmia. Here, we generated a conductive biohybrid hydrogel based on hydrazide-functionalized multiwall carbon nanotubes (MWCNTs) incorporated into decellularized and digested pericardial matrix. Furthermore, we demonstrate that this platform, either in 2D or 3D, is a suitable environment for maturing human-induced pluripotent stem cell (hiPSC)-derived cardiomyocytes. hiPSC-derived cardiomyocytes showed an enhanced contraction amplitude (>500%) on conductive hydrogels compared to cells cultured on Matrigel®, accompanied by enhanced cellular alignment, elevated connexin 43 expressions, and improved sarcomere organization suggesting maturation of the hiPSC-derived cardiomyocytes. Sarcomeric length of these cells increased from 1.3 to 1.7 µm. Furthermore, we generated 3D cell-laden tissues that positively responded to external electrical stimulation and exhibited improved calcium handling compared to tissues without MWCNTs. We then utilized these 3D models of cardiac tissues to study the effect of four different candidate drugs on beating properties. Our engineered tissues showed a more apparent detectable response to drugs that either promote (isoproterenol and epinephrine) or inhibit (verapamil and nifedipine) heart beating rate compared to tissues without carbon nanotubes. Our data collectively indicate that our biohybrid hydrogels consisting of solubilized pericardial matrix and electroconductive positively charged hydrazide-conjugated MWCNTs provide a promising material for generating 3D models of cardiac tissue and stem cell-based cardiac tissue engineering.

A hydrogel scaffold with good mechanical properties, biocompatibility and biodegradability can effectively promote tissue regeneration is essential for hard tissue repair and regeneration. However, there is no bone scaffold that can integrate all these characteristics. Therefore, we hope to use γ-PGA and calcium silicate to produce a hydrogel with adequate strain, osteoinductivity and osseointegration. γ-PGA hydrogel has excellent water retention capacity, biocompatibility and biodegradability. We improve the mechanical properties by adding calcium silicate. The good wrapping and drug loading characteristics of γ-PGA for encapsulating the cells and calcium silicate to form a repair microenvironment inside. Herein, our study used 3D printing to fabricate scaffolds made up of γ-PGA/CS. It was reported that the scaffold was not only able to enhance bone cell proliferation but also induce differentiation by the silicon ions released from calcium silicate. From the results of implantation in animal model showed that the scaffold could promote blood vessel and bone regeneration. Based on the above, it is known that the γ-PGA hydrogel scaffold could be serve as a potential and biological material for bone tissue regeneration applications.

Peripheral nerve injury is one of the problems to be solved in neuro medicine. The current gold standard in clinical practice is autologous transplantation, but the problems of insufficient supply sites and mismatched sizes have made nerve conduits widely used in clinical practice. The rapid improvement of 3D printing technology in recent years has also made nerve conduits an alternative process. Among conductive polymers, poly(3,4-ethylenedioxythiophene): poly(styrenesulfonate) (PEDOT: PSS) has considerable stability and high conductivity, and is a promising conductive material in biomedical research. In this study, conductive nerve conduit with Schwann cells was prepared through 3D bioprinting technology. During electrical stimulation, Schwann cells in the nerve conduit were stimulated to cell proliferate, and expected to secrete more nerve growth factor (NGF). Besides, nerve regeneration was evaluated via the rat animal model of peripheral nerve injury. The results showed that the conductive nerve conduit with Schwann cells had good biological activity, and the Schwann cells also had good performance in immunofluorescence staining results after electrical stimulation. In the in vivo study, conductive nerve conduits with Schwann cells performed better in electrical stimulation. We hope the developed Schwann cell-contained conduit has good potential in nerve tissue engineering in the future.

Today's implant research faces the challenge of improving both the biocompatibility and reproducibility of implants. Biohybrid implants consisting of a technical and a patient-specific component are suitable for this purpose. The aim is the development of a biohybrid heart valve based on a hydrogel matrix with textile reinforcement. A functional toolbox for fibrin-based hydrogels is developed and the direct cell/biomaterial interaction and the long-term behaviour of the cells in the in vitro implant is investigated.

More concrete, new biohybrid hydrogels from fibrinogen and poly(N-vinylpyrrolidone) copolymers are used. For later application of the heart valve, smooth muscle cells (SMC) are required. Therefore, human stem cells are cultured inside the hydrogels for myogenic differentiation induced by the specific growth factors TGF-β1 and BMP4 over 21 days. We focus on the distinction between the contractile and the synthetic phenotype of SMC as the contractile type is mandatory for functional heart valves. Vascularization is essential for the supply of the construct after implantation, thus, the formation of capillary-like structures by endothelial cells in contact with feeder layers of stem cells within the gel is analyzed.

First experiments show long-term stable hydrogels, which trigger the successful myogenic differentiation of mesenchymal stem cells.

The analysis is performed by RT-qPCR, immunofluorescence and scanning electron microscopy as well as two-photon microscopy, with emphasis on the expression of the contractile and synthetic markers.

Compared to conventional heart valves, biohybrid heart valves offer the decisive advantage of personalization using the patient's own stem cells and thus represent a future-oriented technology.

Calcium silicate (CS) has attracted researchers' attention for its favorite bone adaptability and bone formation. Our team has previously developed the magnesium-doped CS (MgCS), which can stimulate the osteogenic differentiation and angiogenesis of human periodontal ligament cells by the released Mg ions, but is concerned about their mechanical strength and rapid biodegradability. On the other hand, we had also created strontium-doped CS (SrCS), which has more high mechanical properties compared with pristine CS, and better biological functions for osteogenic differentiation. Therefore, the methodology here was constructed multi-CS in a single scaffold (MSCS) using direct-ink-writing method. The printed outer struts of the scaffold consist of MgCS, while the central structure consists of SrCS to prevent excessive degradation and collapse of the scaffold, thereby affecting new bone tissue ingrowth. The results confirmed that the strain-stress curve was much higher and the degradation time was prolonged compared with the MgCS scaffold. The doped ions (Sr, Mg) released from MSCS have a huge impact on the behavior of Wharton's jelly mesenchymal stem cells (WJMSC). The MSCS also significantly promoted cell growth, and alkaline phosphatase activity and more calcium deposits were found on the surface of the scaffold. Moreover, the establishment on rabbit critical-size bone defect model demonstrated that more new bone tissue ingrowth by the analysis of BV/TV and histological staining results. This study showed that the 3D printed multi-CS scaffolds could modulate on degradability and maintain the strength of the entire structure, while ions synergistically promote the osteoinduction in vitro and in vivo.

The design of supramolecular hydrogels represents a valuable strategy to develop therapeutic platforms characterized by remarkable processability and high drug encapsulation capacity. The implementation of α-cyclodextrins (CDs) and poly(ethylene oxide) (PEO)-based polymers to form highly-hierarchical hydrogels composed of poly(pseudo)rotaxanes has been exploited to this aim1-3. Nonetheless, the reversible nature of these networks could hinder their stability in biological environments. In this work, a supramolecular network based on a custom-made photo-curable poly(ether urethane) (PEU) and CDs was designed with the aim to develop hydrogels with highly tuneable physical properties and release kinetics. Poloxamer 407(amphiphilic triblock co-polymer composed of PEO (70%) and poly(propylene oxide)), 1,6-diisocyanatohexane and 2-hydroxyethyl methacrylate as end-capping molecule were utilized for PEU synthesis. The formation of poly(pseudo)rotaxanes based on PEU and CDs was demonstrated through X-Ray Diffraction crystallography, Infrared and Proton Nuclear Magnetic Resonance spectroscopies. Supramolecular hydrogels were formulated with CDs ranging between 7 and 10% w/v at low PEU content (1-5% w/v), showing fast gelation kinetics (ranging from minutes to few hours). CD concentration of 8% w/v was selected as the best compromise between good mechanical and self-healing properties. Photo-rheological characterizations (365 nm, 10 mW/cm2) were conducted, showing good photo-responsiveness. Successful encapsulation and protection from degradation of curcumin (up to 570 µg/ml) were attained exploiting its complexation with CDs and PEU4,5. Tuneable release profiles of curcumin (up to 23 days) were obtained through photo-crosslinking, thus making such platforms promising for cancer treatment6,7. Finally, the formulation containing PEU at 5% w/v resulted to be suitable for extrusion-based 3D-printing.

Cartilage is highly specific, but has limited supply of nerves, blood vessels, lymphatics, and low metabolic activity. This avascular structure causes a lack of precursors and vegetative cells, thus the ability of cartilage self-regeneration is severely limited. Due to the lack of nerves and blood vessels, When the pain felt significantly, the extent of damage has usually reached to the subchondral bone, so minor cartilage defects are generally difficult to detect. Despite of using drug or surgical treatment can not restore the function and structure of cartilage in current. With the development of tissue engineering, the possibility of cartilage tissue regeneration has been improved. In order to clinical application, it is necessary to develop implant scaffold which having good biocompatible, biodegradable, and high mechanical properties. In this case, we prove that the photosensitive liquid resin of a hyaluronic acid-based polyurethane for the feasibility of cartilage regeneration. The ability of chondrogenesis with human chondrocyte-laden hybrid scaffold was evaluated in vitro and showed well-proliferation at day 7. Up to 8 weeks, degradation comply with the degradation rate of cartilage regeneration. Also, strength of the hybrid scaffold in the compression test achieved 25 Mpa. Moreover, we discovered the bone recovery surround by cartilage in vivo experiments against defected articular cartilage rabbit model. In this article, the fabricated hyaluronic acid-based polyurethane using DLP printer is a prospective way that could be applied in tissue enginerring and development of cartilage regeneration.

Diabetic foot ulcer is one of the leading causes of leg amputation and mortality in diabetic patients. Autologous stem cell therapy holds some potential to be a solution to this problem, however diabetic stem cells are relatively dysfunctional and restrictive in their wound healing abilities. This study explores the wound healing abilities of a novel pro angiogenic gene activated scaffold (GAS) previously developed in our lab [1] to stimulate human diabetic adipose stem cells (ADSCs) towards wound healing.

Our GAS consisted of a collagen composite containing the pro-angiogenic stromal-derived factor-1 alpha. This was seeded with diabetic ADSCs and compared to healthy ADSC on the gene-free scaffold over 2 weeks period. We analysed functional responses including SDF-1α mediated signaling, bioactive factors production, proangiogenic bioactivity of secreted factors, matrix deposition and proteome profiling,

We found that SDF-1GAS could restore proangiogenic regenerative response in the human diabetic ADSCs, similar to the healthy ADSC gene-free scaffolds. SDF-1α gene-activated scaffold induced the overexpression of SDF-1α in diabetic ADSCs and engaged CXCR7, causing downstream signaling of β-arrestin as effectively as the transfected healthy ADSCs. The transfected diabetic ADSCs also effectively stimulated angiogenesis in endothelial
cells while undergoing matrix remodeling (reduction in fibronectin and increase collagen IV).

Conclusion: We show that the SDF-1α gene-activated scaffold can overcome the deficiencies associated with diabetic ADSCs paving the way for autologous patient stem cell therapies in combination with novel biomaterials to treat diabetic foot ulcers.

CONSTRUCTION OF 3D FIBROUS PCL SCAFFOLDS BY COAXIAL ELECTROSPINNING FOR PROTEIN DELIVERY

Mehrnoosh Rafiei$_P$[1]

[1] *Department of Chemical and Petroleum Engineering, Sharif University of Technology*

Corresponding author's email: mehrnooshrafiei@gmail.com

In this study, a three-dimensional tablet-like porous scaffold, comprising core-shell fibers to host proteins inside the core, was developed. The fabrication method involved the novel combination of coaxial and wet electrospinning in a single setting. Poly (ε-caprolactone) was chosen as the based polymer and bovine serum albumin was used as a model protein. These 3D tablet-like scaffolds exhibited adequate porosity and suitable pore size for cell culture and cell infiltration, in addition to appropriate mechanical properties for cartilage tissue engineering. The effects of different parameters on the behavior of the system have been studied and the 3D scaffold based on the core-shell fiber was compared with that based on the matrix fiber. The core-shell structure showed superior performance in comparison to the matrix structure by sustaining protein release kinetics at least for 12 days in PBS. The results from in vitro cell cytotoxicity study revealed that the presented scaffold was biocompatible and non-toxic. Coaxial electrospinning was shown to be a versatile technique in achieving the delivery of biochemical signals in a controlled manner for the regeneration of cartilage. These 3D tablet-like PCL scaffolds incorporated with protein solutions are engineered systems that closely mimic the characteristics of cartilage tissue.

Enhancing angiogenesis is the prime target of current biomaterial-based wound healing strategies (1). However, these approaches largely overlook the angiogenic role of the cells of the nervous system. Therefore, we explored the role of a collagen-chondroitin sulfate scaffold functionalized with a pro-angiogenic gene stromal-derived factor-1 alpha (SDF-1α) – an SDF-1α gene-activated scaffold on the functional regulation of human Schwann cells (SCs). A preliminary 2D study was conducted by delivering plasmids encoding for the SDF-1α gene into a monolayer of SCs using polyethyleneimine-based nanoparticles. The delivery of the SDF-1α gene into the SCs enhanced the production of pro-angiogenic VEGF. Subsequently, we investigated the impact of SDF-1α gene-activated scaffold (3D) on the SCs for two weeks, using a gene-free scaffold as control. The transfection of the SCs within the gene-activated scaffold resulted in transient overexpression of SDF-1α transcripts and triggered the production of bioactive VEGF that enhanced endothelial angiogenesis. The overexpression of SDF-1α also caused a transient activation of the transcription factor c-Jun and supported the differentiation of SCs towards a repair phenotype. This was characterized by elevated expression of neurotrophin receptor p75NGFR. During this developmental stage, the SCs also performed an extensive remodelling of the basement matrix (fibronectin, collagen IV, and laminin) to enrich their environment with the pro-neurogenic matrix protein laminin, revealing an enhanced pro-neurogenic behaviour. Together, this study shows that SDF-1α gene-activated scaffold is a highly bioinstructive scaffold capable of enhancing pro-angiogenic regenerative response in human SCs for improved wound healing.

Craniofacial bone reconstruction is a clinical challenge due to the demand for fast bone induction, precise shape fidelity, and patients' specific customization. Extrusion-based 3D printing is a promising technique to create patients' specific implants for craniofacial bone reconstruction, however, the current bone tissue engineering scaffolds produced by this method lacks osteoinductivity and hydrophilicity that are crucial for bone reconstruction. In this study, different percentage of TCP was added to PCL for producing PCL/TCP composites. Then macroporous PCL and PCL/TCP composite scaffolds were prepared by an extrusion-based 3D printer. The printed PCL scaffolds were fixed in a customized mold with gelatin methacryloyl (GelMA) followed with UV crosslinking at 365 nm in order to achieve PCL/GelMA composite scaffolds. Physical and chemical characterizations, including gel permeation chromatography (GPC), compressive strength, contact angle, and X-ray diffraction (XRD), of these scaffolds were evaluated. Besides, PCL, PCL/TCP, and PCL/GelMA scaffolds were implanted in a critical-sized calvarial defect model of rats for up to eight months. In vivo characterizations contained degradation kinetics, micro-CT, histology, and immunochemistry. Results indicated that PCL/TCP and PCL/GelMA composite scaffolds showed comparable compressive strength (3-5 MPa) to human cancellous bone. The addition of GelMA filled the macroporosity (~500 um) of PCL scaffolds with microporosity (50-100 um), which enhanced the hydrophilicity of scaffolds. Meanwhile, PCL/TCP and PCL/GelMA composite scaffolds exhibited better craniofacial bone reconstruction after implantation in rats' calvarial defect model for eight months through histological and immunochemical analysis of H&E, Goldern's trichrome, collagen I, vWF stainings.

Various kinds of breast defects exist for which the reconstruction remains a challenge. Conventional reconstruction techniques are accompanied with risks and complications such as infection, rupture, capsular contracture, donor site morbidity and uncontrollable resorption rates. Therefore, a strong research focus is directed towards regenerative adipose tissue engineering.

In the present work, a novel strategy is introduced to enable minimally invasive, patient-specific breast reconstructions. To this end, shape memory copolymers based on aliphatic polyesters were synthesized and functionalized into acrylate end-capped urethane-based polymers (AUPs) to enable chemical crosslinking after 3D-printing. The materials were characterized by NMR, DSC, TGA, GPC and mechanical characterization was performed to study the tensile strength and shape memory effect. The materials were tuned in order to achieve a shape shift right below body temperature. This shift in shape from a temporary reduced size into a permanent large volume, upon implantation in the body, assures the minimally invasive approach of the developed strategy.

Throughout the project, the AUPs were processed into porous scaffolds by means of additive manufacturing. The morphology of the obtained scaffolds was studied using SEM and micro-CT. The results indicated that stable scaffolds can be realized, with pore sizes ranging between 500µm and 1000µm. These structures were further characterized by performing mechanical and biodegradability assays and, after applying a cell-interactive gelatin-based coating, the effect of shape memory on cell behavior is currently being investigated.

As a result, the developed porous shape memory scaffolds can be considered promising candidates towards minimally invasive, patient-specific adipose tissue engineering.

KIDNEY ORGANOID ENCAPSULATION IN SUPRAMOLECULAR HYDROGELS DIRECTS NEPHRON PROGENITOR LINEAGE COMMITMENT

Johnick van Sprangp[1], Patricia Dankers[1]

[1] *Eindhoven University of Technology*

Corresponding author's email: j.f.v.sprang@tue.nl

The differentiation of hiPSCs towards renal lineages allows for generation of tissue that highly resembles the mammalian kidney[1]. These hiPSC-derived tissues are known as kidney organoids and contain four renal progenitor cell populations, which develop into nephrons[2]. These kidney organoids hold translational promise as a regenerative therapy for patients suffering from renal failure[3]. However, their nephrons are not properly segmented, which may negatively impact their function[4]. The segmentation of nephrons is influenced by a proximal-distal gradient of Wnt- and Notch signaling, which determines the final identity of differentiating nephron progenitor cells[5]. These pathways are tuned by a wide array of cues, including mechanotransducive forces from the surrounding environment. Here, we take the first step towards investigating the role of biomaterials, and respective mechanical forces, on lineage commitment of nephron progenitor cells within organoids. To this end, kidney organoids were encapsulated in a fully synthetic hydrogel at different time points. These hydrogels are composed of UPy-based molecules, which are capable of self-assembling into a dynamic, fiber-like network via supramolecular interactions. Furthermore, by coupling integrin-binding peptides to UPy-moieties, it is possible to biofunctionalize the network to allow mechanotransduction. These properties together result in a fully synthetic hydrogel in which kidney organoids remain viable and show nephrogenesis. Furthermore, encapsulation of kidney organoids within UPy-hydrogels shifts the segmentation of nephrons towards the glomerular phenotype, irrespective of encapsulation timing. This demonstrates that the lineage commitment of nephron progenitor cells is susceptible to changes in the surrounding mechanical environment and may be directed in this fashion.

TANNIC ACID-MEDIATED E7/P15 PEPTIDE-FUNCTIONALIZED SCAFFOLD FOR ENDOGENOUS OSTEOCHONDRAL TISSUE REGENERATION

Wei Zhang[P][1]

[1] *Southeast University*

Corresponding author's email: zhang.wei@seu.edu.cn

A leading strategy in osteochondral tissue engineering is the development of cell-instructive scaffolds that provide biochemical cues to direct the recruitment of endogenous bone marrow mesenchymal stem cells (BMSCs), as well as to promote osteogenic and chondrogenic differentiation to stimulate osteochondral regeneration. In this study, we develop a novel peptide-functionalized alginate scaffold by prime-coating the scaffold with tannic acid (TA) followed by conjugation of E7 and P15 peptides. TA coating significantly enhanced the scaffold stability and mechanical properties, increased peptide conjugation rate and maintained the controlled release of peptides without affecting their bioactivity, in a concentration-dependent manner. Due to the conjugation of E7/P15 peptides, the modified alginate-TA scaffold showed satisfactory biocompatibility, significant improvement of BMSCs migration and deposition of cartilage and bone extracellular matrix (ECM) in vitro, as compared to the scaffold without peptide conjugation. The scaffold also simultaneously improved the regeneration of cartilage and subchondral bone when implanted into rabbit osteochondral defect. These findings thus suggest that the developed TA-mediated E7/P15 peptide-functionalized alginate scaffold has great potential to be utilized as a cell-instructive scaffold for osteochondral regeneration.

Decades of clinical experience indicate, that velocity and efficiency of wound healing and bone remodeling in alveolar bone is in part dependent on the exact localisation of the wound. In the maxilla, the upper jaw, these processes are generally faster and more efficient than in the mandible, the lower jaw. Alveolar bone differs in composition, with 23% bone marrow and 46% lamellar bone in the upper jaw, and 16% bone marrow and 63% lamellar bone in the lower jaw. The periodontal ligament (PDL) hosts endogenous stem cells, which were shown to differentiate towards osteoblasts and cementoblasts in 1976. Since 2004, specific PDL cells can be isolated from extracted third molars, demonstrating self-renewal and differentiation capacity towards several mesodermal cell fates and therefore being referred to as stem cells. Human mesenchymal stem cells (MSC) are beneficial for wound healing and tissue regeneration of mesodermal tissue. Periodontal ligament (PDL) cells can be isolated from third molars of the upper and lower jaw. Due to their stem cell like morphology and behavior, they can be compared with human MSC. PDL cells and in particular MSC have been extensively studied with respect to bone replacement strategies. The characterisation of PDL cells from the upper and lower jaw compared to MSC will identify similarities and differences in cellular composition and unravel molecular pathways involved in differentially regulated wound healing in mandible and maxilla.

A REVERSIBLY-SEALED THYROID-ON-CHIP FOR CONTINUOUS MONITORING OF THYROID DISRUPTION

Daniel Carvalho$_P$[1]

[1] *MERLN*

Corresponding author's email: d.carvalho@maastrichtuniversity.nl

There is growing evidence that various environmental factors, such as plasticizers and pollutants, are Endocrine Disrupting Chemicals (EDCs), which are also associated to thyroid malfunctioning in the human body1,2. Currently, the safety of potential EDCs is poorly estimated due to the lack of physiologically relevant toxicological assays for preclinical testing. New, innovative 3D cell culture systems are urgently needed to accurately evaluate thyroid disruption, which can offer both automation and reduced labor for pharmaceutical companies. Moreover, integration of sensing technology has shown promise in precise assessment of the metabolic and functional parameters secreted by cells in response to drug compounds3. Here, we describe the first thyroid-on-chip based on a 3D polymeric membrane for dynamic culture of mouse thyroid follicles4. Cells were Matrigel-embedded on the microstructured membranes containing arrays of 200 thin-walled porous microwells with 350 µm in diameter. Membranes were reversibly sealed between elastomeric gaskets via mechanical clamps and fully integrated with optic sensors for continuous in situ monitoring of culture parameters. The clamping seal was found to withstand internal pressures higher than those obtained by irreversible plasma bonding while enabling re-opening of the chip without damage and direct access to cell culture inserts for downstream immunostaining. The 3D cultured thyroid cells survived up to 7 days and retained an in vivo-like organification characterized by luminal expression of thyroglobulin. We believe that this system has shown how organ-on-chip, sensing and clamping technologies may be leveraged to create next-generation in vitro cell-based assays for EDC screening.

Chronic skin wounds (CSWs) are a worldwide healthcare problem, with a strong effect on patients' life and mortality risk, and an important impact on healthcare systems. Innovative treatments are thus needed to induce better tissue repair/regeneration and to improve patients' life quality. In this work, injectable thermosensitive hydrogels based on amphiphilic polyurethanes have been developed as drugs (e.g., ibuprofen) and biomolecules (e.g., platelet lysate) carriers in the treatment of CSWs.

Two poly(ether urethane)s (PEUs) were synthesized starting from commercial Poloxamer 407 [1], 1,6-diisocyanatehexane and different chain extenders (i.e., N-Boc serinol and L-lysine ethyl ester) PEUs aqueous solutions at appropriate concentrations (10-15% w/v) presented a sol-gel transition around 30-37°C after few minutes. The formulations showed finely tunable mechanical properties and residence time in aqueous environment modulated by PEU concentration, as assessed through rheological and stability tests. Injectability through medical needles and at different temperatures was also proved. The loading of model proteins (bovine serum albumin, BSA, and horseradish peroxidase, HRP) within the gels did not affect gelation and rheological properties. Payload release was completed between 7-14 days, depending on PEU concentration. Moreover, hydrogel ability to preserve the biological functionality of the encapsulated biomolecules was demonstrated by testing the HRP residual activity. Similar results were obtained regarding platelet lysate (PL) encapsulation and release.

The presented hydrogel formulations thus represent a promising tool for localized drug/biomolecule delivery in CSWs treatment, given their tunable gelation properties, residence time in aqueous environment and ability to encapsulate and release biomolecules with a sustained and controlled kinetics.

Hydrogels are biomaterials that recapitulate many of the extracellular matrix properties in tissue engineering applications. However, their use in bone regeneration is limited. Furthermore, most studies utilising hydrogels for bone tissue engineering applications are predominantly focused on osteoblasts and bone formation, while osteoclasts are often overlooked. Yet, the osteoclast role is pivotal for bone homeostasis and aberrant osteoclast activity also is involved in several pathological diseases such as cancer. Thus, we aim to develop customised hydrogels for use as substrates for osteoclast differentiation and culture. We present here new data on a composite hydrogel based on the self-assembling gelator peptides Fmoc diphenylalanine/serine (Fmoc-FF/S) and Fmoc-RGD, which has been modified by incorporation of hydroxyapatite nanopowder (HAp). This new hydrogel shows improved mechanical properties and supports osteoclast adhesion and differentiation. Atomic Force Microscopy and Rheological analysis of the HAp-decorated hydrogels showed a larger fibre network diameter and higher mechanical strength than HAp-free hydrogels, with a doubled storage modulus. Additionally, staining for F-Actin showed that the hydrogels supported cell adhesion and cell viability in vitro. Interestingly, HAp-decorated hydrogels were able to support osteoclastogenesis in vitro as Raw 264.7 cells showed typical morphology of mature osteoclasts such as presence of multinuclei and an actin ring. Moreover, the presence of TRAP-positive granules suggests the differentiation of Raw 264.7 cells into mature osteoclasts. These results suggest that the HAp-decorated hydrogels developed here could be the basis for building a more complex and realistic biomaterial for differentiation and culture of osteoclasts and ultimately improved bone regeneration.

Myocardial infarction, a common occurrence for European and North American population, can result in severe cardiac tissue damage that cannot be successfully compensated by current therapies and surgical methods. Thus, in recent years many studies have been focused on patches able to support the impaired tissue and induce regeneration through cardiac progenitor cell attachment, proliferation and differentiation using appropriate stimuli.

In this contribution, a library of poly(ester urethane)s (PUs) based on poly(ε-caprolactone), 1,6-diisocyanatohexane and aliphatic chain extenders with different chain length (i.e., 1,4-butanediol, 1,8-octanediol, 1,12-dodecandiol) has been developed and characterized. Size Exclusion Chromatography evidenced a number average molecular weight comprised between 30 and 40 kDa for all the synthesized PUs. The thermal and thermomechanical properties obtained through thermogravimetric analysis, Differential Scanning Calorimetry and rheological characterization demonstrated PU suitability to processing through common Fused Deposition Modeling (FDM) printers. This opens to the possibility to develop personalized patches that can be designed to finely reproduce the patient's specific defect. To improve the hydrophilicity of the construct surface, a plasma treatment using allylamine as monomer was optimized to expose –NH2 groups, resulting in a significant decrease in the contact angle values. The exposed amino groups on the surface were then exploited to graft proteins (e.g., laminin-1, collagen) and peptides (e.g., RGD) on the scaffolds to increase biomimicry and cell attachment [2]. Thus, these surface-modified materials show a good potential for employment in cardiac tissue engineering, with the aim to successfully stimulate tissue repair and promote myocardial regeneration toward a fully functional heart recovery.

The discovery of new drugs against breast cancer metastases is a primary goal for research and pharma industry; however, current in vitro and in vivo models oversimplify breast cancer cells (bCCs) interactions with the bone microenvironment or present species-specific differences in biological mechanisms, respectively [1]. To overcome these limitations, based on our previous work [2,3], we embedded up to five human cell types (i.e. osteoblasts, osteoclasts, endothelial cells, macrophages, bCCs) in a 3D fibrin gel model developing a highly complex vascularized metastatic immuno bone minitissue (MIBm). The MIBm closely mimics biological processes seen in vivo as the organ-specific proliferation of bCCs, with respect to other tissue that are not affected by breast cancer metastasis as muscle, and the bCC acquisition of osteomimicry properties. Moreover, the macrophages activation towards M2 phenotype, which are immunosuppressive favoring tumor growth, and the alteration of vascular structure suggest that our minitissue is able to reproduce some key features of the early metastatic niche. We treated MIBm and a bCC monoculture minitissue with rapamycin and doxorubicin, two FDA approved drugs. The dose required to impair bCC growth was significantly higher in MIBm than in the bCC monoculture minitissue, in addition both drugs had an anti-angiogenic effect. In this study [4], we showed that the drug effects were strictly dependent on the presence of the bone-tumor microenvironment and we could investigate drug influence on other cell components suggesting that the MIBm could better perform antimetastatic drug screening than more simplistic models.

The thermoresponsive poly (N-isopropylacrylamide) (PNIPAM) exhibits a lower critical solution temperature (LCST) at 32°C allowing cell detachment by simply decreasing temperature below LCST. Here, layer-by-layer technique has been used to develop thermoresponsive polyelectrolyte multilayer (PNIPAM-PEM) systems that shall be applied for fabrication of cell sheets. Chitosan is covalently grafted with PNIPAM (PNIPAM-CHI) to obtain different derivatization degrees and used as polycation. Heparin is used as polyanion. The degrees of substitution (DS) and thermoresponsive properties of PNIPAM grafted onto chitosan are analyzed by 1H NMR and dynamic light scattering. PNIPAM-CHI with different DS are obtained and higher DS showed significant change in size above LCST. The growth of PNIPAM-PEMs composed of PNIPAM-CHI and heparin fabricated at pH 4 are studied by surface plasmon resonance. PNIPAM-CHI with different DS represent similar linear growth behavior to form multilayers with heparin. Crosslinking of PNIPAM-PEM using EDC/NHS is conducted to enhance stability. The thickness of multilayers measured by ellipsometry show that non-crosslinked and crosslinked systems are not different. However, the thickness decreases significantly in non-crosslinked system after rinsing with phosphate buffer, pH 7.4 compared to negligible changes in the crosslinked multilayers. The applicability of PNIPAM-PEMs as cell culture substrate is examined using multipotent mouse stem cells. Higher cell adhesion on crosslinking system after 24 h cultivation is observed in agreement with the stable thickness and complete multilayer formation. Therefore, the PNIPAM-PEMs with cross-linking provides greater stability as a cell culture system for further investigation of cell sheet generation for application in tissue engineering.

ANGIOGENIC POTENTIAL OF SENESCENT MESENCHYMAL STROMAL CELLS

Andrey Ratushnyy[1], Mariia Ezdakova[1], Ludmila Buravkova[1]
[1] *Institute of Biomedical Problems, Russian Academy of Science*
Corresponding author's email: ratushkin@mail.ru

The mesenchymal stem/stromal cell (MSC) secretome influences the microenvironment upon injury, promoting cytoprotection, and tissue repair of the damaged area. These effects are of particular interest for the treatment of ischemic damaged tissues via angiogenesis promoting. MSC senescence results in secretome modulation (senescence associated secretory phenotype - SASP), which affects the neighboring cell functions.
MSCs were isolated from human adipose tissue. Long-term cultivation was continued until replicative senescence (19-28 passages). Senescence of MSCs was identified by assessing the activity of β-galactosidase, population doubling (PD) per passage, cell morphology etc. Conditioned medium (CM) was collected for further analysis, including chorioallantoic membrane assay in ovo, capillary-like tube formation on Matrigel, cell migration assay, analysis of MSC secreted proteins. Total RNA was extracted from MSCs for qPCR analysis.
Angiogenic potential of senescent MSC CM was attenuated which was characterized by decreased number of blood vessels in chorioallantoic membrane assay in ovo. In the same time long-term cultivation did not affect endothelium cell capillary-like network of tubule complexes on Matrigel and non-directed endothelium cell migration in vitro. Analysis of CM had shown increased concentration a number of cytokines (MCP-3, IL-4, IFN-a2, MDC, IP-10, FGF-2, RANTES, GRO, IL-8, IL-6, MCP-1) with pro- and antiangiogenic activity. PCR analysis revealed both down- and upregulation of some angiogenesis-associated genes.
Thus, modulations of MSC secretory phenotype under senescence result in decreased angiogenic activity in complex model in ovo, but not on Matrigel with endothelium cells only.
This study was supported by the RFBR (project no. 19-015-00150).

Myocardial infarction causes the irreversible loss of cardiomyocytes and the formation of a non-contractile fibrotic scar. Among advanced therapies for myocardial regeneration, in situ release of specific microRNAs (miRNAs) is under study to promote cardiomyocyte proliferation or transdifferentiation of cardiac fibroblasts (CFs) into induced cardiomyocytes (iCMs)[1,2]. Our group has demonstrated that a combination of miRNAs (miRcombo: miR-1, 133, 208, 499), previously identified on mouse model, can trigger direct reprogramming of human CFs into iCMs[2]. In this work, new lipoplexes based on a mixture of cationic and helper lipid were designed for more efficient encapsulation and release of miRNAs to human CFs respect to commercial agents, enhancing direct reprogramming efficiency. Lipoplexes encapsulating negmiR or miR-1 were initially prepared at 3.0 to 0.35 N:P ratios, showing 99% encapsulation efficiency, and average hydrodynamic size and zeta potential respectively ranging from 372 nm to 876 nm and from +40 mV to -26 mV with decreasing N:P ratio. Based on stability experiments in different media at different temperatures (4°C and 37°C), lipoplexes with 3 N:P ratio were selected for in vitro tests with human CFs, showing biocompatibility and efficient miR-1 release to CFs. Then, miRcombo-loaded lipoplexes were characterized for their physicochemical and biological properties, triggering enhanced cardiac markers expression at 15 days compared to commercial transfection agents. A shear-thinning alginate hydrogel is under development for intramyocardial injection and localized release of lipoplexes.

This project is supported by European Research Council (ERC) under European Union's Horizon 2020 research and innovation programme (grant agreement No 772168).

Introduction: In part due to the mismatch of micro-topographical structure and mechanical properties between native blood vessels and their synthetic counterparts, small calibre vascular scaffolds (SCVSs) smaller than ø 6mm have failed to achieve clinical implementation[1]. To overcome these issues, a mechanical profile of native blood vessels was developed through systematic literature review. The profile then guided the manufacture of a biomimetic and biodegradable blended Polycaprolactone and Polydioxanone electrospun SCVS.

Methods: SCVSs were continuously electrospun via a bespoke rotating wire collector[2], with different polymer and pyridine concentrations. From scanning electron microscopy images of the SCVSs micro-topographical characteristics were quantified with FIJI-DiameterJ. The SCVSs were mechanically and structurally profiled using uniaxial tensile testing, microCT, mercury porosimetry, and gravimetric analysis. To aid translation, biocompatibility was evaluated in line with ISO 10993-5:2009.

Results: Varying gross polymer and pyridine concentrations between 0.0925 – 0.193 g/ml and 0.1 – 5 PPM altered the micro-topography, porosity, shape, and mechanical properties of the SCVS. Between these concentrations, microfibre diameter and the Young's modulus ranged between 0.9 – 1.55 µm and 2.09 – 11.45 MPa versus 0.22 – 2.61 MPa for native blood vessels. Additionally, the SCVS had a porosity, pore diameter, lumen diameter and wall thickness of 70 – 85%, 4 ± 1 µm, 100 ± 25 µm, and 300 ± 100 µm respectively.

Conclusion: Successful translation of SCVSs relies on mechanical and micro-topographical mimeticism. For the first time, SCVSs were continuously electrospun and demonstrated to have microstructure and elasticity comparable to that of native blood vessels.

3D NANOGROOVED LIVING PLATFORMS FOR THE AUTONOMOUS DEVELOPMENT OF VASCULARISED BONE TISSUE CONSTRUCTS

Isabel Marinho Bjørgeᵖ[1], Clara R. Correia[1], João F. Mano[1]

[1] *Department of Chemistry, CICECO, University of Aveiro, Portugal*

The influence of surface topography on the differentiation ability of stromal cells has been established in 2D yet is lacking in tissue mimetic 3D-environments. We recently proposed nanogrooved microdiscs (topodiscs) for a bottom-up cell-mediated 3D fabrication, which remarkably resulted in osteogenic differentiation of adipose-derived stromal cells (ASCs) even in basal medium [1]. Inspired in the multiphenotypic environment of bone and taking advantage of the liquefied-core capsule technology [2], 3D-preaggregated topodiscs and ASCs were co-encapsulated with endothelial cells (ECs). Uniform ASC-topodisc microaggregates were encapsulated within an alginate core containing dispersed ECs, enveloped by a permselective membrane. Upon mild core liquefaction, a sequential seeding is established and ASCs and ECs are able to crosstalk directly. By combining topographical cues with cell signalling pathways, we aimed to develop prevascularised bone-like microtissues in an autonomous fashion. Results show that ASC-topodisc microaggregates proved to be optimal supports for EC adhesion, further promoted using bioreactors to create dynamic culture conditions. Successful biological activity was confirmed via increased DNA content and the merging of microaggregates into macro 3D constructs. At 21 days post-encapsulation with topodiscs, ASCs differentiated towards the osteogenic lineage in static and dynamic conditions for both mono and co-cultures as verified by the presence of hydroxyapatite and osteopontin, even without osteoinductive factors. This was not observed in monoculture conditions featuring spherical or non-grooved disc particles, highlighting topodiscs' nanogrooves as an impacting factor to induce osteogenesis. Next, we plan to assess the neo-vascularisation of the established co-culture, and the quality of the bone-like microtissue formed.

IN-SILICO MODELLING AS A TOOL TO RECAPITULATE THE NUTRIENT MICROENVIRONMENT OF THE INTERVERTEBRAL DISC FOR THE DEVELOPMENT OF CELL THERAPIES

Emily McDonnell[P][1]

[1] *Trinity College Dublin*

Corresponding author's email: mcdonne5@tcd.ie

The intervertebral disc is a large avascular structure with a microenvironment characterised by low nutrient concentrations and increased acidity.1,2 A number of in silico models have been developed to provide valuable insights into disc nutrient transport and metabolism.3 However, their reliability is limited by their experimental input parameters. To optimise physiologically relevant culturing conditions, this work developed computational models to predict the metabolite gradients that develop during in vitro and ex vivo organ culture and compared them to in vivo models' nutrient concentrations.

Finite element models governed by coupled reaction-diffusion equations were created using COMSOL Multiphysics. Metabolic rates were dependent on local oxygen and pH by employing equations derived previously.1,4 Results highlighted limitations in cell density parameters most typically used in predictive modelling.5 We also experimentally validated these predictive models within ex vivo disc cultures using microprobe measurements and biochemical assays. Furthermore, by incorporating a viability criterion, predicted pH and oxygen show better agreement with in vivo disc measurements.2,7

This highlights that more robust cell parameters are needed to improve the accuracy of in silico models and that in vitro and ex vivo culturing regimes need to be refined to more closely represent the typical nutrient microenvironments found in vivo.

Endochondral ossification (EO) is the process by which bones are formed, via a cartilage template. We previously demonstrated that chondrogenically-primed human mesenchymal stromal cells (hMSCs) implanted subcutaneously in mice generate bone via EO(1). To understand how best to control the process and ultimately develop strategies for bone repair, we investigated the kinetics of hMSC-mediated bone formation in vivo, which still remain elusive.

Bone marrow-derived hMSCs were cultured as pellets with the chondrogenic inducer Transforming Growth Factor(TGF)-β3 for 7 ("P7") or 21 days ("P21"), or without TGF-β3 for 7 days ("p7"), and implanted subcutaneously in BALB/c athymic mice (2 hMSC donors, 30 mice/donor). While p7 pellets were rapidly resorbed, P7 and P21 pellets were encapsulated by fibrous tissue (d3-d7), underwent mineralization (d14) and microvascular infiltration (d28), forming bone with marrow (d56-d84). Human-specific GAPDH staining proved that human cells persisted until d84. Micro-computed tomography demonstrated increased bone volume for P21 pellets (5-fold), while the bone density was comparable to P7 pellets. Flow cytometry analysis of P7 and P21 pellets indicated consistent presence of CD11b+Ly6G+CD115- neutrophils and CD11b+F4/80+ macrophages from d3 onwards. Characterization of macrophage subsets revealed donor-specific patterns in the expression of pro-inflammatory (CD86), tissue repair (CD206) and anti-inflammatory (CD163) markers.

We provide the first longitudinal analysis of hMSC-mediated EO in vivo. The amount/maturity of the implanted cartilage impacts bone formation, possibly due to differential involvement of innate immune cells, which are rapidly recruited and persist during bone formation. These data lay foundations for new "developmentally-inspired" tissue engineering approaches for bone defects.

THIOUREA-CATECHOL COUPLING CHEMISTRY ENABLING THE DEVELOPMENT AND FUNCTIONALIZATION OF CYTOCOMPATIBLE HYDROGEL ADHESIVES

Kongchang Wei[P][1]

[1] *Empa, Swiss Federal Laboratories for Materials Science and Technology, Laboratory for Biomimetic Membranes and Textiles*

Corresponding author's email: kongchang.wei@empa.ch

Inspired by marine mussels, polymers are typically functionalized with catechol moieties via nonreactive amides or ester linkages, thereafter, the formation of mussel-inspired hydrogels can be induced by in situ oxidation.[1,2] However, with nonreactive linkages, the catechol-functionalized polymers usually need a long cross-linking period (minutes) under basic conditions. Although using strong oxidants such as sodium periodate (NaIO4) could shorten the time, the harsh condition could limit their application in cell delivery.[3] Recent investigations on mussel adhesion have revealed that, besides catechol-rich Mfps, thiol-rich Mfp-6 also plays an important role in the remarkable adhesion of mussel.[4] In this contribution, I will present a dual-mode-mimicking strategy by modifying polymers with thiourea (TU) and catechol (Cat) functionalities to mimic two types of Mfps, namely cate-chol-rich Mfps and thiol-rich Mfps, respectively.[5-8] The TU-Cat coupling chemistry can be used not only for rapid polymer crosslinking, but also for effective fuctionalization of 2D substrates or 3D matrix. The reaction can be catalysized by anzymes under mild conditions in a pH-independent manner, thus showing great potential in novel biomaterials development and bioactivation.

Breast cancer metastasis affects primarily the bones, causing severe symptoms including pain and fractures, and high mortality rate. Unfortunately, the mechanisms and vulnerabilities of bone metastasis are still elusive, and the patients remain incurable. Taking inspiration from endochondral ossification, the natural process whereby bones are formed via a cartilage template, we aimed to develop a new strategy to generate bone constructs in vivo and in vitro for studying bone metastasis.

Bone marrow-derived human mesenchymal stromal cells were chondrogenically differentiated as pellets for 21 days to induce cartilage production, and implanted subcutaneously in athymic mice for 8 weeks. Micro-computed tomography and histological analysis demonstrated that the constructs underwent endochondral ossification forming vascularized bone with marrow. To generate in vitro constructs, chondrogenic pellets were exposed to osteogenic conditions (β-glycerophosphate), inducing cartilage mineralization. In transwell co-cultures, in vivo and in vitro-derived constructs enhanced the migration of human metastatic breast cancer cells (MDA-MB-231) (12-fold and 36-fold, respectively), but did not affect non-metatastic cells (MCF7). Preliminary experiments with exposure of MDA-MB-231 to conditioned medium from mineralized pellets showed enhanced cancer cell proliferation and migration.

We exploited a developmental tissue engineering approach to generate bone constructs for studying aspects of bone metastasis. In vivo- and in vitro-generated bone/mineralized constructs were successfully co-cultured with invasive breast cancer cells, inducing a migratory response. These experimental models will be applied for studying the molecular basis of metastasis and developing new targeted drugs.

Bone is a dynamic tissue that can elself renewal. In some case regarding critical size and pathophysiological state of the bone defect a bone substitute is required. Different biomaterials can be used as pristine injectable biomaterials, granules, dense or porous blocks combined with autologous bone or bioactive molecules. The 3D printing technology has attracted keen attention especially because of the boom of affordable 3D printers and the different advantages offered by this technic namely the customization of the external shape of a bone defect and the design of a suitable interconnectivity porosity for enhancing healing-performance. A 3D printable phosphocalcic cement-based formulation has been developed. Alpha tricalcium phosphate the precursor of the calcium deficient apatite cement was blended with a physical gel of hyaluronic acid. The rheological properties demonstrated specific properties required for a printable formulation: shear-thinning, self-healing, thixotropic, when compared to the pristine cement.

This formulation can be extruded with the pneumatic pression compatible with the marketed printers. The self-hardening of the formulation is compatible with the time of printing and avoide time-consuming steps such as debinding and sintering used for others 3D printing processes.

Mechanical characterizations have shown a higher deformation rate for the composite formulation compared to the pristine cement.

Biological evaluations have validated biocompatibility of the formulation, ability to promote cell adhesion and proliferation.

In vivo experiments are planned for assessing the healing-performance of the formulation.

Modelling the human cardiac pathophysiology in vitro represents a breakthrough to investigate key biological aspects of cardiovascular diseases progression. Organs-on-chip provide unprecedented opportunities to recreate tissue-specific microenvironments and to analyze functional readouts. Here we present uHeart, a beating heart-on-chip integrating i) uBeat technology[1], providing microtissues with mechanical stimulation resembling heart-beating and ii) micro-Electrode Channel Guide (µECG) technology, to extract electrophysiological signals on-line. We exploited uHeart to develop 3D in vitro cardiac models and we demonstrated its efficacy in screening drug cardiotoxicity.

Human induced pluripotent stem cell derived cardiomyocytes and dermal fibroblasts were embedded in fibrin gel in a 3:1 ratio[2] and mechanically trained through uBeat (i.e. 10%stretching, 1Hz). Microtissues' functionality and electrophysiological properties (i.e. beating period, spike amplitude-SA, field potential duration-FPD) were measured on-line by positioning electrodes through µECG and by performing gene expression analysis on ion-channels related genes. Finally, drug screening was conducted using three calibration drugs (i.e. Aspirin, Sotalol, Verapamil) and one vehicle (i.e. DMSO).

After 7 days in uHeart, cardiomyocytes exhibited sarcomeres' striations and beat spontaneously as a syncytium (frequency:0.59±0.12Hz, FPD:0.6±0.2s, SA:590±440µV). uBeat contributed to upregulate potassium channel related genes (i.e. h-ERG, IKs), responsible for the cardiac repolarization phase. uHeart efficiently captured the FPD alterations caused by compounds: DMSO and Aspirin did not alter the FPD, while Sotalol (15µM) and Verapamil (50nM) prolonged and shortened the repolarization phase, respectively, according to previous studies[3].

uHeart for the first time successfully combines mechanical stimulation of microtissues with on-line electrophysiology evaluation on-chip, offering a promising tool for pathophysiological studies.

The central nervous system has a limited auto-regenerative capacity, imposing challenges for the development of new therapies. Previous studies from our lab have demonstrated the applicability of human bone marrow mesenchymal stem cells (hBM-MSCs) secretome, as a modulator of the hippocampal neurogenic niche. Astrocytes are glial cells that control the neurogenic niche through the secretion of trophic factors and neuromodulators. Thus, in the present work, we aimed to evaluate the modulatory impact of astrocyte signaling on the hippocampal neurogenic niche upon application of hBM-MSCs secretome, centering our analysis on niche-specific proliferative events and morphological responses of astrocytes. Hence, we employed both wild-type and dnSNARE mice, a transgenic model that presents a blockage of astrocytic exocytosis and function impairment. Animals received bilateral injections of hBM-MSCs secretome at 8 weeks of age and hippocampal slices were evaluated with immunohistochemistry assays. Results demonstrated increased hippocampal proliferation marked by the number of Ki-67 expressing cells in wild-type animals when treated with secretome. Additionally, we observed that dnSNARE animals injected with hBM-MSCs secretome disclosed increased proliferation of GFAP stained cells at the sub-granular zone which is indicative of a local proliferative response of radial glia and early neural progenitors. Morphometrical evaluation found increased process hypertrophy and branching of dnSNARE astrocytes when treated with secretome. These results are closely related with the trophic factors present in the secretome, but also demonstrate a mechanistic involvement of astrocyte exocytosis in the proliferative response conferred by the secretome, placing astrocytes as key cellular targets for CNS regenerative medicine approaches.

Anterior Cruciate Ligament (ACL) repair using synthetic materials still result in less-than-adequate clinical outcomes and is characterised by high failure rate, owing to their inadequate mechanical and biological properties (1). Consequently, there is a need to produce better solutions. While polycaprolactone (PCL) electrospun materials have showed potential for soft tissue repair, they have not yet been produced into the form of a braided cord that can be produced at large scale.

PCL filaments used for braiding were produced with continuous electrospinning on a metal wire (2). The raw filaments were stretched 7-8 times the starting length, before being carefully assembled in a 9-filament bundles, which were used for braiding. The mechanical properties of the braided patch and individual filaments were measured by uniaxial tensile machine. Scaffold morphology was assessed via scanning electron microscopy (SEM).

The SEM images showed a biomimetic morphology of the aligned microfibres similar to the ACL microstructure. The braided PCL patch, produced with 9 filaments per carrier and using a total of 24 carriers (216 filaments overall) had tensile strengths comparable to market competitor FiberWire®.

We have shown that continuous electrospun filaments made of PCL could be braided by means of a commercial machine. This is a noteworthy improvement in the field of utilitarian bioresorbable clinical materials, specifically for applications in soft tissue repair.

Recombinant human bone morphogenetic protein (rhBMP-2) is an osteogenic morphogen used for orthopedic applications; clinical results, however, are modest. While studying gene transfer to deliver BMP-2, we have consistently noted superior bone healing in animal models with transient expression of small amounts of transgenic BMP-2. This suggests that endogenously synthesized BMP-2 is more potent than rhBMP-2 for osteogenesis. Here we have compared the response of cells to exogenous rhBMP-2 against BMP-2 synthesized endogenously following transduction with recombinant adenovirus encoding BMP-2 (Ad.BMP-2). This study used stably transfected murine mesenchymal cells containing a BMP-2 response element fused to a luciferase reporter gene (1). Cells were exposed to rhBMP-2 or transduced with Ad.BMP-2. BMP-2 activity was challenged with noggin and the BMP receptor kinase inhibitor LDN-212854. Luciferase activity and immunofluorescence staining were performed to determine the BMP-2 response. Intra- and extracellular hBMP-2 concentrations were measured by ELISA. Signaling via P-smad1/5/8 was assessed by western blot. Sub-nanogram amounts of BMP-2 synthesized by transduced cells induced higher luciferase activity than even a supraphysiological dose of rhBMP2 (1000 ng/mL). This superior potency was confirmed by immunofluorescence. Media conditioned by transduced cells did not induce luciferase in naïve cultures, suggesting that the response to endogenously synthesized BMP-2 occurred in an autocrine fashion. This response occurred via p-smad signaling, was resistant to inhibition by noggin but was inhibited by LDN-212854. The existence of a highly efficient autocrine BMP-2 signaling pathway helps explain the superiority of gene delivery over protein delivery as a means of stimulating osteogenesis in vivo.

Additive manufacturing techniques have become increasingly important for fabricating 3D tissue engineering architectures since their introduction to the biomaterials field at the turn of the millennium [1]. While the last two decades have seen remarkable advances in the application of 3D printed biomaterials [2], current fabrication methods are still limited by: (i) a relatively poor resolution, (minimum size of structural elements is typically 200-1000µm); (ii) poor versatility of materials (new materials typically need to be laboriously optimised for printing); (iii) an inability to create highly porous (>80% empty space) structures, necessary for many biological applications; (iv) limitations in structural complexity, particularly in generating interconnected pores facilitating anisotropic diffusion.

Here, we present a new method of fabrication in which we overcome each of these limitations for a wide range of materials including biodegradable polymers, resins, low-melt metal alloys, silicones, ceramics and hydrogels. Our strategy uses a novel templating approach inspired by the ancient metallurgical technique of 'lost-wax' or 'investment' casting which has been used for making complex sculptures for at least 6,000 years [3]. Our high degree of control over feature size and design complexity enables the create of scaffolds over a range of porosities (from 50% to 97%) which translates to compressive stiffness's of over three orders of magnitude (from 10 kPa to >10,000 kPa). This provides the technical platform for creating tissue engineering scaffolds relevant to a range of body tissues, from breast tissue to an array of cartilages.

Retinal degenerative disorders such as age-related macular degeneration (AMD) are a leading cause of vision loss worldwide (1). Medications can slow the progression of some forms of AMD, however, there are currently no treatments to halt or reverse their progression (2). In vitro retinal models present as a high-throughput and cost effective option for studying retinal disorders, however current lack of complexity inhibits their potential to translate outcomes clinically (3-5). A fibrous, acellular layer known as Bruch's membrane, supports the retinal pigment epithelium (RPE) and maintains separation of the retina from the underlying choroidal vasculature. Interactions between RPE and Bruch's membrane are critical in the pathogenesis of AMD.

Commonly used substrates for the culture of RPE cells in vitro, such as synthetic Transwell® membranes, fail to replicate the biomaterial properties of the native human Bruch's membrane (6). We describe here the fabrication and characterisation of ultrathin functionalised collagen membranes that more accurately mimic the native properties of Bruch's membrane. Here we present data elucidating material physical and biochemical properties. We also present material biocompatibility outcomes with the human RPE cell line, ARPE-19. Finally, we highlight the design and fabrication of a membrane perfusion system that allows for robust handling of ultrathin membrane cultures and provides media flow to mimic that of the choroid and retinal vasculature. Together with human pluripotent stem cell-derived RPE cells this system aims to accurately mimic the in vivo microenvironment of the RPE, Bruch's membrane and choroid to a give greater insight into AMD disease mechanisms.

Formation of building-tissue in a uniform manner within a matrix is a major challenge in tissue engineering. This problem arises for various reasons. Prevalently, the lack of nutrients at the core of scaffolds hinders the ability of stem cells to develop tissue homogeneously across the scaffold (1-2). For cartilage formation, the use of human adipose-derived stem cells (hADSCs) and their differentiation towards chondrogenic lineage by BMP-6 and TGFb-3 growth factors have been proposed (3). However, the precise amount and rate at which hADSCs consume and demand these growth factors within cell-laden scaffolds still largely unknown (2). To address this, we first performed a detailed investigation of the minimal amount, dosages, and single-factor dependence that hADSCs required to trigger differentiation. The elucidation of the minimal dosage then led us to investigate the fabrication of a chondroactive scaffold using gelatin methacryloyl (GelMa) functionalized with a thiol-modified-heparin to sequentially deliver BMP-6 and TGFβ-3. This strategy against the bolus integration and periodic exogenous dosage of growth factors was investigated by metabolic assays, mechanical compression, swelling ratio tests and photorheological measurements. The scaffolds with controlled sequential release triggered production of Collagen type I and type II across the scaffold. In contrast in the exogeneous delivery group, mostly peripheral matrix accumulation was observed. Orchestrating the delivery by controlling growth factors rate resulted in higher matrix accumulation when compared to the growth factors alone within the scaffold. These results introduce a step forward in the creation of self-chondrogenic constructs for cartilage repair.

DiGeorge Syndrome is a disorder caused by microdeletions in chromosome 22q11.2, and causes symptoms such as congenital heart defects, poor immune system, and/or hypoparathyroidism. The mechanisms behind the developmental defects that shape its phenotype are still largely unknown. One of the biggest hurdles is that, despite the consistent size of the deletion, the symptoms of the syndrome are widely variable and the expression and penetrance of the symptoms show a high level of heterogeneity between patients (1). For these reasons, cells obtained from a high number of unrelated patients are required to study the development of DiGeorge Syndrome in a meaningful way. This disorder affects the development of pharyngeal arches during early embryogenesis, therefore stem cells or progenitors derived from patients would be the ideal cell resource for examining the flaws in the developmental programs of various affected lineages (2, 3). However, the use of primary stem cells is ethically and practically complicated. Induced pluripotent stem cells offer a solution since they can be generated from differentiated, readily available cells, such as fibroblasts (4, 5).
We here report the episomal vector-mediated reprogramming of three commercially available fibroblast lines derived from DiGeorge Syndrome patients to iPSCs. These cells were characterized based on their expression of established pluripotency markers and their ability to differentiate into derivatives of all three germ layers in vitro. After more extensive characterization, these cell lines can be applied to study the development of DiGeorge Syndrome in vitro, paving the way towards the development of new therapies.

Fabrication of bioartificial islets in the form of pancreatic spheroids (spherical multicellular aggregates) with further transplantation is one of the emerging and highly promising regenerative medicine approaches for diabetes treatment. However, its more active development and application are hampered by the lack of vascular structure inside spheroids. The latter leads to a high percentage of posttransplantation apoptosis due to hypoxia in the core of spheroids and limits the transplantable spheroid size to approximately 100 μm.

The later research shows that apart from the vascular network, the presence of neurons during embryonic development is essential for the formation of the correct architecture of pancreatic islets and their postpartum function. Moreover, some research shows that vascular and neuron cells tend to promote the formation of their networks mutually. Thus, in our work, we investigate the possibility to facilitate vascular network formation by using co-culture of three types of cells: pancreatic beta-cells, vascular endothelial and neuron stem cells. As the process of network formation takes several weeks, we used polydimethylsiloxane microwell array device for spheroid fabrication, which allows decreasing hypoxia in the spheroid core and thus enables long-term culture. Our preliminary results showed the formation of neuron network and elongation of vascular cells. Although more optimization is needed to perfect this approach, we believe that it would be valuable for the investigation of neuron and vascular cells interactions inside pancreatic islets and their influence on islet functioning.

[2] *KU Leuven*

Corresponding author's email: fernanda.godoi@tessenderlo.com

This study correlates the thixotropic behaviour of gelatin methacryloyl (GelMA) with its printing parameters in extrusion printing. GelMA provided by Claro (BGI800) was compared with a conventional GelMA. The experiments were conducted without photoinitiators and constant GelMA concentration (10%w/w) using an Inkredible+ printer at 21 ± 1°C. Parameters like expansion degree, broadening degree and filament spreading were determined for one-dimensional printing. The aspect ratio of 3D printed lattices was calculated by the ratio between printed areas and designed areas (Pr). The thixotropic behaviour was evaluated by a three-interval oscillatory-rotational-oscillatory (ORO) which simulates, respectively: (1) “in the cartridge” condition, (2) flow during printing at 1000s-1 (30 seconds) and (3) recovery of the filament after extrusion. Our study revealed that stable and continuous printing behaviour is achieved by conducting the experiments slightly above the gelation temperature (Tgel) of GelMA. Thus, BGI800 with Tgel = 20°C demonstrated an advantage over the conventional GelMA with a Tgel = 24°C. The lower storage modulus (G’) at rest (ORO test) is associated with lower printing pressures (45-70kPa for BGI800 against 200-304kPa for conventional GelMA). Fast recovery after shear can be assigned to shape-fidelity, however, the extremely fast recovery observed for conventional GelMA at 21°C led to the formation of a brittle gel (high G’), resulting in low Pr and a high expansion degree. Our findings demonstrate that thixotropy is effectively correlated with printing parameters. This approach is a powerful tool to objectively benchmark and to compare bioinks, and aids in the design of improved printing behaviour.

Inflammation after injury influence the repair effect of tendon. However, its exact roles and inherent mechanism in tenogenic differentiation of tendon stem cells are unknown. This study evaluated the regulation effect on tenogenic differentiation of two main inflammatory cytokines interleukin-1β (IL-1β) and tumor necrosis factor-α (TNF-α). It is found that both IL-1β and TNF-α inhibited tenogenic differentiation by decreasing the expression of tendon markers and increasing the expression of MMPs. NF-κB pathway was found to be involved during this process. Treatment by TPCA-1, one inhibitor of NF-κB pathway, rescued the inflammatory cytokines destroyed tenogenic differentiation potential of tendon stem cells. Furthermore, sustained release of TPCA-1 from silk scaffold promoted the tendon repair and regeneration. These results collectively show the roles and mechanism of inflammation in tenogenic differentiation. It is feasible to improve tendon repair and regeneration by modulating the inflammation related pathways such as NF-κB pathway.

Extracorporeal membrane oxygenation (ECMO) is the gold standard for treating respiratory failure, as a bridge to lung transplantation. However, ECMO devices have several issues (max usage to 4 weeks). Thrombus formation is a cause of failure, which limits gas-transport and is associated to device haemodynamics. Endothelialisation of the hollow-fibres (HF) membrane offers a potential solution to thrombogenicity. However, inhomogeneous haemodynamics would subject the seeded endothelial cells (ECs) to variable and potentially damaging blood wall shear stress (WSS).

CFD models of a paediatric (MiniLung) and an experimental (RAT) oxygenator were developed to mimic flows up to 0.8 l/min with blood, DMEM (for EC seeding) and water (for CFD validation). CFD models predicted pO2, O2 saturation, velocity and WSS under different HF configurations on the outer HF walls.

The presence of inhomogeneous WSS on the HF oxygenators was observed among the three fluids in both models. The blood-based models predicted higher WSS compared to the DMEM- and water-based models. Lower blood velocity was associated with low WSS (<0.1 Pa) and areas of recirculating flow. A higher incidence of thrombus formation and clotting is expected to occur in such regions. The results suggested that O2 diffusion resistance across the HF wall and fibers configuration played a role in O2 transport efficiency and WSS distribution.

The CFD models predicted regions of variable WSS, including stagnant and recirculating flow regions, suggesting increased flow-induced blood damage and clotting formation. The predictions highlighted the need for design optimisation in order to minimising thrombus formation allowing efficient endothelialisation.

Induced pluripotent stem cell (iPSC)-derived chondrocytes are currently the only cells that match the ability of primary articular chondrocytes to form cartilage in vitro without succumbing to hypertrophic degeneration. However, in vitro differentiation of iPSCs first into mesoderm and then into chondrocytes is currently insufficiently stringent and cell selection procedures are applied to dispose of misdifferentiated cells, thus causing high cell loss and low tissue yield. During embryonic development a WNT/β-catenin pulse initiates mesoderm commitment. We here hypothesized that an initial WNT/β-catenin pulse could enhance mesoderm commitment of iPSCs and thereby overcome limited cartilage yield.

In two human iPSC lines a short initial WNT/β-catenin pulse with CHIR99021 enhanced mesodermal marker expression, supported exit from pluripotency and inhibited ectodermal misdifferentiation, thus indicating enhanced mesodermal commitment. Importantly, the initial CHIR pulse increased expression of multiple extracellular matrix (ECM)-related genes, adjusted adhesion-related gene expression (CDH3 up, CDH6 down), and yielded more matrix-interacting progenitors with high aggregation capacity. Subsequently, the majority of CHIR-induced cells contributed to chondrogenic pellet formation, thus increasing cell yield after eight weeks 200-fold compared to controls. Moreover, an enlarged collagen-II and proteoglycan-positive area in the CHIR group indicated an increased number of cartilage-forming cells.

Consequently, short initial WNT-activation acted via improved mesoderm commitment, ECM expression and cell aggregation and made cell selection steps before chondrogenesis obsolete. This robust and efficient iPSC differentiation into high-quality mesodermal progenitors rescued low cartilage yield during subsequent chondrogenesis, which is a major step towards iPSC application in clinical cartilage regeneration, disease modelling and drug screening.

Introduction

YAP/TAZ, a transcriptional co-activator, has been shown to play an important role in mechanosensing, although the mechanism is unelucidated [1].

Here, we explore the effect of cell dimension on YAP/TAZ nuclear translocation, by extending the 1D mechanosensing model in [2] to 2D and 3D reaction-diffusion equivalents, which we implemented in VCell [3].

Methods

Parameter values and diffusion coefficients are according to [2,4] and the Stokes-Einstein equation [5] respectively. Model predictions were tested on 2D square cells (44.6µm x 44.6µm) and 3D cuboidal cells (15µm x 15µm x 26µm). The FAK activation occurred in a ring close to the cell membrane in 2D, or one side of the cube in 3D.

Results

For similar FAK activation areas and FAK to nucleus perpendicular distances, the temporal evolution of the concentration of molecules was faster in 2D than in 3D. The peak concentrations were attained more gradually in 3D, with active RhoA having a higher peak concentration in 3D. The YAP/TAZ nuclear fraction was higher in 3D than in 2D.

Discussion

Our preliminary results reveal that the difference in YAP/TAZ nuclear translocation in 2D compared to 3D are opposite to the experimental results of Caliari et al. [6]. Future work will focus on extensively investigating the effect of cell size and shape in 2D and 3D to further understand YAP/TAZ nuclear translocation.

The main clinical indicators of osteoarthritis (OA) include loss of articular cartilage, altered subchondral bone remodeling/vascularization, and inflammation. Given the complexity of OA, multi-cellular and complex human in vitro models are needed to tackle different aspects of the pathology. We developed an engineered vascularized bone (VB) tissue using a mesenchymal stromal cell line (MSOD) and HUVEC within photocrosslinkable gelatin methacrylate as 3D matrix. After verifying MSOD osteogenesis and HUVEC tubulogenesis during an initial culture phase of 2 weeks, we challenged our model with an inflammatory cocktail (IL-6, IL-1β and TNFα) for an additional week, to assess whether OA features could be recapitulated. Inflammation caused demineralization and increased ALP activity, especially in the presence of HUVEC, confirming the role of vasculature in the development of OA. RT-PCR analyses demonstrated an increased VEGF and decreased Wnt5a expression in the MSOD-HUVEC group compared to MSOD control. We also found higher TGFβ-1 in HUVECs upon inflammation (TGFβ-1 is an autocrine proangiogenic signal in response to inflammation). An additional OA feature we were able to model was the abnormal collagen type 1 (Col1) production, showing increased Col1α1/Col1α2 chain ratio in MSOD-HUVEC in the presence of inflammation, which might explain demineralization due to limited capacity of this form of collagen of retaining hydroxyapatite crystals. After verifying the generation of such OA phenotypes, we will integrate VB with a cartilage layer within a microfluidics platform and trigger OA by inflammatory and mechanical stimulation, to identify molecular pathways that can be targeted to reverse the disease.

The cornea is the clear window that lets light into the eye. The inner surface of the cornea is lined by corneal endothelial cells (CECs) that function as an active metabolic pump to maintain the transparency of this avascular tissue. Corneal disease is one of the leading causes of blindness and visual disability, affecting over 15 million people worldwide. In developed countries, corneal endothelial disease is responsible for most corneal opacities. State of the art therapy involves selective replacement of the corneal endothelium with that of a donor. However, only one donor cornea is available for every seventy patients in need.

Endothelial cell transplantation could reduce the dependence on cadaveric donor tissue. In this project, we aim to produce CECs for transplantation and engineer corneal endothelial grafts in order to effectively transplant the CECs.

Human artificial corneal endothelial grafts were developed by culturing primary human CECs on biomimetic material electrospun meshes. The grafts achieved a high CEC density (the primary quality criterion for regular donor corneas) while maintaining the transparency of the construct. Moreover, the grafts showed the characteristic endothelial cell makers: zona occludens-1 (ZO-1), and CD166. The detection of Na+/K+ ATPase suggested proper cellular pump function was intact in the construct.

Overall, we have successfully developed biomimetic electrospun meshes with biological properties that supported the culture and phenotype maintenance of primary human CECs. The resulting artificial corneal endothelial construct offers potential utility for development of implantable tissue-engineered cell-carrier corneal endothelial constructs.

The preclinical testing process for novel therapies for damaged and diseased bone usually consists of in vitro cell experiments followed by in vivo animal studies. The correlation between the outcomes of these in vitro and in vivo studies is poor, which hampers translation into clinical practice [1]. Ex vivo explant cultures could provide a closer representation of the in vivo situation because they maintain all bone cells in their native 3D environment. The aim of this research is to establish an ex vivo culture platform to study bone remodelling. The platform is based on an explant culture model for cartilage defects [2,3].

Osteochondral cores were isolated from porcine femoral condyles and cultured for 6 weeks. Cell metabolic activity was monitored, and histological analysis was performed. Osteoclast activity was measured with TRAP assay and µCT was performed weekly to quantify changes in the amount of mineralized tissue to acquire insight into bone remodelling over time.

Cell metabolic activity was preserved for the tested culture period and cell nuclei were still present in marrow tissue as well as in trabeculae after culture. TRAP activity in the medium indicated the presence of active osteoclasts over the first 9 days only, whereas µCT imaging demonstrated an increase in mineralized volume (9.1 ± 1.4%) and surface (4.2 ± 2.4%) after 6 weeks of culture.

The ability to preserve cell viability and the opportunity to monitor bone formation and -if present- resorption shows a first step towards development of a testing platform to study bone remodelling.

Objective: Despite decades of research, no specific pharmacological therapy to treat acute lung injury (ALI) has been identified. Mesenchymal stem cells (MSCs) are one attractive therapeutic approach. In this study, we aim to investigate the effects of human fetal lung mesenchymal stem cells (hFL-MSCs) in an animal model of bleomycin-induced ALI and fibrosis.

Methods: hFL-MSCs were isolated from lung tissues derived from spontaneously aborted fetuses at 16 and 18 weeks of gestation. After characterization of MSCs, the model animals received intratracheal hFL-MSCs after bleomycin instillation. To assess the effect of cell therapy, all experimental groups were analyzed for cell count and level of cytokines in bronchoalveolar lavage fluid (BALF) at days 3, 7, 14, and 28 post-cell administration. After lung tissue harvest, all tissue changes were evaluated by immunostaining and wet/dry weight ratio and followed by an examination of expression of inflammatory and anti-inflammatory genes.

Results: FL-MSCs highly expressed CD105, CD90 and CD73, did not revealed expression of CD45, CD34 and HLA-DR and showed the capacity for trilineage differentiation. Histopathological analyses in hFL-MSCs therapy groups showed a decrease in infiltration of inflammatory cells and wet/dry weight ratio in lung tissues in compared to untreated group. Also, ELISA test was demonstrated the decrease in TNF-? and IL-6 in BALF. The levels of fibrosis at each time point were significantly reduced by hFL-MSCs treatment.

Conclusion: These data revealed a decrease in inflammatory cytokines and progression of fibrosis following hFL-MSCs administration.

Primary and acquired therapy resistance of solid tumors are major problems in clinical oncology including different mechanisms such as decreased drug influx and/or increased drug efflux. To study and understand variability of such effects novel drug-screening models are required. Of particular interest are primary patient-derived tumor-organoids recapitulating in vivo tumor-biology, since they represent the interaction of cellular and extracellular environments. Of note, expression of genes encoding to enzymes involved in adsorption, metabolism and excretion of drugs are preserved in such culture systems. Here, we describe non-invasive imaging procedures (i.e. Raman-microscopy, Fluorescence Lifetime Imaging Microscopy (FLIM)) allowing label-free and real-time cellular analysis and monitoring effects of drug-treatment. A biobank of colorectal cancer (CRC) organoids was established from surgical specimens and cultivated in Matrigel. Cellular response of organoids upon drug-treatment was analyzed in real-time by Raman-microscopy after applying CRC relevant cytotoxic agents. Spectral fingerprints can be used to identify and image chemical compositions in living biological specimens. To assess information about metabolic activity FLIM was used to monitor the local fluorophore environment of NADH and FAD. Through multivariate data analysis Raman-spectra of treated and non-treated tumor-organoids were compared showing the effects of drugs on e.g. nuclei, cytoplasm and mitochondria by shifts of specific molecular vibrations.Overall, Raman-imaging is an enabling technology to evaluate tumor-drug interactions in a non-invasive manner, with the possibility to screen for patient-individualized effectivity optimizing drug-treatment.Supported by the Deutsche Forschungsgemeinschaft (DFG, German Research Foundation) under Germany's Excellence Strategy - EXC 2180-390900677 and the Robert Bosch Stiftung, Stuttgart, Germany.

Metastases are the main cause of death of pancreatic ductal adenocarcinoma (PDAC) patients and often occur at early stages of PDAC development. In cancer biology, metastasizing is one of the most poorly studied phenomena. Recently, the attention of researchers was attracted by PDX1, the key regulator of the pancreas development, as possible factor involving in suppression of spreading cancer cells. This work is devoted to the study of the role of the PDX1 gene in the progression of PDAC.

PDX1 expression is absent in 6 model PDAC cell lines. To study the effect of PDX1 overexpression on the malignant potential of pancreatic cancer cells, we transduced PANC-1 and Colo357 cells by PDX1-carrying lentivirus. It was shown that PDX1-positive PANC-1 and Colo357 cells possess increased growth rate of 1.7 ($p < 0.01$) and 1.6 times ($p < 0.05$), respectively. Migration through Transwell and the rate of wound healing in PANC-1 and Colo357 cells expressing PDX1 were reduced by 50% compared to control cells ($p < 0.01$). Collagen I and Fibronectin adhesion assay was shown increased adhesion rate PDX1-positive PANC-1 and Colo357 cells relative control cells up to 2 fold. Analysis of motility related genes expression revealed changes in genes of regulators epithelial-to-mesenchymal transition, extracellular matrix proteins, cell-to-cell contacts and growth factors. Our results may indicate that expression of the PDX1 gene inhibits metastatic potential of pancreatic cancer cells via increasing of cell adhesion.

The study was supported by the Russian Science Foundation (project no.14-50-00131).

Tissue engineering strategies provide a promising approach for replacing diseased and damaged tissues in patients. Monitoring mechanical properties of engineered grafts during culture and characterising them prior to implantation into patients is important for defining their ultimate quality and performance. However, most traditional mechanical testing approaches are non-sterile and destructive. We present here a novel technique which utilizes new approaches for using Optical Coherence Tomography (OCT) for non-invasive online monitoring mechanical properties of engineered tissues. We first validated this technique using acellular tissue phantoms. 1%, 2% and 3% agarose gels were fabricated and imaged using OCT. The Young's modulus of the sample was computed by novel algorithms identifying key parameters in the OCT images. The computed Young's moduli correlated well with those obtained by traditional mechanical testing approach. Next, we validated it using engineered bone tissues. Mesenchymal stem cells (MSCs) were pelleted and cultured in an osteogenic differentiation medium for 3 weeks. Samples were continuously monitored in a contactless and sterile manner on day 3, 10 and 21, and meanwhile some samples were harvested for mechanical testing on the same time points. The Young's modulus of the cell pellet was computed using MECHASCAN. As tissues matured in culture, MECHASCAN analysis showed a significant increase in the computed Young's moduli, correlating with the increase in those values obtained by traditional mechanical testing approach. In conclusion, we demonstrated here a new OCT based platform for sterile online monitoring of mechanical properties of tissue engineered grafts.

INTRODUCTION: After myocardial infarction, restoration of local perfusion of the damaged myocardium is essential. Perfusion depends on a branched vascular network which aids tissue repair while also suppressing extensive fibrosis. Vascular network formation is enhanced by extracellular matrix (ECM). Preliminary evidence showed that myocardial-derived ECM hydrogels supported pericyte-driven vascularization by microvascular endothelial cells (HPMEC) [1]. In the current study, we assessed the conditions (seeding density, culture time, type of endothelial cells (EC)) and the mechanism that drives pericyte-free vascularization of myocardial hydrogels.

METHODS: Left ventricles (LV) of porcine hearts were decellularized, freeze-dried and pepsin-digested to prepare pre-gels. Pre-gels were mixed with microvascular ECs (HPMEC) or macrovascular EC (HUVEC) in different cell densities (9^5 to 10^3 EC/ml). Cultures were monitored for >30 days and network formation assessed by fluorescent 2D and 3D microscopy.

RESULTS: The LV ECM hydrogel supported vascular network formation of microvascular endothelial cells in 3D. The seeding density of 10^3 EC/ml was optimal, network formation started at day 2 and was stable for more than 30 days. Also, the ECM hydrogels supported vascular network formation of macrovascular endothelial cells with pericytes in 3D, in a ratio 1:1 (in total 10^3 EC/ml).

DISCUSSION & CONCLUSIONS: Left ventricular porcine ECM hydrogels support vascular network formation by microvascular and macrovascular ECs in 3D. This work can lead to the development of a tissue-engineered implant to stimulate neovascularization and tissue regeneration.

FROM THE LAB INTO THE CLINIC: ELECTROSPINNING OF MEDICAL DEVICES

Mehri Behbehani$_P$[1], Matei Cirstea[1], Ann Kramer[1], Rob McKean[1]

[1] *The Electrospinning Company*

Corresponding author's email: mehri.behbehani@electrospinning.co.uk

Electrospinning has received an ever-increasing amount of attention academically, as judged by the rise in the number of publications over the last three decades. It has been established as a fast and versatile fabrication technique for fibrous materials for use in implantable biomedical devices. Nevertheless, there is significant discrepancy between the academic effort undertaken so far and the relatively low number of approved medical devices utilising electrospun materials. The question therefore remains why this scientific knowledge can rarely be translated into the clinic.

Over the years, The Electrospinning Company has developed to a centre of excellence in biomedical electrospinning and we have a thorough understanding on how to achieve biomaterial characteristics such as mechanical strength, resorption time and architecture, suitable for specific therapeutic indications and target tissues. Having worked with many academic research groups as well as industrial clients, we have seen the challenges involved in moving scientific research to the market. We currently fabricate biomaterials that are used as part of an FDA-approved orthopaedic medical device, and others that are being evaluated in clinical trials in different indications and regions.

In this presentation we will provide an overview of the status of electrospun biomaterials on, or close to, market and share the challenges associated with taking promising electrospinning research out of the lab and into the clinic. We will further focus on how we approach device design and manufacture in order to maximise the chances of clinical and commercial success, and will illustrate this with a case study.

There is no mechanically competent, biologically functional treatment for end-stage cartilage degeneration. In this study, we hypothesise that the fabrication of well-organized microfibre reinforcing scaffolds[1] with locally, covalently immobilised TGFβ1 could support and guide the formation of new cartilaginous tissue. To create a complex mechanical structure with the necessary biomedical cues[2], we combined melt electrowriting (MEW) and atmospheric-pressure plasma (APP) to produce well-organized microfibre scaffolds with selectively, covalently-immobilized TGFβ1.

Poly-e-caprolactone MEW scaffolds were fabricated using a 3DDiscovery (RegenHU), then functionalised using a computer-controlled APP device, generating a controlled functionalisation pattern. TGFβ1 was then immobilized onto the MEW scaffold and covalent attachment was validated using FTIR spectroscopy and immunofluorescence detection. In vitro experiments were performed by seeding equine MSCs into MEW scaffolds and were cultured for 28 days. Neo-cartilage formation was quantified for glycosaminoglycan (GAG) production and confirmed with histological analysis.

Covalent immobilisation of TGFβ1 was achieved using the APP-functionalisation approach. FTIR confirmed a protein signature on the samples following intensive washing and immunofluorescently-labelled TGFβ1 was detected on microfibre scaffolds. In vitro analysis demonstrated that GAG production was significantly enhanced in both the immobilised TGFβ1, and TGFβ1 in medium groups, compared to the control groups. This finding was further validated by the heightened production of GAGs and collagen type II, observed in histological sections.

We have demonstrated that APP-facilitated covalent immobilisation of TGFβ1 retains the growth factor's bioactivity and stimulates the differentiation of MSCs into the chondrogenic lineage. Our results also demonstrate that constructs with locally-immobilised TGFβ1 support neo-cartilage formation.

ENGINEERING CHONDROCYTE GEOMETRY FOR CONTROLLING CHONDROCYTE CYTOSKELETAL STIFFNESS

Marita Voelker$_P$[1], Jasmin C. Lauer[1,2], Mischa Selig[1,2], Bernd Rolauffs[1]

[1] G.E.R.N. Research Center for Tissue Replacement, Regeneration & Neogenesis, Dept. of Orthopedics and Trauma Surgery; Albert-Ludwigs-University of Freiburg, Hugstetter Straße 55, 79106 Freiburg, Germany

[2] Faculty of Biology, University of Freiburg, Schaenzlestrasse 1, D-79104 Freiburg, Germany

Corresponding author's email: berndrolauffs@googlemail.com

INTRODUCTION: The cytoskeleton and its stiffness are important for mechanotransduction, which integrates forces into molecular reactions. Osteoarthritis (OA) has been linked to changes in chondrocyte (CH) morphology and stiffness. We asked (i) whether OA CH stiffness can be controlled via engineering CH shape, and (ii) which geometric aspects of shape are effective in doing so.METHODS: Micro-printed fibronectin adhesion sites (MPs) shaped as H vs. circles and control areas were used for culturing human OA CHs overnight. Using live cell imaging with nano-indentation, CHs were indented above their nucleus (Chiaro Nanoindenter, OPTICS11; AxioObserver-Z1, Zeiss). The displacement was 10.000nm, the tip radius was 3µm, its ¬stiffness was 0.055N/m. Partial-least-squares regression (PLS) was used for finding fundamental relations between CH stiffness and shape. RESULTS: The CH Young's Modulus on controls was 869.58±62.77Pa (average±SE). Circular MPs led to a lower CH stiffness (small circles: 568.29±55.17Pa; large: 498.18±55.62Pa; ρ<0.05). The CH stiffness on small/large H-shaped MPs was in between values on control or H-shaped MPs (small H-shaped MPs: 807.99±78.42Pa; large: 675.79±54.43Pa; ρ>0.05). Geometrical aspects of CH shape such as area, major axis, aspect ratio, roundness, and solidity but not minor axis or circularity correlated with CH stiffness (ρ<0.05). Using PLS loadings for calculating the relative impact of shape on stiffness suggested that roundness (0.50), aspect ratio (0.50), and major axis length (0.35) were more associated with stiffness than area (0.32) and solidity (0.26).CONCLUSION: CH stiffness can be modulated by engineering cell shape. However, not all geometric aspects have equal effects on CH stiffness.

[1] *University of Aveiro*

Corresponding author's email: aderito.amaral@ua.pt

Three-dimensional (3D) bioprinting has contributed significantly to advance engineered hydrogel platforms for tissue engineering and in vitro modelling [1]. Bioprinting technologies stand as ex vivo tools capable to create complex and spatiotemporally controlled tissue-like architectures using the appropriate living cells and biomaterials with tuneable physicochemical and mechanical properties. Of particular interest are marine-derived polysaccharides, which have received increasing attention owing to their abundance, reduced extraction cost, unique chemical and biological properties [2, 3]. This work focuses on the development of a novel dynamic bioink comprising boronic acid-functionalised laminarin and alginate for extrusion-based bioprinting of cell-laden gels through a double crosslinking approach that integrates covalent boronate esters formation and ionic interactions. The resultant hydrogel bioinks exhibit suitable printability and allowed for the fabrication of stable double network constructs with excellent tailorable rheologic properties, homogeneous cell distribution, and high cell viability for prolonged time periods in culture.
This simple and versatile platform is foreseen to accelerate the design of multifunctional 3D structures that will find uses in tissue engineering, delivery systems and in vitro disease modelling applications.

Glioblastoma is one of the most common and invasive primary brain cancers. Novel therapies are being investigated, but the research remains hindered by the limited reliability of currently employed preclinical models, which cannot mimic the complexity of tumor microenvironment. 2D cell cultures are effective but do not provide a reliable mimetic of extracellular matrix (ECM), which is a critical component in models for drug screening and cell biology studies.[1] ECM is a complex three-dimensional network representing the non-cellular part of tissues. The ECM composition differs between tissues and is involved in the maintenance of homeostasis and cell differentiation during tissue morphogenesis. Among the different ECM actors, the role of the glyco-microenvironment in the progression of glioblastoma is still poorly investigated due to the complexity and the dynamism of glyco-code. However, it is well known how glioblastoma shows a differential gradient of hyaluronic acid, associated with proteoglycans and GAGs, compared to the physiological brain tissue. This differential gradient results in both biomolecular and physical differences, playing an important role in the upregulation of cell migration. The design of new hybrid glyco-materials can quicken the characterization of glycosignature role in the progression of GBM. Here, glycoconjugate - ECM mimetics with tailored composition have been developed and characterized to investigate the role of glyco-microenvironment in GBM progression. Functionalized hyaluronic acid and protein-based components have been chemically crosslinked, resulting in a bioprintable hydrogel. The result is a 3D cell culture model, which exhibits multiple advantages over 2D models, mimicking in complexity the native counterpart.

Proper, consistent and correct biomechanical characterization is very important for novel 3D bioprinted constructs and scaffolds. Conventional approach foresees pre-selection of the material model and fitting experimental data to quantify properties in time and spatial scales. Here we present a new patented method of model-free assessment of invariant constitutive parameters of both bioprinted materials and the extrusion-based process with the same logic. This allows determination of e.g. biomaterials viscosity (without usual rheologic tests), stiffness, permeability, and other properties without a need of selection of material model and without use of complex transforms in frequency domain. Another advantage of the method is alignment of the testing parameters closer to intended clinical applications, making it more compliant with regulations such as MDR 2017/745 Annex I.

An injectable polymeric brushite (PDCPD) cement was developed that is mechanically strong. The study aim was to evaluate bone healing with Strontium doped PDCPD (Sr- PDCPD) in a rat model. Rats were divided into: (1) Control (No PDCPD); (2) with PDCPD and (3) with 10%Sr-PDCPD (n=10 each). PDCPD was injected into 8-mm calvaria defects. Calvariae were harvested 12 weeks post-surgery. Bone healing was evaluated by µCT and bone histometric analysis. Data was analyzed by ANOVA. Results: Handling: Both PDCPD and Sr-PDCPD were injectable, moldable, and stable in vivo for up to 12 weeks. Histology: New bone formation was found with both cement groups. There was a close interaction between degrading cement fragments (particles) with surrounding newly formed bones. In vivo fluorescence labeling showed that much stronger fluorescent signals were observed in P-DCPD group (85%± 2.5) and in the Sr-P-DCPD group (60%± 2.5), as compared to control (<1%). In addition, no host inflammatory response to implanted cements was found. There were more cement fragments left in the Sr-PDCPD group than the P-DCPD group. µCT: The Sr doping significantly reduced the porosity of P-DCPD. It was difficult to define an appropriate threshold setting that could be used to quantify the dynamic interaction between new bone formation and cement degradation due to the high density of the implanted cements. Conclusion: P-DCPD is biocompatible, degradable and enhances new bone formation. The unoptimized Sr loading dose and the reduction of cement porosity may explain the inferior results of bone healing observed in Sr-PDCPD group.

TOWARDS A NOVEL ALTERNATIVE TOXICITY MODEL WITH NORMOTHERMICALLY PERFUSED EX VIVO LIVERS BASED ON WHOLE PORCINE SLAUGHTERHOUSE ORGANS

Introduction

The development of highly predictive liver models for toxicity screenings is both important and challenging. Ex vivo liver perfusion has emerged in the last years as a promising tool to maintain organ functions and complexity. We here present a normothermic ex vivo liver perfusion model based on slaughterhouse material to reduce animal testing.

Methods

Procurement and treatment protocol of livers in the slaughterhouse was executed. Livers were attached to an extracorporeal perfusion circuit and reperfused at 39°C, applying pressures of 10 and 80 mmHg to veins and arteries, respectively. To assess liver function, we performed the indocyanine green (ICG) test, blood gas analysis, and quantified bile production and oxygen consumption.

Results

Blood gas values and pH were kept at physiological levels. Physiological flow rates of 864.3 ± 133.2 mL/min in the portal vein and 379.7 ± 92.8 mL/min in the hepatic artery were achieved without added vasodilators. Bile was produced continuously (6ml/h). The ICG functionality test resulted in an ICGt1/2 value of 12.86 min. Average oxygen consumption was 5 ml/min.

Conclusion

A normothermic perfusion model was developed to successfully perfuse an ex vivo liver obtained from a slaughterhouse. Functionality and viability were demonstrated by continuous bile production[1], which was confirmed by an ICGt1/2 result comparable to literature[2] and stable oxygen consumption[1]. Further analyses and circuit optimization will lead to extended perfusion and a versatile platform for interventional studies and drug treatment.

Acknowledgment

The project was funded by EU's Horizon 2020 research program under the Marie Skłodowska-Curie grant agreement No.860715.

In a developing tissue, spatiotemporally controlled growth factor bioavailability is crucial. The current growth factor delivery systems often focuses on growth factor immobilization or its coupling within the matrices (hydrogel), through which passive release rates and on-demand delivery could be achieved. However, it fails to adapt their release rates in accordance with the developing tissue. To this end, the present study employs oligonucleotides based aptamers for spatiotemporally controlled growth factor delivery. Aptamers are affinity ligands selected from DNA/RNA libraries to recognize proteins with high affinity and specificity.1 In the present study, authors have patterned aptamer-functionalized bio-inks using 3D bioprinting to study their potential for growth factor sequestering, programmable release and controlling vascular network formation. The aptamer-functionalized bio-inks were prepared via visible light induced photo-polymerization of gelatin methacryloyl (GelMA) and acrydite functionalized aptamers having sequence specific for binding to vascular endothelial growth factor (VEGF165). For studying the effect of growth factor (VEGF) bioavailability on vascular network formation, human umbilical vein endothelial cells (HUVECs) and mesenchymal stem cells (MSCs) were encapsulated within the bio-inks. The results obtained from ELISA assay confirmed the sequestration and triggered release of VEGF in response to complementary sequence (CS) addition after 4 days of culture. Interestingly, the immunostaining results showed vast CD31 positive endothelial network formation within the VEGF bound aptamer-patterned regions instead of GelMA regions. These observations altogether confirms the potential of aptamer-functionalized bio-inks in spatiotemporally controlling the bioavailability of VEGF via aptamers within the 3D printed constructs.

Because chondrocyte (CH) morphology is associated with type I & II collagen expression levels [1], CH expression can be controlled by engineering CH shape using micro-patterned adhesion sites (MPs). The aim was to test rationally designed MP models that vary geometric aspects such as area, width, length, aspect ratio, circularity, and solidity to control CH cytoskeleton and phenotype.

MP reductionist models were designed as fibronectin-coated circles/ellipses with increasing area, circles with increasing prong numbers but constant area (star shapes), and non-solid MPs. MPs were used for human CH culture, ddPCR for quantifying mRNA expression, and fluorescence microscopy and nano-indentation for assessing the cytoskeleton. Partial least square (PLS) regression was used to analyze the impact of geometry on CH characteristics.

MPs altered CH shape, all mRNA expression levels ($p<0.05$), and cytoskeletal properties such as actin intensity, distribution and stiffness. Subsequent PLS analyses revealed COL2A1, the COL2A1/COL1A2 ratio, ACAN, SOX9 were positively regulated by solidity and COL1A2 by aspect ratio, whereas solidity, and, to an even larger extent, circularity negatively regulated COL1A2 expression. Systematically varying MP area of sets of circles or ellipses did not modulate mRNA expression levels in linear dose-responses. Instead, maximizing the resulting expression levels was achieved by using defined ranges of MP area. When using star-shaped MPs, defined ranges of circularity and solidity maximized the resulting expression levels similarly.

Thus, specific combinations of geometric features - and not a specific feature alone - are needed for inducing high mRNA expression levels of chondrogenic genes in human CHs.

Lack of vascularization is a major limitation for all engineered tissue. One possible way to facilitate formation of blood vessels could be recruitment of endothelial cells to bioactive surfaces.

In the present work, tunicate nanocellulose hydrogel surfaces were oxidized with sodium periodate and bioconjugated with laminin produced from mouse Engelbreth-Holm-Swarm sarcoma cells. A population of CD34+(CD45-) endothelial progenitor cells (EPCs) were sorted from human Stromal Vascular Faction (SVF) by Fluorescence Activated Cell Sorting (FACS) and cultured in vitro for 13 days in ECGM MV2 medium. EPCs (passage 1) was incubated for 3 days with the bioconjugated surfaces. For comparison, unsorted SVF was also applied. Unconjugated surfaces served as negative controls. Cell adhesion was evaluated by confocal laser microscopy using immunofluorescent CD 34 antibodies and DAPI for nuclear staining.

Surfaces bioconjugated with laminin showed extensive adhesion of CD34+ cells from SVF whereas laminin-free surfaces showed no adhesion of these cells. Direct application of SVF also allowed adhesion of CD34+ cells but to a lesser extent than the EPC population.

In summary, here a method to increase functionality of nanocellulose hydrogel constructs by bioconjugation with laminin improved adhering of EPCs from SVF. This is a possible step towards autologous vascularization of 3D bioprinted constructs.

Chronic obstructive pulmonary disease is one of the main causes of death worldwide. Currently, lung transplantation is the only currently available treatment; however, donor shortage and organ rejection represent major limitations. The current short-term alternative, the extracorporeal membrane oxygenators (ECMO), comprises highly-hydrophobic hollow fibres (HFs) made of polymethylpentene. Thrombogenicity and associated clotting of the ECMO limits its operation to about 30 days. Endothelialisation of the HFs in the ECMO has been proposed to enhance hemocompatibility and decrease thrombogenicity of the device. This study was aimed at optimising the seeding of the HFs of the oxygenator with endothelial cells (ECs).Human cord blood endothelial cell (HCBEC) adhesion was assessed on rheoparin®-coated and rheoparin®-fibronectin-coated HF mesh samples (3×2.6 cm) from commercially-available oxygenators (Xenios, Hilite 2400 LT). The HF mesh samples were mounted in custom-made frames. Seeding was carried out dynamically (4 h, 1 rpm rotation) on falcon tubes filled with cell suspension at defined cell densities (1.72E4, 3.43E4, 6.88E4, 8.56E4, 1.03E5 and 1.20E5 cells/cm2). After 2 days of static culture in culture dishes, the samples were assessed through live/dead staining. Rheoparin® alone did not allow HCBEC adhesion. Rheoparin®-fibronectin-coated samples demonstrated improved cell adhesion. Confluent HCBEC coverage was achieved around the HFs coated with rheoparin®-fibronectin at an optimum seeding density of 1.03E5 cells/cm2. These results provide the starting point for scaling up the seeding strategy for endothelialisation of the whole HF stack in commercially available oxygenators.

Non-autologous beta cells can be protected from the patient's immune system using biomaterials such as immunoprotective microcapsules. Although several material formulations have been developed, clinical translation of immunoprotective microcapsules is challenged by their non-permanent nature, fibrous capsule formation upon implantation, and low production rates. We here report the development of a novel, immunoprotective biomaterial that allows ultra-high throughput microfluidic production of beta-cell containing microcapsules.

Enzymatically crosslinkable polyethylene-glycol 8 arm–tyramine (PEG-TA) conjugates were synthesized in a two-step reaction. Microfluidic droplet generation was optimized for production of hollow PEG-TA microgels using a delayed outside-in crosslinking strategy based on horseradish peroxidase and cytocompatible levels of hydrogen peroxide. Production rates and regimes, permselectivity, cytocompatibility, immune reactivity, glucose responsiveness were analyzed in vitro, and fibrous capsule formation was analyzed in vivo.

We were able to produce monodisperse microcapsules with a diameter of 200 µm and a shell thickness of 20 µm using conventional microfluidics and in ultra-high throughput using in-air microfluidics. Incubating microcapsules with FITC-IgG of different Mw revealed that molecules from 150 kDa onwards were unable to diffuse into the microcapsules. Exposing microcapsules to monocytes and whole blood did not result in macrophage activation or cytokine release based on immunofluorescence and multiplex ELISA. Histological analysis revealed minor fibrotic structures surrounding the particles, most likely due to the micromaterials' geometry. Microencapsulated beta-cells remained viable, metabolically active, and responsive to glucose.

High throughput production of immunoprotective PEG-TA microcapsules using microfluidic droplet generation is a promising novel combinatorial approach for delivery and protection of non-autologous beta cells.

Introduction

A previous study has shown that elastomeric poly(ε-caprolactone-urethane-urea) (PEUU)-based scaffolds display a good biocompatibility and biointegration in an in vivo bone healing model [1]. However, the structural and physico-chemical characteristics of scaffolds have to be optimized when dedicated to soft tissue regeneration. The objective of this work was to study the effect of PEUU scaffold pore size on cell infiltration and migration and tissue reconstruction in a subcutaneous pockets model in rats.

Materials and method

A homologous series of PEUU scaffolds were obtained by cross-linking a high internal phase emulsion [2]. Scaffolds were evaluated in vivo by subcutaneous implantation alongside the dorsal midline of rats. Seven day after implantation, rats were sacrificed and the implanted scaffolds and the surrounded tissues were biopsied and prepared for histological studies.

Results and Discussion

The PEUU scaffolds were developed with differences in pore size ranges and mean pore diameters (490, 715, and 1075 µm), but with no significant variation in others parameters. Histological analysis showed that fibroblast-type cells were able to migrate within the porous structure of all scaffolds. The tissue invasion seemed to be more important when the scaffold pore size increased. However for smaller pore size, the connective tissue appeared more structured, dense and fibrillar with presence of newly formed vessels. The study provides evidence that mean pore diameters much larger that those recommended by the literature for soft tissue engineering can be used. The study also demonstrated that scaffold pore diameters had a strong influence on tissue structuring.

Bioengineered liver tissue can recapitulate the hepatic microenvironment for disease modelling. Bioreactors overcome challenges in engineering and culturing tissue constructs. However, novel bioreactors are needed to support long-term culture of bioengineered constructs allowing non-invasive longitudinal monitoring of culture parameters and cell behaviour. In this study we designed and validated a custom-made bioreactor for long-term perfusion 3D culture of whole liver constructs with traceable hepatocytes.

Whole scaffolds were generated by perfusion decellularisation of rat livers. The bio-inert and chemical resistant custom-made bioreactor was produced in nylon. Luc+HepG2 cells or primary human hepatocytes (PHH) were perfusion-seeded into scaffolds and cultured in static vs dynamic conditions using the bioreactor with a programmable syringe pump, providing continuous unidirectional flow. The bioreactor was designed to provide non-invasive monitoring of perfusion parameters, media sampling and evaluation of cellular rearrangements and growth measured with bioluminescence; cell function analysis was performed with immunofluorescence and ELISAs.

Luc+HepG2 viability, distribution, and function in bioengineered livers were monitored using bioluminescence for 11 days. Bioreactor-perfused scaffolds had significantly higher cell viability, homogenous distribution, and functionality in comparison to static conditions. PHH cultures were followed for up-to 30 days, showing remarkably higher cell viability and function in bioreactor culture compared to static conditions: albumin secretion, expression of HNF4α, CYP3A4 and FOXA2 and urea production were increased in perfusion-culture vs static.

The bioreactor novel design permitted longitudinal monitoring of whole-liver constructs, supporting PHH viability, metabolism, media sampling and maintaining sterility, making it well suited for liver tissue engineering and potentially culture multicellular constructs.

LIGHT-ASSISTED ELECTROSPINNING OF CORE-SHELL P(NIPAAM-CO-NIPMAAM) HYDROGEL-BASED NANOFIBERS FOR THERMALLY SELF-REGULATED DRUG DELIVERY

Recently, stimuli-responsive drug delivery systems are gained researchers' attention, targeting sustained and controlled drug release in order to deliver the requested active molecule dose, while avoiding unwanted cell uptake. The adjustment of drug release at different stages of therapy is highly desirable because changes and related timing are crucial factors in most biological processes. In this frame, several nanostructured biomaterials have been developed to meet those requirements. However, only materials able to release drugs over long term were obtained, without taking into account the optimization of the bioactive molecule secretion level at the first stage after implantation.

In this work, a co-axial electrospinning technique is used to fabricate core-shell fully cross-linked copolymer poly(N,N-isopropylacrylamide-co-N-isopropylomethacrylamide) (P(NIPAAm-co-NIPMAAm) hydrogel-based nanofibers, as thermal-responsive drug delivery system. The custom-made electrospinning apparatus enables the in situ cross-linking of P(NIPAAm-co-NIPMAAm) hydrogel core into a nanoscale confined PLCL shell, hence improving the electrospun nanofiber drug dosing process by reducing its provision and allowing a self-regulated release control.

Furthermore, the thermoresponsivity of the system also acts as drug release self-regulating factor, revealing temperature dependent drug delivery kinetics driven by an optimized temperature-controlled desorption. Thus, tuned thermoresponsive properties of the material lead to a decrease of the drug delivery at early stages while long-term release is guaranteed, hence showing that the system is a promising candidate as a "smart" drug delivery platform.

STUDY OF THE LIVER FIBROGENIC MICROENVIRONMENT IN A BIOENGINEERED MODEL OF CHRONIC LIVER DISEASE

Sara Campinoti[P][1,2], Omolola Ajayi[1], Lai Wei[1,2], Sveva Fagiolino[1,2], Lorenzo Caciolli[1], Dipa Natarajan[1,2], Shilpa Chokshi[1,2], Luca Urbani[1,2]

Chronic liver disease (CLD) poses a significant health burden world-wide. Its progression is characterized by chronic injury, inflammation, and fibrosis, caused by the accumulation of extracellular matrix (ECM) by activated hepatic stellate cells (HSC). These mechanisms of chronic inflammation remain poorly understood, mainly due to the inability of conventional cell culture models to mimic the liver microenvironment.

Here, we used bioreactor-based bioengineered systems to culture hepatic cells in 3D conditions as a tool to examine cell-ECM crosstalk in the context of CLD.

We isolated human HSCs from total and partial hepatectomy and provided an in-depth cell characterization in comparison to commercially available HSC lines.

Cells were cultured in 3D systems generated using decellularized human liver ECM-scaffolds from normal and fibrotic livers. 3D cultures were maintained using a custom-made confined-perfusion bioreactor. HSCs were also co-cultured with primary hepatic endothelial cells. HSC activation and cell phenotypes were analysed.

Phenotypic and gene expression analysis of seeded scaffolds were performed using immunofluorescence and qPCR.

Culturing HSCs in 3D ECM-scaffolds reduced cell activation in comparison to standard 2D cultures, possibly due to change in substrate stiffness. Primary HSC activation and ECM production was achieved within the 3D construct with the addition of profibrogenic factor TGFβ. Cell-cell and cell-ECM crosstalk produced various levels of HSC quiescence/activation, based on the fibrosis score of ECM-scaffold used.

In conclusion, confined perfusion supported the culture of liver constructs populated with primary human hepatic cells, generating a dynamic 3D model useful to investigate the liver microenvironment in CLD.

The final outcome of extrusion-based bioprinting procedures is highly affected by a number of process variables, such as bio-ink properties, nozzle diameter and extrusion pressure. Introducing in silico (computational) models as an integral part of the bioprinting design pipeline would allow to increase innovation, productivity, scalability and robustness. To date, simulations are not employed in the field since theoretical and computational models for describing the physicochemical mechanisms occurring during/after bioprinting are not available or refined enough for giving quantitative predictions.
The objective of this work is to develop a computational model for the extrusion of non-Newtonian shear-thinning hydrogels with a cellular component. In fact, cell densities affect both the extrusion flow rate and the final cell viability. The aim is to explicitly describe the extrusion of cells through the nozzle, predicting the cellular membrane stresses during the process, and then the onset of cell damage or apoptosis. The computational framework has to account for both multiscale dimensionality and fluid-structure interactions. In fact, cell diameter is significantly smaller than the extruder and the final construct but is comparable with nozzle size. Moreover, cells significantly deform when moving within the hydrogel. Global-local strategies are then employed and coupled with immersed boundary formulations of the FSI problem. The proposed model is a first step towards a predictive tool for the optimal setting of process variables such to guarantee a delicate balance between the biological request of high cell densities and the engineering constraint of bio-inks printability.

Chronic pain (CP) is one of the most frequent medical condition that affects 20% of adult population limiting their life and work activities. Over 90% of CP patients receive treatment based on opioids which increased the prevalence of opioid use disorder, resulting in a national crisis for public health, social and economic wellbeing.

Opioid drugs act through MOR, DOR and KOR opioid receptors activation. MOR, the main target and most studied receptor is highly distributed in areas related to pain perception and sensorimotor integration and when activated produces analgesia. Our preliminary results showed the presence of MOR, DOR and KOR in Cerebral Organoids (CeO) with higher MOR expression. CeO are self-organized, functional and multicellular 3D structure that resemble the brain. These results suggest CeO as a powerful tool to understand opioid receptors modulation and brain plasticity.

Chronic opioid consumption involves alterations in neurotransmission, dendritic branching, spine density and pro-apoptotic proteins at reward circuit regions. To overcome these issues, efforts have been made to find an alternative treatment for CP. Recent interest on bioactive molecules secreted by Stem Cell, known as secretome has increased. Secretome include a broad spectrum of growth factors, cytokines and vesicular fraction already described effective in pain models. Nevertheless, to our knowledge, no study regarding central pain mechanisms at brain level were made using secretome. Recent result from our lab showed modulation of opioids receptors when CeO were incubated with secretome. Herein, we aim to prove the prolonged analgesic effect of secretome, without negative outcomes of opioids.

DESIGN OF BIOMATERIALS TO MODULATE INFLAMMATION

Kam Leong$_P$[1]

[1] *Columbia University*

Corresponding author's email: kam.leong@columbia.edu

Inflammation plays an important role in responding to danger signals arising from damage to our body and in restoring homeostasis. Controlling the inflammatory response is a major strategy in managing diseases such as cancer, autoimmunity, and wound healing. While conventional drug therapies are the norm in tackling inflammation, biomaterials are increasingly proposed to join the battle. Through drug delivery strategies, biomaterials potentiate the efficacy of anti-inflammatory drugs by improving bioavailability and diminishing side-effects. Applied in inhibitory or scavenging strategies, they reduce inflammation by removing the pro-inflammatory factors. For instance, the scavenging approach may be applied to inflammatory diseases such as rheumatoid arthritis, psoriasis, multiple sclerosis and systemic lupus erythematosus, which are increasingly linked to inappropriate and chronic activation of inflammatory cells. A central event in the pathogenesis of these diseases appears to be an aberrant activation of innate immune sensors, most prominently the Pattern Recognition Receptors (PRRs), by nucleic acids that are released from dead and dying cells. In this presentation, I will discuss the application of nucleic acid-binding polymers in the configuration of either soluble polycation or cationic nanoparticle to scavenge these nucleic acids as a molecular strategy to combat inflammation.

Despite advances in microsurgical techniques to repair peripheral nerve injuries (PNI), full regain of function is rarely achieved. Neuron growth rate is limited to ~1 mm/day meaning long periods of time can elapse before the neurons reach their target organs. The lack of nerve stimulation leads to atrophy of the muscle over time causing irreversible wasting. Therefore, there is a unmet clinical need to accelerate nerve regeneration. Despite drug candidates demonstrating beneficial effects on nerve regeneration rate in preclinical models, there are currently no drugs routinely used in clinical practice. The main hindrance of such drugs is the side effects associated with sustained systemic administration. A local controlled release drug delivery system could potentially address this challenge, particularly through the use of drug-loaded biomaterials that could be implanted at the repair site during the microsurgical repair procedure. This study tested this concept by delivering PPARγ agonists from nanofibrous polylactic-co-glycolic acid (PLGA) locally in a controlled manner in a rat sciatic nerve injury model. Following characterisation of release parameters in vitro, PLGA loaded with ibuprofen sodium or sulindac sulfide were used in vivo to treat a nerve crush injury in rats. The results demonstrated that ibuprofen sodium, but not sulindac sulfide caused an increase in neurites in the distal nerve and improved functional recovery. This study has shown for the first time that the local delivery of ibuprofen using biomaterials has beneficial effects on neuron regeneration. This will underpin future development of drug-loaded biomaterials suitable for clinical translation to treat PNI.

Following a peripheral nerve injury the nerves have capacity to regenerate naturally, however, in a gap injury surgical repair is required. Current microsurgical interventions use an autograft as the clinical gold-standard therapy for gap repair, however, there are challenges in achieving full recovery and limitations associated with tissue availability and donor-site morbidity. Tissue engineering provides an opportunity to overcome these limitations by building a construct from therapeutic cells and biomaterials to artificially recreate the autograft. In this study engineered neural tissue (EngNT) was manufactured using human neural stem cells (CTX0E03) to bridge a critical-length (15 mm) sciatic nerve gap injury in athymic nude rats. The ability of EngNT-CTX to enhance regeneration and functional recovery was compared to an autograft. A range of outcome measures that assessed neuronal regeneration and functional recovery were investigated at 8 and 16 weeks post-repair.

Histological analysis showed the number of neurons (motor + sensory) detected in the distal nerve stump was equivalent in both groups at 16 weeks. At the 8 week time point there were more sensory neurites detected in the autograft group than the EngNT-CTX group, indicating increased sensory sprouting, although motor neuron numbers were equivalent. These results were consistent with the electrophysiology, which showed EngNT-CTX restored electrophysiological nerve conduction and functional reinnervation of downstream muscles to an equivalent or greater extent than the autograft at both time points.

In conclusion, this study provides evidence that in a critical-length preclinical peripheral nerve injury model EngNT-CTX demonstrates equivalent performance to an autograft.

Introduction: Tissue engineering is a balance between the functional restoration of tissue and the reconstruction of matrix to allow full integration with the surrounding healthy tissue. Bespoke biomaterials offer the ability to do both by fine-tuning the chemical and physical characteristics of the material.

Method: We present de novo alpha-helical peptides, designed and manufactured using standard solid-phase synthesis protocols. The peptides are purified using reversed-phase HPLC and masses confirmed through mass spectrometry. The peptides form novel hydrogels that are chemically tuned using click chemistry methodology and can be used as in vitro 3-dimensional structures or injected in vivo.

Result: The alpha-helical hydrogels encourage cell attachment, directional migration and promote functional differentiation in a variety of cell types. Hydrogel stiffness is modifiable and can be used to create an injectable scaffold, which over 28 days increases cell infiltration at the wound interface. No foreign body reaction or encapsulation is observed during that time. In a rat abdominal model we also note an upregulation of myogenic differentiation markers as well as the promotion of an anti-inflammatory environment. After 28 days the hydrogel-tissue interface is not discernible, indicative of full integration.1

Conclusion: Designing peptides using a bottom-up approach allows control over the final material. These alpha-helical hydrogels offer a chemically and physically tuneable environment that can be easily manipulated to suit different tissue types. They offer the ability to promote functional restoration of tissue while also integrating fully with healthy tissue. These peptide-based materials offer great potential towards unmet clinical needs.

Spatiotemporal organization of micro and macrovascular networks within engineered tissues can be controlled using mechanical and chemical cues. Recent studies have shown that the local geometric shapes [1], external fluid flows [2] and growth factor signals [3] influence the development, organization, and orientation of sprouting blood vessels. Nevertheless, the physiological relevance is unknown and yet this has not been tested directly on the in vivo culture platforms. Here we developed two types of PDMS based ex ovo culture systems that allow us the long term observation of developing vascular networks within chick CAM and compatible with multivariable mechano-biochemical perturbations. We perturb the developing vascular networks using mechano-biochemical signals such as geometric shapes, external fluid flows, and VEGF concentrations in three different ex ovo models. Time-lapse image analysis showed the differences in the vascular organization as well as variation in the vascular response to the effect of these signals. Furthermore, we performed quantification metrics on vessel diameter, vessel length, and sprouting percentage on the above-mentioned test conditions, in comparison to the control samples. Our strategy implies the possibility of adding multiple mixed combinations of mechanical and chemical signals within a single in vivo culture system and offers to probe local as well as global structural changes over the development. We anticipate our culture system to be a foundation for directing in vivo vascular network development, remodeling, and organization.

The scarcity of donor tissue has led to the development of tissue engineering products that replace bone grafts. However, the development of bone tissue engineering products that mimic the microstructural characteristics of native bone continues to be challenging. In this work, we developed and characterized type I collagen scaffolds with two different pore orientations, unidirectional pores (UC) characteristic of cortical bone, and multidirectional pores (MC) characteristic of trabecular bone. Microstructural, physicochemical, mechanical, and biological characteristics were evaluated in vitro. We also assessed the scaffolds' ability to support bone growth when loaded with BMP-2 or BMP-2 plus VEGF in an ectopic rat model. Both scaffolds had porosity above 90% and interconnected pores. The MC scaffolds' tensile strength, elasticity, and liquid sorption capacity were significantly higher than the ones found in UC scaffolds. Culture of rat bone marrow mesenchymal stem cells demonstrated that scaffolds support cell adhesion, growth, and osteoblastic differentiation in the presence of BMP-2. In vivo evaluation of scaffolds loaded with BMP-2 or BMP-2 plus VEGF demonstrated they promoted bone formation ectopically. Histological and calcium analyses content showed pore directionality impact osteogenic differentiation because UC scaffolds loaded with BMP-2 plus VEGF contained significantly more bone than the MC loaded with these same factors. Overall, longitudinal bone formed in the UC scaffolds, and random bone formed in the MC scaffolds indicated bone deposition is guided by scaffolds' pore directionality.

Introduction: Mesenchymal stem cells (MSCs) were proposed as a critical therapeutic candidate in diabetic nephropathy (DN). Renal stem cells as a source for repairing are controversial. The purpose of the present study was to evaluate the effect of kidney rat stem cells on DN.

Materials and methods: After separation of renal stem cells from rat kidney, the surface stem cell markers were assessed by flow cytometry analysis. To establish the diabetic nephropathy rat model STZ(60mg/kg) was used. The cells were injected to experimental groups via tail vein (2×106cells/rat). Biochemical and histological parameters were evaluated in order to determining the impact of stem cells on kidney structure. Phosphorylation of Smad2/3 two weeks after induction of early diabetic nephropathy was evaluated by using standard western blotting.

Result: The cells significantly reduced blood nitrogen (BUN), serum creatinine(Scr) and 24 urinary proteins. The phosphorylation of smad2 and smad3 significantly down-regulated in diabetic group. PAS staining showed in the presence of adult kidney stem cells histopathological changes were improved.

Conclusion: Adult kidney stem cells may be a candidate for treatment of early DN to improve the kidney function and regenerating kidney tissues in DN rats.

Breast reconstruction utilizes autologous fat injection, flap reconstruction, and silicone breast implants. However, these methods have poor take rate, donor site morbidity, and the occurrence of breast implant-associated anaplastic large cell lymphoma. Adipose tissue has been regenerated by combining scaffolds, growth factors (GFs), and/or adipose tissue-derived stromal cells (ASCs). However, the safety of GFs or ASCs after mastectomy has not been confirmed. We reported that a poly L-lactic acid (PLLA) mesh implant containing a collagen sponge (CS) maintained the internal space and the formed adipose tissue in vivo for up to 12 months. We developed a PLLA capsule implant and compared adipose tissue formation at 12 and 24 months after implantation between the PLLA mesh with CS implant and the PLLA capsule implant with or without CS in rabbit models.

All implants maintained the internal space at 12 months. At 24 months, the PLLA mesh implant maintained the internal space and the formed adipose tissue as well as that at 12 months, while the PLLA capsule implant collapsed and accumulated a large number of macrophages around the PLLA.

The PLLA mesh implant containing CS is a desirable bioabsorbable implant replaced by autologous adipose tissue after implantation in vivo without additional GFs or cells. Furthermore, we think that the main indication of this implant is the reconstruction after breast-conserving surgery. We are trying to regenerate larger amounts of adipose tissue using multiple PLLA mesh implants with CS in a porcine model and to create an irradiation model using a rodent.

Skin wounds are a challenging problem in the medical field and an economical burden. Skin substitutes (SS) are promising choices for wound healing since they mimic skin architecture and supports its regeneration. Here, we present a preliminary study about the application of a sea urchin-derived collagen-based SS [1, 2] in a second intention wound healing model. Two wounds were surgically created on the back of three sheep: one wound was treated with the SS and one was left untreated. The wound healing process was assessed with clinical observations and histological plus molecular analysis at 7, 14, 21 and 42 days.

The SS led to a better re-epithelialization than the placebo while no differences in wound contraction were observed. Histologically, treated wounds showed skin appendages already at day 14 and a higher cellular proliferation (Ki67+) with a faster resolution of the granulation tissue (GT) respect than the placebo. These results were further corroborated by gene expression levels of Collagen type I and III at 14 and 21 days. Concomitantly, a higher gene expression of VEGF (day 14) and a lower positivity for α-SMA+ cells (day 21 and 42) were observed in treated wounds.

The application of a sea urchin-derived SS led to a faster re-epithelialization, a better development of skin appendages and a properly maturation of GT. On the contrary, control wounds showed epidermal hyperplasia and dermal fibrosis. Overall, these preliminary findings suggest that this collagen-based SS possess beneficial properties, worthy of further investigations, for the treatment of full-thickness skin wounds.

A wide diversity of procedures to isolate mesenchymal stromal cells (MSCs) from adipose tissue (AT) has been described in different species, including cattle. Although a high number of MSCs is often required for various tissue engineering approaches, isolation efficiency is rarely evaluated. To this end, diverse enzymatic digestion methods and one culture explant method were compared using subcutaneous AT samples of adult cows. Within the enzymatic digestion methods, different enzymes (collagenase I, collagenase I + trypsin, liberase, collagenase IV and MMP-12), enzymatic concentrations (0.25%, 0.1%, 0.04% and 400 ng/mL) and incubation times (3h, 6h, overnight and 24h) were evaluated. Plastic adherent cells were observed using most isolation methods on subcutaneous AT samples of 5 adult cows except when cells were isolated with: 0.1% collagenase I for 24h, 0.1% collagenase I + 0.25% trypsin overnight, 0.1% collagenase I + 0.25% trypsin for 24h, 0.04% collagenase IV for 3h and 0.04% collagenase IV overnight. Cells were collected in at least 4 out of 5 isolation repeats for the following methods: 3u coll I 0.1%, 3u lib 0.1%, 3u lib 0.04%, 6u lib 0.1% and 6u lib 0.04%. Enzymatic treatment with 0.1% liberase for 6h resulted in the highest average cell concentration (2,48 x 106 cells/mL) and cell viability (98,84%) when compared to the other methods. These cells were subsequently immunophenotyped and differentiated towards the osteogenic, chondrogenic and adipogenic lineage to confirm their MSC identity. In conclusion, the optimized protocol ensures the isolation of a high bovine MSC yield from subcutaneous AT.

Spheroid cultures are frequently used in vitro models and gain importance in clinics for regenerative applications. Drawbacks of current systems, especially for chondrogenic differentiation, are high reagent/time consumption and unavailability of early read-out parameters. Herein we present a system for self-assembly of chondrogenic spheroids from monolayers facilitated by growth surface subdivision using CO2-laser engraving (grid plates). Human telomerase reverse transcriptase immortalized adipose-derived stem cells (ASC/TERT1) mono- or co-cultures with primary human articular chondrocytes (hAC) were seeded on grid plates in low-dose differentiation media (1ng/ml TGF-β3/BMP-6), leading to self-assembly into spheroids. The diameter of generated spheroids was easily controlled by altering grid size, yielding approximately 340µm and 130µm for 3mm and 1mm grids respectively. Co-cultures formed spheroids significantly faster, reducing formation time from 3 weeks in mono-cultures to 1-2 weeks with increasing hAC content ($p<0.05$ and 0.01 for 1:1 and 1:4 ASC/TERT1:hAC ratio respectively). When comparing grid plate generated spheroids to standard pellets, similar differentiation capacity was observed. Internal structure however, showed differences in matrix distribution and cortex alignment. Grid spheroids were tested for applicability in regenerative settings by embedding into fibrin hydrogels, showing clear cellular outgrowth and collagen type 2 matrix deposition into the hydrogel, especially in co-cultures. First data also shows clear influence of pro- (IL-1β) and anti-inflammatory (dexamethasone) compounds on formation kinetics, making it a promising early read-out parameter candidate. In conclusion the herein presented system allows for efficient and reliable generation of spheroids via self-assembly from monolayer, showing promising results for in vitro and clinical applications.

Novel approaches to treat diabetes can include cell encapsulation and transplantation in order to mitigate graft rejection and restore physiological insulin secretion and normoglycemia [1]. In this work, a surface engineering approach was used to modify the plasma membrane of MIN-6 cells using a Mal-PEG-Lipid. The Mal-PEG-Lipid provides an anchorage site to the multiple hyaluronic acid derivate (HA-SH and HA-PD) coatings. The in vitro cell viability analysis for surface engineered MIN-6 cells showed that different Mal-PEG-Lipid concentrations (50, 250, and 500 µL per 1x106 cells) do not decrease cell viability as compared to control (approximate 90%). The incubation period for the cell membrane modification also shows no significant difference in cell viability after 30 minutes or 1 hour of incubation. After tagging Mal-PEG-Lipid with fluorescein, cells were incubated with the aforementioned concentrations, showing that cell fluorescence is time and concentration-dependent, with 500 µL Mal-PEG-Lipid per 1x106 cells incubated for 1 hour recording the highest fluorescence intensity and uptake. In conclusion, this novel encapsulation method is not harmful to pancreatic beta cells and has promising use in transplantation to treat diabetes.

Tendons display poor intrinsic healing properties and are difficult to treat[1]. In this study, we investigate whether there are specific mechano-active regions of the Activin A receptor which can influence the tenogenic differentiation of mesenchymal stromal cells (MSCs) using a magnetic bioreactor (MICA Biosystems Ltd)[2,3]. The role of oriented 3D collagen models[4,5,6] combined with Activin A activation is further explored.

Magnetic nanoparticles (MNPs) functionalized with 3 anti-Activin Receptor IIA antibodies targeting different regions of the receptor, were screened by FACS and immunofluorescence. MNPs-labelled cells were then stimulated with MICA and the activation of the Smad2/3 pathway assessed by ELISA. MNPs-labelled cells were then differentiated in tenogenic media for 21 days with 1h daily MICA stimulation in 2D and 3D oriented collagen models. Tenogenesis was assessed by histological staining and IHC. 3D oriented fibres collagen models were achieved by labelling MSCs with MNPs and setting the gels under a constant magnetic field. The fibres alignment was assessed by polarized and confocal microscopy.

Screening of multiple antibodies revealed binding to MSCs. Cells treated with tenogenic media in MICA-stimulated conditions showed an increase in collagen deposition and tenomodulin and scleraxis expression in 2D and 3D. Increased phosphorylation of the Smad2/3 complex was detected in MICA-activated groups as determined by ELISA. The polarised and confocal microscopy showed significant orientation of collagen fibres in gels set under magnetic conditions. In conclusion, the MICA remote activation of Activin A receptor using tagged MNPs enhances the tenogenic response in MSCs both in 2D and 3D models.

Adipose-derived mesenchymal stem cells (ASCs) have the potential of multi-lineage differentiation and differentiate into either chondroblasts or osteoblasts, leading to bone formation and bone regeneration. Long-non coding RNAs (lncRNAs) play crucial roles for gene transcription and mRNA expression in regulating various cellular processes such as cell differentiation, cell development, and cell proliferation. The previous studies have confirmed that lncRNA DANCR (DANCR) upregulated chondrogenesis in mesenchymal stem cells. However, the role of DANCR in controlling chondrogenic differentiation of stem cells and its molecular mechanism in chondrogenesis remains unknown. In this study, we further aimed to harness CRISPR activation (CRISPRa), which exploits single guide RNA (sgRNA) and nuclease-deficient Cas9 (dCas9) protein. dCas9 can be fused with a tripartite transcription activator domain (dCas9-VPR) that can stimulate endogenous DANCR expression. To this end, we constructed different baculovirus vectors to express CRISPRa VPR system fused with dCas9 derived from different organisms. We observed that the CRISPR-SadCas9-VPR activator significantly upregulated DANCR expression and stimulated the expression of chondrogenic differentiation markers such as Sox9, Col2, Acan. Moreover, implantation of the engineered rASC into the critical size defects at the calvaria of SD rats significantly enhanced the calvarial bone healing. Furthermore, we identified that DANCR promoted the rASC chondrogenic differentiation through inhibition of miR-203a and miR-214. Taken together, our results indicated that DANCR activation by SadCas9-VPR-based CRISPRa provides a novel therapeutic approach for regenerative medicine to improve bone healing.

MESENCHYMAL STEM/STROMAL CELLS (MSCS) ARE DEVELOPMENTALLY PROGRAMMED – IMPLICATIONS FOR TISSUE REPAIR APPLICATIONS

Cristina Esteves[P][1], Emma Weatherall[1], Viktorija Avilkina[1], Yennifer Cortes-Araya[1], Susan Dan-Jumbo[1], Claire Stenhouse[1], Francesc Xavier Donadeu[1]

Consistency in clinical outcomes is key to the success of therapeutic Mesenchymal Stem/Stromal cells (MSCs) in regenerative medicine. However the properties of MSC preparations can vary significantly with different factors. We studied the effects of developmental programming associated with intrauterine growth restriction (IUGR) on MSC properties. IUGR affects 10-40% of newborns worldwide, results from inadequate uterine capacity and placental insufficiency of multifactorial origin, and is linked to increased risk of metabolic (e.g. diabetes) and other diseases later during life.

Here, we compared the properties of adipose-derived MSCs from IUGR (IUGR-MSCs) and normal (Normal-MSCs) newborn pig littermates. IUGR occurs spontaneously in multiparous species such as the pig where it shows features that recapitulate human IUGR.

Both MSC types grew clonally and expressed typical MSC markers (CD105, CD90, CD44) at similar levels. Importantly, tri-lineage differentiation capacity was significantly altered by IUGR. IUGR-MSCs had higher adipogenic capacity than Normal-MSCs as evidenced by significantly higher adipocyte content and expression of the adipogenic transcripts, PPARg and FABP4 after 12 days of differentiation. A similar trend was observed for fibrogenesis, where IUGR-MSCs expressed significantly higher levels of C1A1 than Normal-MSCs. In contrast, chondrogenic and osteogenic potential were decreased in IUGR MSCs as shown by a smaller chondrocyte pellet and osteocyte staining, and lower expression of the transcription factors SOX9 and RUNX2 implicated in chondrogenic and osteogenic differentiations, respectively.

In conclusion, the regenerative potential of MSCs appears to be determined prenatally and this should be taken into account when selecting cell donors in regenerative therapy programmes.

Background：

Achilles tendinitis is a common disease, which is characterized by pain, swelling, and stiffness of Achilles tendon. The purpose of this study was to investigate whether the injectable CeO2 nanoenzyme@PEG hydrogel could alleviate inflammation and degeneration of Achilles tendon.

Methods：

Thirty male SD rats were received collagenase injections into their bilateral Achilles tendons (collagenase-induced tendinopathy model). The rats were randomly divided into five groups: CeO2 NPS, CeO2 NPS+hydrogel, hydrogel, diclofenac, and control group. After four weeks' intratendinous injection, the Achilles tendons were harvested and subjected to histological analyses (HE and Masson staining). Tertiary butyl peroxide of hydrogen (TBHO) was used to treat primary tenocytes to mimic oxidative stress-mediated injury. And, inflammation levels and Nrf2 expression was evaluated after CeO2 NPS treatment. The inflammation levels were also evaluated after the cells were transfected with Nrf2 small interfering RNA.

Results:

Compared to the control and diclofenac group, CeO2 NPS treatment resulted in better healing of injured tendon with improved histological outcomes. Combination PEG hydrogels with CeO2 NPS significantly enhanced the effects of CeO2 NPS treatment along. QPCR and Western showed that IL-1β and IL-6 activity were enhanced in tenocytes after TBHO treatment. While, CeO2 NPS could induce Nrf2 activity and suppress IL-1β and IL-6 expression.

Conclusion

CeO2 NPS could enhance healing of injured Achilles tendon by NRF2 mediated inflammation suppression. CeO2 NPS PEG hydrogels composite has the potential to be clinically used to treat tendinitis.

DETERMINATION OF MINIMAL METABOLIC REQUIREMENTS OF STEM CELL SURVIVAL USING A GRADIENT GENERATING DYNAMIC MICROFLUIDIC CELL CULTURE PLATFORM

Melvin Gurian$_P$[1], Yvonne Schreurs[1], Liliana Moreira Teixeira[1], Jeroen Leijten[1]

[1] *Department of Developmental BioEngineering, University of Twente, The Netherlands*

Corresponding author's email: m.gurian@utwente.nl

Metabolites are essential for the survival, function, and fate of cells(1,2). However, current knowledge is typically based on static culture systems in which cells are exposed to an initially chemically controlled medium, which rapidly decreases in its nutrient content over time(3). Consequently, this has limited our understanding of the critical metabolite concentrations that determine cell survival and function. We here report on the development and use of a dynamic microfluidic-based cell culture platform for the determination of minimal metabolic requirements for the survival and function of mesenchymal stem cells. The microfluidic devices was contained a gradient generator, offering long-term stable and linear control over the media used for the perfusion of a parallelized array of cell culture chambers. Subsequently, approximately 6000 cells were seeded per cell culture chamber and exposed to a range of metabolite concentrations. We confirmed that the dynamic media flow was sufficiently fast to maintain constant metabolite concentrations, while keeping the hydrodynamic shear sufficiently low (<0.3 dyn/cm2)(4) to avoid causing effects on cell behavior. Cells were then cultured over a maximal period of seven days to quantitatively determine the minimal concentrations to sustain cell survival as well as function for a panel of relevant metabolites in a time-resolved manner. This approach allowed the determination of the relative importance of individual metabolites on the survival of mesenchymal stem cells, which offers novel fundamental insights what is required to avoid starvation-induced cell loss of implanted cells and prevascular tissues.

Keywords

microfluidics; metabolites; cell survival

The key role of skeletal muscle tissue in the human body is undoubted being the controller of several vital functions including respiration and all voluntary locomotion activities. However, its regenerative capability is limited and, in the case of a significant tissue loss, there is often no medical treatment available to restore or repair the lost tissue. Therefore, it is of the utmost importance the development of new biotechnological approaches that would eventually enable the manufacturing in vitro of functional, spare tissue part ready to be implanted in the patient. In this context, we propose a biofabrication approach combined with a custom electro-mechanical bioreactor to rapidly fabricate myo-substitutes that exhibit a bio-mimetic histoarchitecture and a functionality close to native tissue.

FLUIDISED-BED BIOREACTOR FOR REGULATORY T CELLS EXPANSION; THE EARLY PHASE OF DESIGN AND OPTIMISATION

Piyanan Boonprasirt$_P$[1], Marianne J Ellis[1]

[1] *Centre for Integrated Bioprocessing, Department of Chemical Engineering, University of Bath, Bath, BA2 7AY, UK*

Corresponding author's email: pb676@bath.ac.uk

The challenge after organ transplantation is graft rejection, which can be prevented by using immunosuppressants. However, there are side effects after long-term treatment with the medications. Recently, cell-based therapy using Regulatory T cells (Tregs) to modulate the immune system has been extensively studied to replace conventional treatment. As a billion cells are needed for the treatment, cell culture device for large-scale production is required. Fluidised-beds reactors (FBR) have been developed for several chemical systems. However, only a few numbers of studies are presented in the area of mammalian cell cultures. The advantages of using a fluidised bed bioreactor (FBB) for cell culture is the system provides a realtively high cell density and well-mixing condition with low shear force [1, 2]. This study aims to design and optimized cell culture conditions in FBB for ex vivo Tregs expansion.

This study is the early phase of FBB design using the non-adhere cell line HL60 as a cell model. The first stage of FBB design was to determine two important factors; minimum fluidising velocity (umf) and terminal velocity (ut). The velocity for cell culture in FBB was selected between these two values where the cells were proliferated without losing them from the bioreactor. Then the parameters that affect mass (nutrient, oxygen, toxic metabolites) transfer and shear stress were identified. In this study, three parameters include velocity, column diameter, initial cell number were studied using Design of Experiments, with the aim of selecting operating regions ready for ex vivo Tregs expansion studies.

SMALL EXTRACELLULAR VESICLE-MIR-381 DERIVED FROM KARTOGENIN-PRECONDITIONED MESENCHYMAL STEM CELLS PROMOTE CHONDROGENESIS

Xiaomin He[P][1], Hui Jing[1], Jinghao Zheng[1]

[1] *Shanghai Children's Medical Center*

Corresponding author's email: mrxmhe@163.com

Small extracellular vesicles (sEVs) derived from mesenchymal stem cells have been shown to possess potent regenerative potential. In this research, we evaluated the chondrogenic effect of sEVs derived from Kartogenin-preconditioned human umbilical cord mesenchymal stem cells (hUCMSCs). sEVs were isolated from the supernatants of KGN-preconditioned hUCMSCs (KGN-sEV) by gradient ultra-centrifugation, and internalized by native hUCMSCs, thereby inducing the chondrogenic differentiation. The underlying mechanism of KGN-sEV induced chondrogenesis was explored by high-throughput sequencing and verified by transfection with the corresponding mimic and inhibitor. Sequencing identified the unique enrichment of a set of miRNAs in KGN-sEV, compared with sEVs derived from unpreconditioned cells (un-sEV). Overexpression/inhibition in vitro and in vivo demonstrated that this chondrogenic potential was primarily attributed to miR-381-3p, one of the most abundant miRNAs in KGN-sEV. Dual-luciferase reporter assays showed that miR-381-3p promoted chondrogenesis, through directly suppressing TAOK1 by targeting its 3’ untranslated region and thereby suppressing the Hippo signaling pathway. Collectively, our results highlight the regenerative potential of KGN-sEV to induce chondrogenic differentiation of MSCs, which is achieved mainly by delivering sEV-miR-381-3p, which targets TAOK1.

HGF/HEPARIN-IMMOBILIZED DECELLULARISED LIVER MATRIX FOR ACUTE CHEMICALS-INDUCED LIVER INJURY REGENERATION

Yi Cheng Hsieh[P][1]

[1] *Department of Biomechatronics Engineering, NTU*

Corresponding author's email: r09631037@ntu.edu.tw

Liver cirrhosis has long been considered as a common death in the world. However, the existing methods remain some challenge, such as alleviating or ceasing the symptom of the liver cirrhosis instead of regenerating hepatocytes. Notably, many research mentioned that liver fibrosis is reversible, thus once we treat liver fibrosis properly in time, it will not lead to end stage (liver cirrhosis) or even be cured.

Therefore, for the first time, a HGF/heparin-immobilized decellularised liver matrix (HGF/heparin-DLM) was developed for hepatocytes regeneration in acute chemicals-induced liver injury, which the chemicals we chose such as CHCl3 were proved to induce liver fibrosis. The amounts of immobilized heparin on DLM film was approximately 180 μg/cm2 when the initial concentration of heparin was 1 mg/mL. After three days of culture, the relative cell viability and albumin synthesis of the hepatocytes on HGF/heparin-DLM was 20-30% and 20% superior than that on normal dish, respectively.

From the result of CHCl3-induced model, the lactate dehydrogenase activity of injured hepatocytes on HGF/heparin-DLM showed lower cytotoxicity than normal one, meanwhile the relative viability of those on the film were higher, both of which showed the ability of regeneration. Last but not least, the albumin synthesis of injured hepatocytes on HGF/heparin-DLM can recover to almost 70%-80% the same level as non-toxic hepatocytes cultured on normal dish.

In summary, the HGF/heparin-DLM has positive effect on culturing hepatocytes and regenerating damaged ones. Furthermore, the HGF/heparin-DLM can be utilized for future application of liver tissue.

Corresponding author's email: saranadine@ua.pt

The immune system plays an indispensable regulatory role in the progress of bone regeneration, with special focuses on macrophage activity.[1] Inspired on the native dynamics between immune and skeletal systems, we propose an in vitro bioengineering system of a biomimetic bone niche that comprises liquefied and multilayered microcapsules co-encapsulating macrophages, mesenchymal stromal cells (MSCs), and endothelial cells (ECs). Additionally, surface-functionalized poly(ε-caprolactone) microparticles are loaded into the liquefied core to provide cell adhesion sites. To better mimic the dynamic environment of native tissues, microcapsules are dynamically cultured in spinner flasks.[2] Afterwards, liquified microcapsules are cultured up to 21 days in basal or osteogenic differentiation media. Microcapsules without macrophages are used as control. The main goal is to promote a well-orchestrated cell-to-cell interaction enabling the evaluation of the bioperformance of macrophages toward bone tissue repair. Results show that cellular viability remained uncompromised after 21 days of culture. Notably, the osteogenic osteocalcin marker was only found in microcapsules encapsulating macrophages. Mineralization evidence can be observed in all conditions, with a Ca/P ratio similar to the native hydroxyapatite. Additionally, microcapsules encapsulating macrophages released significantly more osteoprotegerin, osteopontin, and vascular endothelial growth factor comparing with the MSCs+ECs condition. Accordingly, we intend to use the proposed system as hybrid devices implantable by minimally invasive procedures for bone tissue engineering applications.

Sara Nadine acknowledges FCT for the doctoral grant (SFRH/BD/130194/2017). COATINGS OF LOW ENDOTOXIN GELATIN IMPROVE STEM CELL SEEDING EFFICIENCY AND PROLIFERATION ON 3D PRINTED DISCS IN VITRO

Jos Olijve[P][1], Barbara Vanhoecke[1]

[1] *Rousselot - Gelatin*

Corresponding author's email: JOS.OLIJVE@ROUSSELOT.COM

INTRODUCTION

Endotoxins are contaminants which can trigger immune responses in vivo. The FDA has imposed restrictions on endotoxin content in medical device for in-body use. However, in cell-based in vitro experiments there is limited attention for the side-effects of endotoxins even when endotoxin-sensitive cells are used. We examined stem cell seeding efficiency/proliferation on coatings of different materials containing different endotoxin levels.

METHODS

3D printed and plasma activated acrylic discs were coated with gelatins of different purities and molecular weights (Rousselot and Sigma) and with 'standard' materials fibronectin and laminin (Sigma). Endotoxin levels were evaluated using the EndoZyme assay. 1µg/ml of the materials were added to the discs and allowed to adhere for 90min at RT. hTERT adipose derived MSCs were seeded at a density of 5,700 cells/cm² onto the coated discs and cultured in AdipoUp medium at 37°C. Lactate release in the medium was evaluated over 7 days as read-out for cell proliferation.

RESULTS

hTERT MCS cells grew better on gelatin coatings compared to laminin and fibronectin. More lactate was released when purified gelatins were used compared with unpurified gelatins suggesting a negative effect of endotoxins on cell growth. Best results were obtained when purified, low molecular weight gelatin was used indicating that molecular weight of the gelatin coating material play a role in cell adhesion and proliferation.

CONCLUSIONS

The results from this study show that endotoxin might affect stem cell behavior. The results indicate that it is important to work with purified materials in-vitro also to enhance clinical translation.

HIGHLY POROUS, ELASTIC, INJECTABLE AND BIODEGRADABLE BIPHASIC CALCIUM PHOSPHATE CERAMIC SPONGE FOR BONE REGENERATION

Yonggang Zhang[1], Pamela Habibovic[1]

[1] *MERLN Institute for Technology-Inspired Regenerative Medicine, Department of Instructive Biomaterials Engineering, Maastricht University*

Corresponding author's email: y.zhang@maastrichtuniversity.nl

In the past decades, extensive research efforts have been expended in the fields of materials science and scaffolding technologies to fabricate synthetic bone graft substitutes. Among various types of biomaterials, biodegradable porous calcium phosphate (CaP) ceramics, such as beta-tricalcium phosphate (β-TCP) and biphasic calcium phosphate (BCP, mixture of hydroxyapatite (HA) and β-TCP) are potentially interesting bone graft substitutes, owing to their excellent osteoconductivity and, depending on their physico-chemical properties, even the ability to induce de novo bone formation [1, 2]. However, the intrinsic brittleness of CaP ceramics leads to poor processability, stability and handling properties, and their clinical application is limited to non load-bearing- applications. Herein, we developed a BCP ceramic sponge that is fully inorganic but elastic, highly porous and biodegradable, by using anisotropic calcium phosphates crystals as building blocks. The BCP sponge comprises a self-supporting highly porous network of seamlessly interwoven HA nanowires and β-TCP nanofibers. This BCP ceramic sponge exhibits several interesting properties including ultrahigh porosity (>99% free volume), interconnected porous structure and mechanical stability which are crucial factors to provide a suitable environment for cell attachment, migration, proliferation, mass transport and tissue deposition [3]. Besides, this BCP ceramic sponge is surprisingly elastic, endowing it very good stability and handling properties. Moreover, the BCP ceramic sponge is injectable and shows exciting shape-memory behavior. Taken together, the BCP sponge developed here presents an appealing alternative to current brittle ceramics for bone regeneration applications.

Acknowledgements: YongGang Zhang gratefully acknowledges the financial support by the Materials Driven Regeneration (MDR) program.

This study has investigated the capacity of secretome from bone marrow-derived mesenchymal stem cells (BM-MSCs) to prevent dopaminergic neuron degeneration caused by overexpression of alpha-synuclein in two Caenorhabditis elegans models of Parkinson's Disease (PD).

Secretome prepared in two different concentrations was tested in a more predictive model of PD that overexpresses alpha-synuclein in the dopaminergic neurons. These animals display progressive dopaminergic neurodegeneration that is age dependent. Moreover, given the transparency of the animal and the expression of green fluorescent protein in dopaminergic neurons, is possible to observe the presence/absence of these cells. Animals were treated with secretome since the embryo stage for 7 days. At the seventh day the number of intact dopaminergic neurons was scored. One of the prepared secretome was also tested in a C. elegans strain that overexpresses alpha-synuclein in the body wall muscle cells. Given the transparent body of the animal and the expression of alpha-synuclein fused to yellow fluorescent protein, is possible to observe alpha-synuclein inclusions throughout the entire body of the animal. After 4 days submitted to treatment with secretome since the embryo stage, the number of alpha-synuclein inclusions in the head region was determined. Animals treated with secretome 1x concentrated showed reduced dopaminergic neurodegeneration. Furthermore, secretome displayed a mild effect in the reduction of the number of alpha-synuclein inclusions.

These results show that secretome from BM-MSCs plays a neuroprotective role against the action of alpha-synuclein, a hallmark of Parkinson's Disease, indicating its potential as a new therapeutic solution for future regenerative medicine strategies.

"Simple but useful" is the title that can be given to the amniotic membrane after years of research in the field of tissue repair and regenerative medicine. The success of amniotic membrane process in restoring various tissue has been reported. Amniotic membrane is one of the few materials used in both soft and hard tissue engineering. However, some its mechanical and biological properties such as rapid biodegradability are an obstacle to human amniotic membrane widespread and effective use in hard tissue engineering. In the present study, human amniotic membrane decellularized matrix was developed as a substrate and then mineralization was performed by a biomimetic method. In this way, calcium and phosphate ions were deposited on the surface and inside of decellularized human amniotic membrane and strengthened its properties for hard tissue engineering application. Real-time PCR results showed a high expression of osteogenesis related genes from adipose-derived mesenchymal stem cells (ADMSCs) cultured on the surface of mineralized human amniotic membrane. Further in-vivo experiments were conducted using mineralized human amniotic membrane pre-seeded with ADMSCs and in a critical-size rat calvarial defect model. Histopathological results confirmed that the mineralized human amniotic membrane with ADMSCs sample has great potential in bone regeneration.

Neural progenitor cells (NPCs) in the adult central nervous system (CNS) have the innate capacity to regenerate specialized cells lost due to injury or disease. However, their response is often not sufficient to restore function. Biomaterials are promising tools to improve NPC-mediated repair as they can provide a pro-regenerative microenvironment and a carrier for transplantation of exogenous NPCs. Previously, we reported that hydrogels based on hyaluronic acid (HA), a native component of CNS matrix, support 3D culture of human NPCs for at least 70 days and, compared to 2D controls, bias differentiation towards neurons and oligodendrocytes (1). Culture in HA-based hydrogels with mechanical moduli on the order of those in native CNS tissue (<1 kPa) has also been reported to improve viability and affect differentiation (1,2). Here, we used a biomaterial platform to investigate the combined effects of hyaluronic acid (HA) content and matrix mechanics on the regenerative potential of human NPCs. A full factorial experimental design was used where HA was varied from 0.1–1 wt% and shear storage modulus from 200–800 Pa. Over 1 week in culture, NPC proliferation rate generally increased with increasing HA concentration and decreasing modulus. Of the 9 formulations evaluated, 200 Pa hydrogels with 0.5 wt% HA best promoted NPC differentiation towards neuronal and oligodendrocyte lineages after 2 weeks of culture. As previously reported (2), GFAP expression was not observed in 3D cultures. Results will inform future designs of NPC-instructive, hydrogel scaffolds for CNS regeneration.

We report the development of a biodegradable coaxial electrospun nanofiber scaffolds for the electrical stimulation of NSCs. This coaxial fiber consists of an external layer of polycaprolactone(PCL) and polyaniline(PANI) and a core layer composed of poly(glycerol sebacate)(PGS). The construction of such platform required the accomplishment of 3 sequential research steps:

1. Optimization of PANI to PCL ratio;
2. Electroconductivity enhancement through solvent system modulation;
3. Production of an electrospun conductive coaxial fiber.

Electroconductive fibers can be obtained from different PCL-PANI ratios 88:12,91:9,93:7,94:6 and 95:5, with conductivities ranging from 0.014 to 0.077Scm-1. All combinations tested are biocompatible for NSC culture. Electroconductivity was dependent on environmental humidity.

The solvent system for PCL-PANI fibers was optimized using TFE and hexafluoropropanol (HFP). The best combination was used to produce electrospun fibers with higher electroconductivity (0.2Scm-1) at a higher humidity (50%). This effect was attributed to the pseudo-doping of PANI by HFP. The AC electrical stimulation of NSCs was performed and differentiation was enhanced.

Finally, coaxial PCL-PANI/PGS fibers were produced (951±465nm of diameter, electroconductivity of 0.063±0.029Scm-1). The mechanical properties (ε=1.3MPa) and hydrophilicity (38º) were also favorable for NSC culture. iPSC differentiation towards the neural lineage was favored by the presence of the coaxial fibers as shown by the upregulation of DCX, NCAM, NEUN and GAD67 neural markers, without and with electrical stimulation.

Electrical stimulation can have various beneficial effects on stem cells, including the promotion of their proliferation and differentiation profiles. This is essential for tissue engineering strategies, as the phenotype of the obtained cells is better suited to mimic that of the target tissue. They can be used as reliable in vitro models for disease study and cell transplantation.

The design of platforms suitable for electrical stimulation of stem cells requires a multidisciplinary approach. Through the manipulation of material's chemistry, tri-dimensionality and bioactive cues it is possible to direct cell colonization and create different cell domains that can mimic the in vivo complexity of tissues.

Our group has worked on different electrospun composites to create suitable electroconductive platforms for the electrical stimulation of stem cells, aiming at neuronal, cardiovascular, cartilage and bone tissue engineering applications. Some of the strategies include (a)optimization of poly(3,4-ethylenedioxythiophene)(PEDOT) composites, (b)doping of polybenzimidazole(PBI), (c)cross-linking of polyacrylonitrile(PAN), (d)optimization of polycaprolactone(PCL)–polyaniline(PANI) blend, and (e)production of electroconductive coaxial fibers.

Our results justify a combined approach of materials science with the glycobiology of the cultured cells for the development of biomimetic electroconductive platforms. We believe such strategy is essential to develop biomaterials capable of enhancing stem cell survival and differentiation. In the future, such strategies can be used to improve the tissue integration of transplanted cells.

Osteosarcoma (OS) is a highly aggressive primary bone tumour, which preferentially arises in the metaphysis of actively growing long bones. OS predominantly affects children and young adults, and it is characterized by synthesis of disorganized mineralized bone by the tumour cells (1). Unfortunately, current in vitro preclinical models such as monolayer cell culture, fail to recapitulate the tumour microenvironment and thus accurate neoplastic behaviour, ultimately hindering therapeutic discovery (2). The employment of three-dimensional OS models has the potential to better recreate the spatial, mechanical, and biological complexity of the tumour microenvironment, key elements crucial for understanding tumour prognosis and treatment effectiveness (3).

In this study, we propose an in vitro primary 3D OS Model (3D-OSM) comprising an inner core of OS cells embedded within biocompatible Gelatin Methacryloyl (GelMA), a surrounding shell of bone-mimicking scaffold (Polycaprolactone), and cultivated in a microfluidic system device. The core mimics the stromal fraction of OS, while the shell represents the bone niche where the tumour usually arises and growth. The model has been validated using OS cell lines and patient derived tumour cells (canine osteosarcoma) with metabolic assays to measure cell viability during time. Non-destructive computed tomography and confocal imaging was used to evaluate the extravasation of tumour cells toward the scaffold.

Our findings establish the conditions that ensure optimal survival and proliferation of OS tumour cells and validates our biofabrication approach. Further development of the 3D-OSM could revolutionize preclinical high throughput compound discovery, together with potential personalized medicine treatments.

Pancreatic ductal adenocarcinoma (PDAC) has the lowest survival of any solid tumour, with a cumulative five-year survival rate of 6.8% (1). Despite the development of new anticancer agents and immuno-oncology drugs, PDAC remains highly refractory to systemically delivered therapies. This is due in part to impaired drug delivery caused by the (i) lack of local vasculature at the tumour site and (ii) dense fibrotic tissue restricting penetration and distribution of drug within the tumour [2]. These factors cannot be easily overcome by systemic therapies because of dose related toxicities that preclude the use of high drug concentrations to achieve therapeutic response. In situ drug delivery strategies could overcome those difficulties. We fabricated pNIPAM-Au structures able to release Doxorrubicin on-demand upon short near- infrared (NIR) light exposure at determined time points over 3 days. The release from pNIPAM-Au stimulated was compared against passive release, free-drug, pNIPAM and pNIPAM-Au alone. The release profile of the samples showed an increment of drug release upon NIR exposure (~30%) compared to the non-stimulated samples. In vitro testing was carried using pancreatic cell lines BxPC-3, MIA PACA-2 and PANC-1 in 2D cell cultures and 3D spheroids models. The results showed that local delivery initiated by NIR triggered cell apoptosis thus providing a promising approach for localised management of PDAC.

TOWARDS A BETTER TISSUE REGENERATION THROUGH BIOMATERIAL-AIDED IMMUNOMODULATION: HARNESSING THE INNATE AND ADAPTIVE IMMUNE RESPONSES

Donghui Zhu[P][1]

[1] *Stony Brook University*

Corresponding author's email: donghui.zhu@stonybrook.edu

Immune system plays critical role in the process of tissue regeneration after injury, therefore, it is particularly important to take advantage of immune response to achieve the desired tissue restoration. In recent decades, biomaterial-aided immunomodulation has shown promising potential towards improved regeneration through harnessing the immune response during tissue repair process. A variety of factors, including physical signals, chemical cues and biological modulators, play great influence on immune cell functions and consequently regulate tissue regeneration. With respect to topological structure, rounded shape, large particle size and porosity, as well as high roughness are reported to reduce inflammation and resulted in less fibrosis when comparing to sharp, small and smooth structures. Other physical properties, such as low mechanical strength, low charge density and high hydrophilicity, help to inflammation resolution. Chemical carboxyl groups result in much less inflammatory cytokines comparing to amine-modified surface. Metal element such as magnesium is found to promote macrophage toward M2 phenotype (anti-inflammatory) polarization with increased production of anti-inflammatory cytokines. Besides the aforementioned methods, delivering biofactors to the target site with the help of biomaterials is considered a more effective way for immunomodulation. One strategy is to suppress pro-inflammatory cytokines production. An alternative way is to directly deliver anti-inflammatory agents such as IL-10 cytokine, genes, exosomes and even stem cells to help resolve inflammation and promote tissue regeneration. Based on these knowledges and strategies, further application of immunomodulation aided with biomaterials to regenerate bone, cartilage, muscle, skin and nervous system showed exciting prospect for tissue regeneration.

Articular cartilage, distributed at the joint surface mainly consists of hyaline cartilage playing a role in load-bearing and lubricating. The formation of hyaline cartilage with healthy biological function is the main challenge in cartilage repair. Several studies reported that the regulation of cytoskeleton on chondrocyte differentiation by different mechanisms. In this study, the stability of microtubule (a member of the cytoskeleton) was positively correlated with cartilage-related gene expression in human osteoarthritis (OA) cartilages and the process of cartilage degeneration in the mouse OA model. The up-regulation of Ace-tubulin by docetaxel, a marker of the stable microtubule, improved the expression of collagen II, SOX9, and the SMAD3 (down-stream of the TGF-β pathway) in chondrocytes (CHs) and synovial mesenchymal stem cells (SMSCs), and promoted the cartilage regeneration in vivo. Then, we found that microtubule stabilization exhibited different mechanisms in the chondrogenesis of CHs and SMSCs. In the CHs, microtubule stabilization first promoted the yes associated protein (YAP), an important mechanotransduction protein, translocated to cytoplasm, and became p-YAP, which was inactive form. The increases of p-YAP kept the number and length of primary cilia and promoted cartilage-related proteins. As for SMSCs, microtubule stabilization directly led to the inhibition of YAP expression and primary cilia formation to prompt the TGF-β pathway and chondrogenesis differentiation. Taking together, the multistep effect of microtubule stabilization through the regulation of YAP and primary cilia to the different stages of the chondrocyte cell line, including CHs and MSCs promoted the hyaline cartilage phenotypes gene expression and cartilage regeneration.

Chronic skin wounds are characterized by a persistent and dominant pro-inflammatory stimulus that delays tissue repair1. Cell-derived extracellular matrices (CDMs) hold a native tissue-like constitution and can be engineered in vitro to exhibit specific bioactivity and biophysical properties2,3. By combining the pro-regenerative secretome of bone-marrow mesenchymal stem cells (MSCs) with anti-inflammatory high-molecular weight hyaluronic acid (HA), we anticipated the generation of CDMs with enhanced healing potency for the treatment of chronic wounds.

Addition of HA to MSCs increased the deposition of fibronectin, a phenomenon we demonstrated to stem from HA's participation in fibronectin fibrillogenesis. To enhance ECM deposition further we used ficoll, a macromolecular crowder used in tissue engineering applications that by definition occupies space and enhances the kinetics of biological reactions4. The resulting CDMs, isolated at day 6, were rich in fibronectin, collagens I/IV, and heparan sulfate proteoglycans. To confirm that the CDMs exhibited the desired bioactivity, pro-inflammatory macrophages were exposed to CDMs in vitro. As a result, macrophages secreted lower levels of pro-inflammatory factors (i.e. tumor necrosis factor-α), as compared to controls without CDMs and CDMs without HA/ficoll.

Hydrogels formed with anti-inflammatory CDM were implanted in a murine chronic skin wound model, where they accelerated wound closure, as compared to empty hydrogels and CDMs with unspecific bioactivity.

In conclusion, we have elucidated one of HA's mechanisms of action, important to formulate fibronectin-rich platforms for tissue engineering. Moreover, the combination of MSC's secretome, HA and ficoll produced an anti-inflammatory CDM with enhanced properties capable of promoting wound healing.

ACTIVATION OF TRPV1 ALLEVIATES OSTEOARTHRITIS BY INHIBITING TYPE I MACROPHAGE POLARIZATION VIA CA2+/CAMKII/NRF2 SIGNALING PATHWAY

Zhongyang Lv[P][1], Xingquan Xu[1], Ziying Sun[1], Jiawei Li[1], Hu Guo[1], Yannick Xiao Fan Yang[1], Rui Wu[1], Qing Jiang[1], Dongquan Shi[1]

Osteoarthritis (OA) is now well accepted as a low-grade inflammatory disease. Type I macrophage (M1) plays an important role in promoting synovitis during OA progression. Transient receptor potential vanilloid 1 (TRPV1), a pronociceptive non-selective cation channel, has been found expressed by M1 in OA synovium. The purpose of this project is to investigate whether targeting TRPV1 can inhibit M1 polarization and further retard OA progression. After stimulated by the TRPV1 agonist, capsaicin (CPS), the expression levels of M1 markers (IL-1β, IL-6, TNF-α, iNOS, and Cox2) in LPS-induced M1 cells were significantly down-regulated. Activating TRPV1 in M1 could promote nuclear factor E2-related factor 2 (Nrf2) nuclear localization, which was abolished by Nrf2 inhibitor, ML385. Under the stimulation of CPS, ML385 promoted M1 markers expression. CPS could stimulate Ca2+ influx in M1 cells. Both of using EDTA or Ca2+-free medium inhibited the CPS-stimulated Nrf2 nuclear localization. TRPV1 activation-induced Ca2+ influx promoted the phosphorylation of Ca2+ /calmodulin-dependent protein kinase II (CaMKII) in a time-dependent manner, and further promoted Nrf2 nuclear localization, which was abolished by CaMKII antagonist, KN-93. In vivo, compared with the OA group, intra-articular injection of CPS could reduce the joint swelling and osteophyte formation significantly. MicroCT and histological staining of 4- and 8-week rat knees showed less osteophyte formation, cartilage loss, and inflammatory cells infiltration in the OA+CPS group. In conclusion, we found that activating TRPV1 can inhibit M1 polarization via the Ca2+/CaMKII/Nrf2 signaling pathway and then alleviate OA in vivo, these findings provide a potential therapeutic target for OA.

WORKING TOWARDS A REGENERATIVE THERAPY FOR OSTEOARTHRITIS: INFLUENCE OF STEM CELLS

Background: Osteoarthritis is incurable and a leading cause of disability worldwide. Mesenchymal stem cells (MSCs) have recently been used to treat osteoarthritis due to their anti-inflammatory and pro-regenerative characteristics. Interestingly, the few clinical trials utilising MSCs to treat knee osteoarthritis have not demonstrated consistent benefits[1]. This study aims to understand the variable efficacy of stem cell therapy using an in vitro model of a human osteoarthritic joint.
Methods: MSCs were co-cultured with human synovial fibroblasts (HSFs) isolated from osteoarthritic tissues, for 21 days in growth, osteogenic and chondrogenic media (simulating relevant conditions in the joint). Cell interactions were assessed using RT-PCR (n=4) and histology (n=2).
Results: MSCs co-cultured with osteoarthritic HSFs showed increased inflammation (MMP2, ADAMTS5) and impaired ability to form new bone (reduced BSP, SPP1 expression and calcium deposition) and cartilage (reduced COL2A1, ACAN expression and proteoglycan deposition) at 21 days, suggesting that the osteoarthritic joint is an inhibitory environment that reduces the therapeutic effects of MSCs. Furthermore, short-term (3 days) exposure of the osteoarthritic HSFs to MSCs ('pre-conditioning') was insufficient for sustained modifications to their diseased phenotype. The osteoarthritic HSFs, whether previously exposed to MSCs or not, had similar expression profiles of inflammatory markers, and also similar negative effects on MSCs, including inflammatory marker upregulation (e.g. IL-8, ADAMTS4) and impaired chondrogenesis.
Conclusion: Diseased cells in an osteoarthritic joint can create an inhibitory environment that negatively affects the therapeutic effects of MSCs following injection. Future regenerative therapies for osteoarthritis may benefit from using the secreted products of stem cells.

Critical-sized bone defects require additional interventions to restore. 3D-bioprinting has emerged as a promising approach in bone tissue engineering to recapitulate a living tissue with greater precision. However, development an ideal bioink with high osteogenic potential remains challenging. Herein, we developed an ECM-based hydrogel employing decellularized bovine bone and calcium phosphate cement(CPC) as a bioink for 3D-bioprinting. A demineralization/decellularizion protocol was set up and the decellularized bone ECM (dECM) was further characterized in terms of morphology, collagen and DNA contents. dECMhydrogel combined with different concentrations of CPC was mechanically and rheologically analyzed to achieve the appropriate bioink based on physical properties. Adipose derived mesenchymal stem cell (ADMSCs)-laden hydrogels were then assessed using Live/Dead, real-time PCR and histological analysis to evaluate cell proliferation and osteogenic capacity of fabricated hydrogel. H&E staining and DNA contents demonstrated that our protocol could efficiently decellularize bone tissue and the number of cells had extremely decreased. Collagen assay showed that the decellularization process did not affect the amount of collagen present in the tissue. As expected, CPC increased the mechanical strength of hydrogel. The rheological analysis confirmed gel behavior trait as well as shear-thinning property of bioink, which is necessary for 3D-printing. Cellular experiments revealed the viability of cells and their differentiation into osteogenic lineage in hydrogel after 21 days. In sum, these findings highlight the promising potential of this hydrogel as a suitable bioink for 3D-bioprinting and hold great promise as a novel therapeutic approach in bone tissue engineering for future studies.

IMPROVED LONG-TERM VOLUME RETENTION IN FAT GRAFTING USING 3D PRINTED PCL SCAFFOLDS WITH BIONIC STRUCTURE

Wanting Bao[P][1,2,3]

[1] *Shanghai Key Laboratory of Tissue Engineering*

[2] *Shanghai Ninth People's Hospital*

[3] *Shanghai Jiao Tong University School of Medicine*

Corresponding author's email: bigbaobao@sjtu.edu.cn

Background: Autologous fat grafting has played an increasingly important role in breast reconstruction. However, mature adipocytes are sensitive to stress and hypoxia, which causes a high rate of necrosis, absorption, and fibrosis. The anatomical structure of breasts shows that adipose tissue is surrounded by suspensory ligaments. These ligaments provide mechanical support to keep the special shape of breasts. Inspired by this, bionic scaffolds are assumed to be beneficial for fat grafting.

Objective: To evaluate the effect of bionic scaffolds on long-term volume retention in fat grafting and to explore potential mechanisms.

Method: PCL scaffolds were fabricated by 3D-printing technique. Liposuction fat was compounded with scaffolds and implanted subcutaneously in nude mice. After 2,4,8, and 12 weeks, gross and histological observations were performed to evaluate the survival of adipose tissue. The percentages of adipocytes, vacuoles, and fibrosis were estimated through HE and Masson staining. The adipocyte viability was analyzed by Perilipin-1 and vascularization by CD31. IHC and qPCR were used to detect the expression of HIF-1α and VEGF.

Results: The retention rate of the experimental group (fat with scaffolds) was significantly higher than that of the control group (fat without scaffolds). The experimental group exhibited fewer vacuoles, less fibrosis, and elevated vascularization. The lower expression of HIF-1α in the experimental group indicated that hypoxia was reduced at early stage.

Conclusion: The scaffold can provide mechanical support to resist skin tension and tissue internal pressure. Therefore, the state of hypoxia can be alleviated, which improves the long-term retention rate of implanted fat.

Myocardial Infarction causes the irreversible loss of billions of cardiomyocytes and the beginning of reparative healing, resulting in excessive deposition of highly crosslinked collagen by Myofibroblasts (MyoFs), fibrosis, stiffening, and cardiac function impairment [1]. Currently, there is no effective treatment to reverse cardiac fibrosis, so heart transplantation remains the only available clinical approach. In this context, in vitro models able to reproduce post-infarct microenvironment for preclinical drug screening are needed.

In this work, an engineered in vitro 2D-model of human cardiac fibrotic tissue was designed in order to reproduce small extensions of early stage myocardial fibrosis. In detail, bioartificial scaffolds based on polycaprolactone (PCL) and Gelatin (G) were fabricated. PCL scaffolds were prepared by electrospinning having random morphology, narrow nanofibers size distribution and interconnected porosities, closely mimicking the architecture of native extracellular matrix (ECM). To further mimic the ECM chemical composition, PCL scaffolds were surface modified using a mussel-inspired strategy: G (Type A) was grafted exploiting an adhesive 3,4-Dihydroxy-D,L-phenylalanina (DOPA) precoating. Physicochemical and mechanical characterizations were performed to assess functionalization success and coating stability. Human Cardiac Fibroblasts (HCFs) isolated from human ventricle were then cultured on the scaffolds at a density of 7x104 cells/cm2. Their adhesion, functional organization and biomatrix deposition were analysed at long-term culture times. Biological validation demonstrated that bioartificial scaffolds promote HCFs adhesion, spreading and deposition of the typical cardiac ECM proteins.

This project has received funding from the European Research Council (ERC) under the European Union's Horizon 2020 research and innovation programme grant agreement No 772168.

The liver as a vital organ can suffer from various diseases that make the survival of the patient critical. The only current treatment is liver transplantation, which has many challenges. One alternative approach is liver tissue engineering to using scaffolds assisting or replacing the damaged liver. For the liver, as soft tissue, biopolymers coupled with natural hydrogels are commonly used. In this study, PLA (Poly Lactic Acid) was used as the input of a Fused Deposition Modeling-FDM 3D printing machine to investigate the effect of gelatin surface coating methods on HepG2 cells. The 3D printed scaffolds were coated with 1 and 2% gelatin by three methods “Duplex, Entrapment, and M-Entrapment.” The printing process and coated gelatin were structurally examined by micro and macro images to compare the homogeneity of the coating. In vitro toxicity MTT assay was performed by HepG2 cell culture on scaffolds that showed no toxicity. Also, cell morphology was observed by SEM images, in gelatin-free samples, the cells were aggregated due to low affinity for adhesion to a PLA surface. By comparing cell adhesion and surface homogeneity, the M-Entrapment method was considered to be a more hostile surface for cells.

Direct reprogramming of cardiac fibroblasts into induced cardiomyocytes (iCMs) represents a promising strategy to restore cardiac functions after myocardial infarction [1]. Previous studies have identified a combination of microRNA-mimics (miRcombo: miR-1, 133, 208, 499) able to directly reprogram mouse fibroblasts into iCMs [2]. Respect to methods based on the expression of cardiac transcription factors via viral vectors, microRNAs can be delivered into the cell cytoplasm by safer nanocarriers, paving the way towards in situ treatments [3]. The work was aimed at the development of injectable hydrogels for in situ delivery of microRNA/nanocarriers, further provided with biochemical cues enhancing direct reprogramming of adult human cardiac fibroblasts (AHCFs) into iCMs. Initially, miRcombo was found to trigger transdifferentiation of AHCFs into iCMs, inducing cardiac markers upregulation (11% cTnT-positive cells after 15 days) and cardiac-like functionality (38% cells with calcium transients after 30 days) [4]. Cardiac markers were further upregulated for miRcombo-transfected cells cultured on 2D plates coated with gelatin, laminin or AHCF-derived biomatrix [5] with biomatrix triggering significantly higher cTnT expression. As Algisyl (based on alginate) and Ventrigel (based on porcine extracellular matrix) [6] are the only hydrogels under clinical trials for post-infarct treatment, we prepared injectable hydrogels based on alginate functionalized with RGD and/or biomatrix with dual (ionic and click-chemistry-driven) crosslinking ability. Hydrogels loading lipoplexes/miRcombo [7] are under study for their ability to directly reprogram AHCFs in vitro.

This project has received funding from European Research Council (ERC) under European Union's Horizon 2020 research and innovation programme (grant agreement 772168).

PHEMA-based hydrogels are well-studied materials for tissue engineering due to their biocompatibility, controllable synthesis and tuneable physicochemical properties [1]. These properties allow PHEMA hydrogels to be suitable candidates for use in peripheral nerve regeneration. This work shows the synthesis, characterisation and initial biocompatibility studies of a range of PHEMA-based hydrogels. Homogeneous hydrogels with storage moduli in the range of 8-12 MPa were obtained via redox-initiated free-radical polymerisation, with maximum liquid uptakes of approximately 200 % obtained over 48h without disturbing the bulk dimensions. Copolymerisation with gelatin methacryloyl (GelMA) in concentrations up to 20 % w/w allowed the improvement of both degradability and biocompatibility [2]. GelMA containing hydrogels displayed sustained losses in mechanical properties after incubation in collagenase I solution, showing a 5 MPa decrease in storage modulus and increased liquid uptake. Functionalisation of gel surfaces with proteins present in the peripheral nerve extracellular matrix allowed improvement in cell viability and proliferation for adipose-derived stem cells, Schwann cells and DRG populations [3]. Therefore, the aforementioned PHEMA-based hydrogels are envisioned to be used as synthetic platforms to investigate these important cell populations in peripheral nerve regeneration and ultimately their suitability as artificial nerve conduits.

Studies on new modalities that can accelerate the healing process of skin injuries are still in progress. One of the attractive areas in this field, which has shown promising results, is application of cellular and tissue engineered products. The aim of this study is to use a macrophage-containing tissue engineered amniotic membrane as a dermal substitute in an animal model. After written consent, human amniotic membrane (HAM) was collected at the caesarian section in the operating room. HAM was decellularized using a detergent-based method. Macrophages were extracted from peritoneum of C57 male mice and characterized using CD68, CD163 and CD206 markers by flow cytometry and then, were seeded on the decellularized HAM. The cytobiocoampatibilty of the scaffolds were investigated using MTT assay. Afterwards, the scaffolds were implanted on the back skin of C57 male mice. Results were analyzed on days 1, 3, 7 and 28 post-injuries for the quality of healing using both visual scale and H&E staining of histological sections. The results have shown significant difference in acceleration and promotion of wound healing in HAM scaffolds seeded with macrophages compared to other experimental groups (HAM alone and control) on days 3, 7 and 28 post-injuries. Accordingly, the macrophage-containing skin substitute could be considered as a potential modality for acceleration of skin wound healing.

Understanding the effects of storage time and preservation method on the biological and physical characteristics of biomaterials have always been a concern in tissue engineering and regenerative medicine. In the present study, we evaluated the impacts of storage time on decellularized placental sponges (DPS) in vitro and in vivo. For this purpose, the scaffolds were incubated for one, three and six months after decellularization at -20 °C and their antibacterial, angiogenic and biocompatibility properties were examined on each time intervals. The decellularized samples demonstrated a uniformed structure with interconnected networks in comparison with intact placental scaffolds. The preservation time did not affect the cyto-biocompatibility of DPSs against Hu02 foreskin fibroblast cells and also collagen and VEGF contents. Compared to other experimental groups, the six months preserved samples showed a decreased neovascularization assessed by chorioallantoic membrane assay and subcutaneous implantation on NMRI male mice. Also, in six months DPSs, the levels of CD4+ and CD68+ infiltered cells were elevated dramatically compared to other DPSs. The antibacterial characteristics of the samples decreased over the storage time. According to the results, the three months-stored DPSs were considered as the optimum preserved samples due to maximum antibacterial activity and increased new blood vessel formation. This presented storage method can be considered for other decellularized placental products used in biomedical applications.

The most common treatment for corneal blindness is donor cornea transplantation, but a severe worldwide shortage of donor corneas leaves an estimated 12.7 million patients awaiting transplantation.[1] Donor transplantation needs to be supplemented with bioengineered solutions in order to reach the millions of patients. In Fagerholm et al. [2,3], we showed that cell-free, bio-responsive hydrogels grafted as corneal implants induced the patients' own endogenous stem cells to regenerate their corneas. We have subsequently shown that inflammation suppressing polymers can be integrated into the implants for use in patients with more severe pathologies [4]. Most recently, to address corneal perforation and conditions that can be treated by an anterior lamellar graft, we developed a synthetic, biocompatible and adhesive liquid hydrogel (LiQD Cornea) that would be used in place of toxic cyanoacrylate glue used to seal perforations, as well as human donor tissue for anterior lamellar graft replacements.[5] LiQD cornea is applied as a liquid, but quickly adheres and gels within corneal tissue defects – a bit like a dental filling. Then its similarity at a molecular level to a natural tissue framework promotes tissue regeneration, treating corneal perforations effectively without the need for transplantation. Further, due to the synthetic nature of the material, risks associated with immune rejection and disease transmission are also reduced compared to natural products in both our solid and liquid implants. We see LiQD Cornea potentially allowing for clinical application in outpatient clinics instead of operating theaters, maximizing practicality, and minimizing healthcare costs.

Bioprinting is a technology with high potential in enabling the tailored arrangement of different cell types in a tissue mimetic spatial manner. However, it is not yet completely understood how the printing process affects the mechanobiological cues of the cells. To characterize better how the bioprinting process impacts the bioink embedded cells, we simulated the fluid flow inside the nozzle. Two well-established bioprinting methods (drop-on-demand and microextrusion) were analyzed using FEM and data were validated experimentally. Our simulation results reveal that in drop-on-demand bioprinters, the flow is mostly in the transient regime and the onset and duration of the deformation of the cells in the nozzle is in order of microseconds (~500-10000µs). Using the microextrusion technique, the flow regime is in steady-state condition and onset of deformation is in the same order; however, its duration is comparatively higher (~seconds) and still a function of needle length and flow rate. While cells are continuously under the effect of hydrostatic pressure during entire duration of printing, the shear stress imposed on the cells is verified just at the moment that bioink is ejected from the nozzle (micro/milliseconds). Preliminary experiments show that the application of long-term hydrostatic pressure affects the expression level of genes involved in focal adhesions and ATP-level. In conclusion, our results confirm that the bioprinting process affects specific functional cell characteristics. These findings could guide the development of printer nozzles with cell-preserving features and may be adopted as initial strategies for optimizing the technology used for cell-laden hydrogels printing.

Corresponding author's email: iml28@cam.ac.uk

Cochlear implants (CI) have brought sound to millions with profound hearing loss. However, today's CI performance is still limited by the imprecise control of electrical stimulus and, thus, 'blurring of the perceived sound'. The electrical spread characteristics in cochleae depends on the CI positions in cochleae, and the electrical and anatomical features of human cochleae, which cannot be fully replicated in animal models or human cadaver models. Here, we report the development of a library of 3D printed electro-anatomical cochlear phantoms via constructing human representative cochlear geometry in a tuneable electro-mimicking bone matrix. By measuring the stimulation spread characteristics of all 3D printed phantoms using electric field imaging and deploying a machine learning model to simulate the experimental data, our platform can comprehensively emulate the stimulation spread characteristics resulting from the wide-ranging electro-anatomical features of the human cochleae. Validated with clinical data, our platform can correctly predict patient intra-cochlear stimulation spread characteristics with over 85% accuracy. We then exploited this platform to decipher the intricate relationship between the stimulation spread characteristics and the cochlear electro-anatomical features, hence predicting the patient cochlear features that will be more prone to the stimulation spread. Further to this, our platform can reproduce patient's stimulation spread characteristics via a physical 3D printed phantom. We anticipate that such platform will be particularly beneficial in facilitating the development of CIs. Our methodology can be readily transferrable to other anatomical sites, paving the way for advanced testing platform to screen new electronic implants.

3D PRINTED JANUS SCAFFOLDS FOR NANOVIBRATION-DRIVEN BONE REGENERATION

Sandra Camarero-Espinosa$_P$[1,2], Lorenzo Moroni[2]

[1] *POLYMAT*

[2] *Maastricht University*

Corresponding author's email: sandra.camarero@polymat.eu

Physical stimulation of cell cultures activates mechanotransduction pathways that result on the modulation of cellular functions such as migration, differentiation or survival. Despite the great potential shown by in-vitro models, these are generally based on sophisticated systems with compromised potential to be exploited in-vivo, being the main short-coming the incapability to apply the stimuli “externally” and on a controlled manner. Here, we present the first report on dynamic 3D printed scaffolds that can be remotely actuated via application of ultrasounds, resulting on a controlled mechanical nanovibration that is transmitted to neighboring cells. Dynamic scaffolds are based on Janus structures that are spontaneously formed via phase-segregation of polycaprolactone (PCL) and polylactide (PLA) blends during the 3D printing process. Janus scaffolds behave as ultrasound transducers (acoustic to mechanical) with a mechanically active, PLA and a backing material (PCL). Remote stimulation of Janus scaffolds led to an enhanced cell proliferation, matrix deposition and osteogenic differentiation of cultured bone marrow derived stromal cells via formation of voltage-gated calcium ion channels.

Chondrocytes residing in the articular cartilage are surrounded by a pericellular matrix which sustain the compression and shear strain forces exerted during movement. Little is known about the development of this native pericellular matrix. Here, we employed a cartilage-on-chip platform which allow application of multi-modal mechanical stimulation [1] to identify the type of mechanical stimulation required for the formation of this protein shell around chondrocytes grown in an agarose matrix (2% w/v). After 7 days of culture in static conditions, human chondrocytes were cultured for other 7 days in static or dynamic conditions (compression or compression & shear stress) (1 Hz for 1 hour a day). Medium was collected from the chip to quantify IL-6 using enhanced SPRi [2]. IL-6 secretion by the mechanically stimulated samples was significantly higher compared to the static conditions for the first 7 days, suggesting a role of mechanical stimulation in IL-6 production. In both dynamic and static conditions IL-6 secretion reduced over time suggesting cell adaptation to their on-chip environment. Aggrecan, Col II & Col VI immunofluorescence revealed higher pericellular matrix formation in dynamic conditions compared to static culture. Interestingly, cells exposed to the combined compression and shear strain, compared to only compression, presented double cells and higher Col II matrix deposition, both characteristics of healthy articular cartilage. Alcian blue stain revealed pericellular matrix formation (2,5 µm thickness) in both dynamic conditions further supporting the development of a native pericellular matrix. Our cartilage-on-a-chip platform supports the formation of quasi-native pericellular matrix.

In recent decades tissue engineering has seen a revolution in the development of novel materials and bio-fabrication methods. The move from classical 2D to 3D scaffolds, which mimic the natural habitat of cells, is important and novel 3D printing technologies are constantly being developed.[1] 3D printing (additive manufacturing) is becoming one of the preferred methods to generate complex scaffolds for a large variety of biomedical engineering applications e.g. wound healing patches, patient specific implants and devices. Successful implementation of these scaffolds depends on the biomaterials, their properties and the manufacturing technologies used. In this context, Polyhydroxyalkanoates (PHAs) have exhibited exceptional value.[2-3]

PHAs are natural biopolymers that are sustainably produced via bacterial fermentation and have been steadily gaining popularity for biomedical engineering applications due to their excellent biocompatibility towards a large variety of cell types.[4] Moreover, their tuneable mechanical properties, as well as non-toxic biodegradability via surface erosion make them excellent candidates for scaffold materials.[2] Furthermore, PHAs are easily processable and therefore excellent materials for additive manufacturing.

Here, we demonstrate the successful 3D printing of PHAs via fused deposition modelling of various CAD-designed structures for use in tissue engineering.[1] Further, we demonstrate the ability to tune the mechanical properties of our scaffolds via both material properties as well as by altering the design of the printed structures. Short-term degradation studies are performed with the printed constructs and cell compatibility is assessed. Finally, the prospects of PHA-printed scaffolds for next generation in-vitro and in-vivo studies are discussed.

The synovial membrane preserves the integrity of the knee joint and is a key player in the development of rheumatoid diseases. These tissue is mainly composed of synovial fibroblasts and macrophages. During joint movement cells in the synovial membrane are exposed to mechanical stress. Despite this well known fact, little is known about the synovial tissue response to mechanical stimulation. Here, we present a synovial-membrane on-chip platform that combines both synovial fibroblasts and macrophages and allows multi-directional mechanical stimulation (inspired by [1]), by independently addressing 6 actuation chambers deforming a flexible membrane covered by a monolayer of fibroblasts and macrophages. The system exerts up to 60% of deformation which allows both physiological and hyper-physiological stretching of the cell-covered membrane. Negative pressure (-350 mbar) can be applied to each of the 6 actuation chambers independently or in combination, allowing multi-stretching patterns. After a collagen coating of the flexible porous PDMS membrane, synovial fibroblasts were seeded and cultured for 7 days in static conditions (confluency reached after 1 day). Application of hyper-physiological stretching of the membrane, but not physiological stretching for 1 hour a day (1 Hz) induced a high level of cell death of synovial fibroblasts cell four days later. In addition the system was compatible with co-culture of synoviocytes and macrophages (cell viability up to 14 days). With this innovative organ-on-chip platform we are, for the first time, able to recapitulate and study the mechanical actuation of an engineered synovial membrane in healthy and diseased conditions.

Stem cells, with their inherent ability to self-renew and differentiate, play an important role in tissue development, tissue homeostasis, and wound repair. Due to these properties, stem cells offer great potential in the field of tissue regeneration. However, their regenerative ability and cellular process is controlled by multi-factorial signals presented in their natural resident microenvironments. Therefore, to effectively direct tissue regeneration in vitro, the development and engineering of smart interfaces that can finely regulate stem cell behavior is highly desired. Mesoporous silica nanoparticles (MSNs) represent an interesting material to create bio-interfaces for enhanced regenerative application by enabling close control over surface physiochemical properties. Moreover, the mesoporous structure and versatile surface functionalization properties make MSNs excellent materials for cargo-loading and controlled drug delivery.

In this project, we aim to use DNA functionalized MSNs (MSNs-ssDNA) to create 2D bioengineered films to guide stem cell function, where short DNA duplex can serve as a highly programmable linker to capture specific bioactive ligands over the MSNs surface and MSNs can be used as biomolecules delivery carrier. For this, monodisperse MSNs with a narrow size distribution around 200 nm have been synthesized. Oligonucleotides were grafted to MSNs and the DNA graft ratios were quantified by Nanodrop. MSNs-ssDNA based film was further prepared and characterized by Scanning Electron Microscope. This platform is useful for diverse applications in tissue engineering. It can be applied as highly tailored biomimetic interface to elicit desired cell response, or as coating materials to improve biological properties and tissue integration of implants.

Biotherapeutics have achieved global economic success due to their high specificity towards their drug targets, providing exceptional safety and efficiency. The ongoing shift away from small molecule drugs towards biotherapeutics heightens the need to further improve the pharmacokinetics of these biological drugs. Three pervasive obstacles that limit the therapeutic capacity of biotherapeutics are proteolytic degradation, circulating half-life, and the development of anti-drug antibodies. These challenges can culminate in limited efficiency and consequently warrant the need for higher drug doses and more frequent administration. We have explored the coupling of biotherapeutics to long-lived and biocompatible red blood cells (RBCs) to address limited pharmacokinetics. Butyrylcholinesterase (BChE), for example, provides prophylactic protection against organophosphate nerve agents (OPNAs), yet the short circulation life of the drug requires extraordinary doses. Herein, we report the rapid and tunable chemical engineering of BChE to RBC membranes to create a cell-based delivery system that retains the enzyme activity and enhances stability. In a three-step process that first pre-modifies BChE with a cell-reactive polymer chain, primes the cells for engineering, and then grafts the conjugates to the cells, we attached over 2 million BChE molecules to the surface of each RBC without diminishing the bioscavenging capacity of the enzyme. Critically, this membrane-engineering approach was cell-tolerated with minimal hemolysis observed. These results provide strong evidence for the ability of engineered RBCs to serve as an enhanced biotherapeutic delivery vehicle.

Corresponding author's email: llingens@ukaachen.de

Human adipose stem cells (ASCs) hold huge potential for regenerative medicine approaches, including osteogenic regeneration. In vivo, osteogenic differentiation is dependent as well as stimulated by the impact of different bio-physical stimuli, such as mechanical manipulation and oxidative stress . In our study, we tested the effects of different bio-physical impacts to enhance the osteogenic differentiation in ASCs.

During 14 days of osteogenic differentiation, ASCs were intermittently stimulated with hypergravity (10x g, 20x g, 30x g, 40x g) to create a mechanical force acting on the cells. In a second experiment ASCs underwent osteogenic differentiation at hypoxic conditions (3% O2, 8% O2, 20% O2). In both approaches, the calcification using cresolphtalein staining, and the enzymatic activity of alkaline phosphatase (ALP) was analysed to detect and quantify the differentiation process.

Hypergravity increased significantly the ALP activity as well as the cellular calcification with highest values at 20x g and 30x g. Furthermore, we found a significant increase of calcification and ALP activity at hypoxia of 3% and 8% with highest values at 8%. Also, the proliferation was significantly higher under hypoxic conditions compared to standard culture.

The stimulation of ASCs during osteogenic differentiation with hypergravity and hypoxia show new pathways to possibly improve osteogenic tissue engineering or osteogenic regeneration using ASCs.

[1] *Maastricht University*

Corresponding author's email: v.shankar@maastrichtuniversity.nl

The peri-implantation stage in a mammalian embryo is characterized by crucial cell fate decisions by the embryonic and extra-embryonic compartments that ensure developmental progression. Around embryonic day 4.5-5.0, the primitive endoderm (PrE) differentiates into parietal endoderm (PaE), that later forms the parietal yolk sac, and visceral endoderm (VE), that will form the visceral yolk sac and part of the definitive endoderm [1]. Although embryos have been informative on the bifurcation of PaE and VE, the mechanism behind this process remains elusive. We hypothesize that the PrE differentiation into PaE and VE follows a stochastic, salt and pepper distribution, similar to the ICM differentiation into epiblast and PrE, and later migrate out with some of them undergoing an epithelial-mesenchymal transition (EMT). Recently, stem cell-based embryo models that mimic the epiblast-PrE co-development [2], recapitulate the formation of PaE and VE through chemical induction. We use this model to investigate the plasticity of these cell types and the instructive cues required to reinforce their identity. It has been shown that the signals from trophectoderm (TE) and extracellular matrix (ECM) influence differentiation and migration of PaE in natural embryos [3]. Here, we explore these parameters by screening the effect of ECM components and make use of high-throughput microwell-based platforms to identify the signaling pathway modulators and morphogenetic factors underlying this process. Understanding the implantation process of a mammalian embryo would be a developmentally relevant concept and can help in understanding the implantation failures or fertility related problems in humans.

Bone marrow is still the most common source of mesenchymal stem cells (MSC) for bone regeneration despite the limited yield of these cells by aspiration (<1%). It is thus crucial to find alternative sources for MSC and one attractive source is from induced pluripotent stem cells (IPSC). IPSC are generated through reprogramming adult cells into an embryonic like state by activating certain pluripotency genes (OCT4, SOX2, KLF4, MYC). The objective of our study was to compare the efficiency of oral and skin fibroblasts (gold standard) for reprogramming into IPSC, and the efficiency of deriving MSC from the generated IPSC.

Matched oral and skin fibroblasts were reprogrammed into IPSC via episomal plasmid transfection. The IPSC showed typical IPSC morphology (tight colonies surrounded by a light outer rim) and expressed a set of pluripotency genes (NANO-G, OCT4, SOX2). Following their characterization, oral-IPSC were differentiated into MSC (IPS-MSC) using alpha-MEM expansion media. The IPSC lost their morphology and developed a spindle shaped fibroblast morphology, typical for MSC. The resulting phenotype was characterized by expression of mRNA and protein of a standard set of MSC markers. The IPS-MSC showed in-vitro ability to differentiate into osteocyte, adipocyte and chondrocyte lineages.

The findings of our study demonstrated that oral fibroblasts can generate IPSC capable of differentiating into MSC-like cells. Oral fibroblasts were found to be comparable to skin fibroblasts in terms of IPSC generation and differentiation to IPS-MSC.

Abstract

Objective: Natural extracellular matrix (ECM) of lung tissue can be used as a component for improvement of regeneration in lung injuries. However, the mechanical prosperities of the ECM prepared after decellularization of lung tissue can affect its regeneration-inducing potential. We aimed to manipulate the mechanical properties of lung ECM by a cross-linking method while preserving its biological properties.

Methods: Rat lung tissue was decellularized using an SDS-Triton protocol and cross-linked by 1-Ethyl-3-(3-dimethylaminopropyl) carbodiimide (EDC). The cross-linked ECM was assessed for its potential to induce cell proliferation and angiogenesis. Cell proliferation assay was performed using human fetal mesenchymal stem cells (hFMSCs) and angiogenesis assay was performed using a chick embryo chorioallantoic membrane model. H&E and Masson's trichrome staining were also performed where appropriate.

Results: The results indicated a higher proliferation of hFMSCs on the EDC-cross-linked tissue (86.19 ± 5.973, N=3) compared to the acellular non-cross-linked tissue (67.24 ± 3.374, N=3). Also, the EDC-cross-linked tissue showed higher potential for induction of angiogenesis compared to the acellular non-cross-linked group (acelluar cross-linked group; 75.33 ± 5.044 N=5 vs acellular non-cross-linked group; 54.00 ± 4.933 N=5).

Conclusion: Lung decellularized ECM could be cross-linked by a carefully selected method without negatively affecting its biological properties.

The aim of this work is to design a robotic bioprinting platform able to fabricate a three-dimensional structure onto irregular surfaces. Regarding the limitations of in-vitro bioprinting approach, widely used in scaffold-based tissue-engineering (handling difficulty, risk of contamination, shape not matching the defect), this bioprinter allows a direct dispensing (i.e. in-situ bioprinting) of biological material onto and into the damaged site [1-2]. The robotic platform was developed starting from the open source BCN3D-MOVEO robot [3-4]. The hardware was rebuilt to control the robot using LinuxCNC [5], the original end-effector was substituted by a syringe pump module, and joints were equipped with optical encoders. A path planning algorithm that automatically projects any generic printing pattern on an irregular surface, was developed in Matlab. For each point, the normal direction is calculated to successively constrain the end-effector orientation (always perpendicular to the surface). An inverse kinematic algorithm calculates joint angles for each position of the end-effector and a gcode file is then exported to LinuxCNC. Resolution and repeatability were estimated and preliminary in-situ bioprinting tests were carried out extruding a hydrogel onto various substrates.
The possibility of dispensing material onto irregular surfaces opens the way to a number of possibilities in the field of tissue-engineering. In this context, in-situ bioprinting could become a reality in the near future especially for the easiest accessible organs such as skin. Having a "collaborative" bioprinter, capable of assisting the surgeon during the operating phase, will allow a more precise intervention and will minimize human errors.

Keywords

in-situ bioprinting; robotic bioprinter; tissue engineering

Bioprinting is a leading biofabrication technique for the recreation of 3D tissue-like materials.1-3 The extracellular matrix (ECM) is a complex and dynamic structural support for cells within tissues and plays an important role in regulating cell functions.1 While significant progress has been made in bioink (cell-laden hydrogels) development, few of these materials show both stiffness and viscoelasticity comparable to native tissue, and shear-thinning properties needed for printing.4-5 Here, we developed double network (DN) hydrogel bioinks by combining a dynamic and a static cross-linked network. We investigated the combination of oxidized alginate cross-linked by Schiff-base reactions (OA, dynamic network) and polyethylene glycol diacrylate (PEGDA, static network), to develop a small library of hydrogels (OA0/2/2.5/3wt%; PEGDA0/10/15/20wt%). First, we assessed the injectability of DN and SN hydrogels, demonstrating that the polymer concentration allowed us to modulate the DN hydrogel properties, changing from soft and sticky to tough and brittle. We optimized the bioprinting parameters of hydrogels (OA2.5wt%-PEGDA0/5/10/15wt%; OA2/3wt%-PEGDA10wt%). Self-healing tests showed that hydrogels were able to heal even at 15wt% of PEGDA. A first cell-viability test corroborated their biocompatibility. Furthermore, cell seeded on the hydrogel could migrate and spread within the hydrogel, a crucial necessity for tissue maturation. So far, by combining dynamic and static networks, we developed stronger hydrogels than single networks, retaining the self-healing properties and improving the printability of DN formulations. Furthermore, both crosslinking chemistries will also allow us to incorporate bioactive molecules on both dynamic and static networks, envisioning a great potential for mimicking the dynamic ECM complexity.

Human platelet lysates (PL) play a well-known role in cell function and tissue repair[1,2]. We recently reported a bioactive PL-derivative precursor (PLMA) that can be cured upon light exposure to form hydrogels with tuneable mechanical properties able to support human-derived cells culture[2]. Animal-derived serum is widely used as supplement in cell culture, nevertheless, its use, raises many safety, scientific, and ethical concerns[1]. Following a humanized and completely xeno-free strategy we propose PL-sponges as a support for 3D cell culture in animal serum-free conditions.PLMA was prepared following a previously reported protocol[2]. Hydrogels were formed by light irradiation of PLMA solutions with photoinitiator. The human protein based sponges were produced by freeze-dry of hydrogels. Their structural and mechanical properties were assessed. To assess sponges biological performance, human adipose derived stem cells (hASCs) were seeded and cultured in medium with and without FBS supplementation. Viability tests showed that hASCs exhibit high cell viability when cultured in FBS-free medium. DNA quantification and MTS results revealed the ability of hASCs to proliferate and stay viable for 14 days even in the absence of FBS. Protein release assays results demonstrate the controlled release of proteins and growth factors involved in cell function.Our results showed that PLMA sponges are a promising platform for 3D cell culture, offering the possibility to culture cells avoiding the use of animal-derived supplements. It is also a platform that could have an autologous origin, being adequate to produce personalized matrices with no risk of cross-reactivity, immune reaction or disease transmission.

Bone infection management after open bone fracture or implant surgery remain a challenge in the orthopedics field, and can derive into non-unions. In order to locally prevent or eradicate infections while supporting bone healing in these scenarios, 3D scaffolds with local antibiotic release properties are desired. In this study, 3D scaffolds loaded with antibiotics were processed via high temperature melt extrusion additive manufacturing (~190 °C). This was done, for the first time, by the intercalation of ciprofloxacin and gentamicin into the interlamellar spaces of the inorganic fillers magnesium aluminum layered double hydroxides (MgAl) and α-zirconium phosphates (ZrP), respectively, prior to their dispersion within a thermoplastic polymer. The inorganic fillers allowed a more sustained release of the antibiotics from the composite scaffolds, compared to no-filler systems. Moreover, it was demonstrated that the release mechanism of the antibiotics from the fillers through the polymer matrix was governed by antibiotics counter ions exchange and pH conditions in the eluent. Importantly, the manufacturing at high temperatures did not affect the antibiotics functionality, as verified by their activity against both Gram + and Gram - bacterial strains. In addition, human mesenchymal stromal cells were able to undergo osteogenic differentiation when seeded on filler-antibiotic scaffolds, as suggested by the expression of relevant osteogenic markers, such as collagen I and osteopontin, and the observation of calcium deposits in the extracellular matrix. Overall, these results suggest the possibility of improving infection management and allowing bone regeneration with these dual functionality 3D scaffolds fabricated via high temperature melt extrusion.

5% of traumas result in Peripheral Nerve Injuries (PNI), affecting more than 1M people per year in Europe and the USA [1], with healthcare costs exceeding £1Bn/year in the USA alone [2]. Gold-standard treatments for large-gap PNIs use an autograft to fill the space between nerve stumps, however they also induce donor-site morbidity and often have underwhelming functional recovery [3]. Engineered Neural Tissues (EngNT [4]), made of anisotropic biomaterial hydrogels, represent a seducing alternative as their design can be tailored to support nerve repair processes.

Vascularisation of the nerve graft is key for neurite regrowth and nerve regeneration [5]. To promote vascularisation, EngNT constructs may be seeded with therapeutic cells that release vascular endothelial growth factors (VEGF) to stimulate the sprouting of new microvessels [6]. The identification of the mechanisms driving vascularisation and subsequent EngNT design optimization can be costly and time-consuming using experiments in isolation.

Here, we present a mathematical model, parameterised against in vitro data using statistical inference. The model comprises a system of coupled, non-linear, diffusion-reaction equations describing seeded cell density, oxygen and VEGF concentrations, overlaid with a discrete model for endothelial sprout growth, blood flow and intravascular transport of oxygen, representing the rich spatio-temporal dynamics between blood flow, angiogenesis, oxygen delivery, VEGF production and seeded cell survival.

This approach enables the screening of a large range of EngNT designs (e.g. seeded cell types and spatial distributions, biomaterial properties) to inform future experimental decisions along with the identification of key mechanisms driving early stages of nerve repair.

The application of pluripotent stem cells (PSCs) as regenerative medicine strategies represent an important for patients affected by kidney disease1. Nephron progenitor cells (NPCs), the precursors of nephrons, can be generated from PSCs. Differentiation of PSCs depends on the response of the stem cells to the external induction cues. Deriving a homogeneous population of NPCs, is an essential prerequisite to generate a pure cell population. In this study, we established protocols to improve differentiation efficiency of PSCs into NPCs. The two progenitor populations, metanephric mesenchyme (MM) and ureteric bud (UB) were generated with optimized efficiency. MM and UB were combined in two-dimensions and in three-dimensions to generate kidney organoids. Results showed that an efficient synchronization of cell that respond to WNT agonist CHIR99021, thus efficiently stimulating the directed differentiation of PSCs to a homogenous population of NPCs. The NPCs homogeneity was characterized by gene expression and by immunocytochemistry and flow cytometry analysis. NPCs when synchronized gave a higher yield of renal vesicles, which eventually would give higher number of nephrons-like structures. Kidney ECM-derived hydrogel further improved the generation of renal vesicles from NPCs. Upon induction with exogenous Activin A and FGF9 in kidney derived sacrificial ECM hydrogel, NPCs successfully formed renal vesicles. Furthermore, ECM hydrogel was further combined with alginate-based materials and bioprinted showing high cell viability post-printing and up to 7 days in culture. These initial steps might allow further development of renal in vitro models for nephrotoxicity assays and for the development of future regenerative medicine strategies.

Melt extrusion additive manufactured (ME-AM) scaffolds are ideal for tissue regeneration, due to their high porosity, customizability, and reproducible fabrication. Yet, cell-material interactions are limited on synthetic polymers used as scaffold materials, which can hinder an efficient cell adhesion, compromising the development of a functional construct. Here, a hybrid AM technology1, which combines a standard ME-AM technique with an atmospheric plasma jet, was employed to fabricate scaffolds and render their surface more bioactive in a single process. The monomers (3-Aminopropyl) trimethoxysilane (APTMS) and maleic anhydride-vinyltrimethoxysilane (MA-VTMOS) allowed the deposition of positively charged amine and negatively charged carboxyl functional groups on the scaffolds surface, respectively, while argon plasma activation led to a more unspecific surface treatment. Yet, all plasma treatments enhanced fibronectin and vitronectin cell adhesive proteins adsorption to their surface, and allowed for homogeneous human mesenchymal stromal cells (hMSCs) attachment along the scaffold cross section, compared to untreated scaffolds. Interestingly, electrostatic interactions between hMSCs and the APTMS scaffolds also allowed for homogeneous scaffold population on these scaffolds in the absence of serum. In addition, aging of the surface treatment upon scaffolds storage was also investigated, as per its clinical relevance. Notably, the scaffold wettability, as well as hMSCs attachment and proliferation were not significantly affected, compared to freshly prepared scaffolds, and osteogenic genes were expressed. Overall, the use of the hybrid AM technology enabled an efficient workflow of scaffold production and surface treatment, which proved to enhance cell-scaffolds interactions towards the creation of more functional tissue substitutes.

Decellularized extracellular matrix (dECM) is emerging as a valuable tool for generating 3D in vitro tumor models that better recapitulate tumor-stroma interactions [1]. However, the development of dECM enriched heterotypic freestanding spheroids exhibiting a controlled morphology is yet to be materialized [2]. Precisely controlling microtumors morphologic features is key to avoid aberrant cellular behavior and consequently an inaccurate evaluation of therapeutics bioperformance during preclinical screening [2]. To address this challenge, herein we employed microfiber-processed dECM for bioengineering 3D metastatic breast cancer-fibroblast models via liquid overlay technique as a bottom-up strategy to include key cellular/matrix components in reproducible spheroid-shaped microtissues. This biomimetic approach enabled the self-assembly of heterotypic dECM-3D tumor-stroma spheroids with tunable size and highly reproducible morphology. Overtime, dECM-enriched heterotypic cancer-stromal microtumors exhibited a physiomimetic necrotic core, metastatic potential, altered biochemical profiles and distinct response to different standard-of-care chemotherapeutics, recapitulating major hallmarks of the native microenvironment. Exometabolomics profiling of multicellular dECM-3D in vitro models further identified important breast cancer metabolic features including intense glycolytic activity, thus being in close correlation with in vivo breast cancer metabolism. The produced dECM-3D microtumors overcome the morphologic variability and low cell density associated with conventional cell-laden dECM hydrogel models, while providing a scalable and biomimetic testing platform that can be leveraged for high-throughput drug screening of innovative therapeutics.

Scaffolds with gradients of physico-chemical properties and controlled 3D architectures are crucial for engineering complex tissues. These can be produced using multi-material additive manufacturing (AM) techniques. However, they typically only achieve discrete gradients using separate printheads to vary compositions. Achieving continuous composition gradients, to better mimic tissues, requires material dosing and mixing controls. No such AM solution exists for most biomaterials.
A novel hybrid AM solution with dosing- and mixing-enabled, dual-material printhead and an atmospheric pressure plasma jet (APPJ) to selectively activate/coat scaffold filaments during manufacturing were combined on one platform. Continuous composition gradients in both 2D hydrogels and 3D thermoplastic scaffolds were fabricated. An improvement in mechanical properties of continuous gradients compared to discrete gradients in the 3D scaffolds. The creation of surface gradients by means of APPJ allowed a selective treatment in predesigned regions of the scaffold and the ability to selectively enhance cell adhesion was demonstrated. Bulk composition gradients have been evaluated in vitro and in vivo in a critical size long bone defect of a rabbit model. Results show a selective induction of new bone formation depending of the gradient used in comparison with controls.
The developed hybrid platform opens endless possibilities to create different gradient and non-gradient scaffolds with the possibility to fine-tune material composition and surface properties that can be valuable assets for the next generation of thermoplastic scaffolds for a plethora of TE applications.

The use of bioscaffolds made of photocrosslinkable hydrogels and stem cells is widely endorsed in the field of cartilage repair (1, 2). Cell mediated degradation of the implanted bioscaffolds is critical for their therapeutic efficacy (3). Thus, tuning the balance between biodegradability and deposition of a distinct new extracellular matrix is key to control the chondrogenic potential.

In this study we generated FLASH, a Fluorescently LAbelled Sensitive Hydrogel to correlate the degradation of a bioscaffold with neocartilage formation. Gelatine Methacryloyl (GelMA) was covalently bound to the FITC fluorophore to generate FLASH and bioscaffolds were produced by casting different concentrations of FLASH GelMA, with and without human adipose-derived stem cells (hADSCs) undergoing chondrogenesis. The loss of fluorescence from FLASH bioscaffolds was correlated with changes in mechanical properties, expression of chondrogenic markers and accumulation of a cartilaginous extracellular matrix. The ability of the system to monitor the bioscaffold degradability during chondrogenesis was evaluated in vitro, in a human ex vivo model of cartilage repair and in a full chondral defect in vivo rabbit model. Regardless of the experimental models used, the extracellular matrix production within the hydrogel correlates with the fluorescence loss profiles, demonstrating that FLASH is a sensitive tool to monitor photocrosslinkable hydrogels in tissue engineered constructs. This study represents a step towards the generation of a high throughput monitoring system to evaluate de novo cartilage generation in tissue engineering therapies.

More than 117 million units of blood are transfused worldwide, annually1. These units are sourced from donors, however whilst demand is rising, donor numbers are falling 2. In the UK alone, ~400 new donors are required daily to maintain provision. Compounding these shortfalls are the risks of infectious blood-borne diseases1, the scarcity of rare blood-group donors, and the extensive typing required to limit immunogenicity in the chronically transfused3. Safe, reliable, and cost-effective sources of blood are therefore required, particularly for its erythrocyte component. The recent creation of the first erythroid cell-line (BEL-A) provides a novel, scalable source for in vitro production of erythrocytes without need of donors2. However, low yields and high costs pose challenges for clinical translation.

Our research focuses on designing and optimising a novel fluidised bed bioreactor (FBB) to scale-up BEL-A cell production to therapeutically-relevant levels. When fluidised within the FBB, each cell remains individually suspended in media, achieving superior mass transfer under low-shear compared to traditional systems. Hence, when optimised, FBBs present attractive large-scale cellular manufacturing platforms. Following successful culture of BEL-As in our proof-of-concept studies, our current focus is identifying FBB design and operating conditions which improve yields. In addressing this, we have adopted a design of experiments approach to analyse the individual and interactive effects of these conditions. Furthermore, we are performing stoichiometric analysis of BEL-A culture to define media recirculation capacity. Results of this study are a major step towards efficiently producing erythrocytes at clinical-scale and establishing a platform technology for cell-therapy manufacture.

Porcine reproductive and respiratory syndrome (PRRS) is a serious infectious swine disease, causing major economic losses to the world-wide pig industry. PRRS manifests differently in pigs of all ages but primarily causes late-term abortions and stillbirths in sows and respiratory disease in piglets. The causative agent of the disease is the positive-strand RNA PRRS virus (PRRSV). Therefore, it is necessary to develop a new type of PRRSV vaccine that can efficiently induce specific immune responses quickly in order to produce cross protection. In this study, we aim to develop a new mRNA-based PRRSV vaccine by self-replicating VEE-RNA replicon that expresses the antigens of PRRSV by using in-vitro transcription. Primary test for PK-15 (Porcine Kidney cell line) confirmed that VEE replicon can persistently express the antigens for 4 weeks. Moreover, we demonstrate that a single low dose intradermal immunization with lipid-nanoparticle-encapsulated nucleoside modified mRNA (mRNA–LNP) encoding glycoproteins (GP5) of PRRSV VR-2332 elicited persistent neutralizing antibody responses in mice. Compared to traditional attenuated vaccine or modified live virus (MLV), mRNA vaccine can induce specific immune responses earlier and is safer to use.

Keywords

PRRSv; mRNA vaccine

Background:

Cancer drug screening studies rely heavily on the use of conventional two-dimensional (2D) cell culture systems, which has significant limitations in its ability to model tumour cell morphology, signalling, gene expression, architectural features and response to oxygen. Therefore, development of 3D cell culture models has attracted growing interest in cancer research. Malignant pleural mesothelioma (MPM) is an aggressive asbestos-related thoracic cancer. Chemotherapy is an important palliative treatment option but almost every patient will be confronted with recurrence of disease and drug resistance.

Methods:

MPM tumour spheroids and MPM cells grown in decelluarised porcine lung scaffolds were developed and examined. MicroRNA gene expression profiling was investigated, while hypoxia (Hif1a, one of the major hallmarks of solid tumours) was analysed using immunohistochemistry. Drug cytotoxicity of cisplatin and gemcitabine was investigated.

Results:

MPM 3D spheroids and MPM-scaffolds represent mini-tumour models as indicated by the visualization of cell junctions under TEM. Tumour suppressor biomarkers we analysed showed down-regulation of mRNA expression level compared with cells in 2D. MPM spheroid showed up-regulation of genes that contribute to drug resistance such as Hif1a and YAP1. The 3D models exhibited a greater resistance to cisplatin and gemcitabine compared to 2D cultures. Immunofluorescence studies showed a gradient of hypoxia from the centre of the spheroids or scaffolds where high Hif1a expression is observed.

Conclusions:

3D cells grown with the newly optimised method provide a more realistic mimic of clinical drug response to MPM, as evidenced by the greater resistance of MPM cells to cisplatin and gemcitabine.

RETHINKING OF ANTIMICROBIAL BIOMATERIAL DESIGNS - IMPLICATIONS FROM AN IN VITRO COCULTURE STUDY

Phong Tran$_P$[1]

[1] *Queensland University of Technology*

Corresponding author's email: phong.tran@qut.edu.au

There is significant interest in anti-infective biomaterials that have a dual property of promoting tissue integration and inhibiting bacterial adhesion to prevent device-associated infection. However, it is also known that bacteria such as S. aureus have abundant surface pathogen-associated molecular patterns can readily interact with mammalian cells such as osteoblasts. Using tissue culture plastic, we found that S. aureus were electrostatically repelled from this surface and that when they were inoculated onto this surface pre-seeded with MC3T3-E1, they formed aggregates that adhered strongly to these osteoblastic cells. Importantly, the bacteria in the aggregates were more resistant to gentamicin compared to those in bacterial monoculture. This finding thus suggested that the bacteria repelled from such a surface might end up establishing a biofilm-like community on adjacent mammalian cells or tissue and that anti-infective biomaterials should actively kill bacteria.

NUMERICAL AND EXPERIMENTAL STUDY OF HAEMODYNAMICS AND WALL COMPLIANCE IN THE ANASTOMOSIS OF SMALL-DIAMETER VASCULAR GRAFTS WITH PATIENT-SPECIFIC GEOMETRIES FOR TRANSLATION TO TISSUE ENGINEERING

Sabrina Schoenborn[P][1], Mia Woodruff[1], Mark Allenby[1]
[1] *Queensland University of Technology*
Corresponding author's email: s.schoenborn@uq.edu.au

The primary cause of mid-term occlusive failure in small-diameter vascular bypass grafts is the development of intimal hyperplasia driven by mechanical compliance mismatch [1-3]. While current tissue-engineered vascular grafts (TEVGs) achieve physiological tubular compliance, (pre)clinical outcomes remain limited due to the lack of compliant and biodegradable TEVG anastomosis solutions [4-6]. To address this unmet need, computational and experimental models have been developed to design and test anastomosis solutions for TEVGs.This numerical study is based on a three-dimensional computer model of an artery-graft anastomosis with investigation of wall compliance being facilitated via a two-way fluid-structure interaction (FSI) model. The wall deformations and fluid dynamics around the anastomosis site are investigated in patient-specific geometries derived from medical imaging data for different anastomosis solutions with graft types of varying compliance. The numerical results are then experimentally validated in a vascular testing rig using arterial phantoms to create anastomoses.We have developed FSI simulations of blood flow within a compliant artery for an idealised patient geometry which shows mechanical compliance consistent with published literature. We will create idealised and patient-segmented peripheral artery simulations of different anastomosis techniques to investigate the effect of anastomotic and tubular compliance on shear stress and fluid flow profiles. Using these numerical results, we will design, 3D print, and experimentally validate TEVG anastomosis devices for improved anastomotic compliance.A numerical FSI model capturing the complex relationship between anastomotic wall compliance and haemodynamics can be an important tool in the design and evaluation of patient-specific graft-anastomosis solutions enabling TEVG translation.

Peripheral nerve regeneration is usually slow and incomplete. Currently, inflammation has been identified as a therapeutic target of peripheral nerve regeneration. We are interested to evaluate the novel potential of thrombomodulin (TM) in promoting peripheral nerve regeneration by regulating macrophage polarization. We found that TM can facilitate M1 switching toward M2, indicated by reduced inflammatory cytokine levels and a concomitant increase in M2 markers, through a STAT6-PPARγ pathway. The conditional medium derived from TM-treated M1 exhibited a mild inflammatory induction capacity as compared to that of M1. When testing in nerve transcended model, TM treatment led to better nerve regeneration and preserved effector muscle mass. We also observed evident M1 to M2 transition in TM-treated nerve. TM appears to be a drug for the promotion and modulation of functional recovery in peripheral nerves by enhancing M1 to M2 transition. Myelination is an important process during functional nerve regeneration. We also discovered the Schwann cells (SCs) can be derived from the formation of adipose-derived stem cells (ASCs) into spheres on a chitosan-coated microenvironment with the supplement of FGF9 peptide (FGF9-NLCs). The FGFR2 and FGFR4 were significantly increased during NLCs induction. The FGF9 treated FGF9-NLCs spheres became smaller and changed into SCs with expressing of S100β and GFAP. Transplanted FGF9-NLCs participated in myelin sheath formation to enhance axonal regrowth. Taken together, we found several drugs that can target on microenvironmental and therapeutic cell modulations to promote nerve regeneration and functionalization.

Critical-sized craniofacial bone defects (CCDs) arising from trauma, congenital abnormalities, tumor resections, etc. often require surgical reconstruction to restore aesthetics and functionality. Autografts still remain the gold standard treatment, however, suffer from challenges like donor site morbidity, limited tissue availability and anatomical mismatch. To address this, we have developed a point-of-care (POC) cell-based strategy for treatment of clinically relevant large craniofacial bone defects and demonstrated its feasibility and efficacy using a pre-clinical porcine model.

2 cm full thickness, segmental defects were created bilaterally in the zygomatic bones of skeletally mature, castrated, male Yucatan pigs to mimic CCDs. The defects were treated with custom-designed, 3D-printed hybrid scaffolds comprised of polycaprolactone (PCL) and decellularized bone (DCB). Autologous stromal vascular fraction (SVF) harvested from subcutaneous porcine fat were seeded into the scaffolds. There were three experimental groups: (i) Empty (untreated), (ii) Acellular (scaffold only), and (iii) Cellular (scaffold + SVF). CT scans were performed post operatively and at 6, 12, 24 and 52 weeks to evaluate new bone formation. On reaching endpoint zygomas were harvested and biomechanical testing was performed to assess osseo-integration of scaffolds.

After 52 weeks, we have found non-union of defects in the empty group. Acellular and cellular groups exhibited robust bone regeneration with mean bone to defect volume (BV/DV) calculated to be 0.64±0.09 and 0.65±0.08 respectively with no statistically significant difference. Interestingly, mean fracture torque for zygomas from cellular group (7.1±2.3 Nm) was found out to be higher and statistically significant as compared to acellular group (2.8±0.2 Nm).

CELL SUICIDE-BASED FUNCTIONAL CONTROL OF GENETICALLY MODIFIED CELLS FOR CELL-BASED GENE THERAPY

Kosuke Kusamori[P][1], Mari Tsujimura[1], Makiya Nishikawa[1]

[1] *Tokyo University of Science*

Corresponding author's email: kusamori@rs.tus.ac.jp

Transplantation of genetically modified cells that continuously produce a specific protein is expected to be an excellent cell-based gene therapy approach. However, an additional strategy is required to control the function of the transplanted cells for effective and safe cell-based gene therapy. We have focused on drug-induced cell death, in which the cells transduced with a suicide gene undergo cell death by addition of an inactive prodrug. The herpes simplex virus thymidine kinase (HSVtk) gene is the most famous and frequently used suicide gene, which induces cell death in the cells expressing it in combination with ganciclovir (GCV). In a previous study, we selected this combination and developed the cell regulation system, in which the proliferation and function of transplanted cells can be controlled as required by adjusting the GCV concentration. In this study, we tried to apply this cell regulation system to cell-based gene therapy to control the transgene expression level and profile. To achieve this, mouse mesenchymal stem C3H10T1/2 cells and interferon-gamma (IFN-g) gene, an antitumor cytokine, were selected, and C3H10T1/2/HSVtk/IFN-g cells were established by transfecting the cells with HSVtk gene and IFN-g gene. C3H10T1/2/HSVtk/IFN-g cells released IFN-g and underwent cell death by addition of GCV. C3H10T1/2/HSVtk/IFN-g cells significantly inhibited the proliferation of mouse adenocarcinoma colon26 cells in cell culture and retarded tumor growth in colon26 tumor-bearing mice. Moreover, transplanted C3H10T1/2/HSVtk cells were eliminated by GCV administration. These results indicate that we have succeeded in controlling the function of the transplanted cells using cell suicide-based cell regulation system.

3D PRINTING OF SILK-BIOCERAMIC NANOCOMPOSITES FOR THE REGENERATION OF INNERVATED AND VASCULARIZED BONE TISSUE

Vincent Fitzpatrick[P][1], David Kaplan[1]

[1] *Tufts University*

Corresponding author's email: vincent.fitzpatrick@tufts.edu

Bone is a dynamic, innervated and vascularized tissue with the inherent ability to regenerate after injury. Nevertheless, non-union fractures remain a major issue in orthopedic surgery. Autografts and allografts are the gold standard for repair but can be associated to donor site morbidity, donor material availability, and increased operative times. Alternative biomaterial-based solutions are promising, including synthetic bone fillers. However, these fillers do not allow refined control of graft geometry, and seldom offer adequate porosity for rapid cell colonization, efficient nutrient exchange, or implant degradation. Further, these approaches usually do not actively promote bone growth, nor account for the complexity of bone, and in particular the neurovascular network.

We developed a silk-ceramic bioink to 3D print porous constructs for bone regeneration. The resulting material was mechanically close to bone, promoting osseointegration. These structures were biocompatible, their shape well-controlled even for complex geometries, and their porosity could be precisely tuned for efficient osteogenesis.

Our constructs supported osteoblastic differentiation in vitro, and a rapid cell response and efficient neoosteogenesis when combined with osteoinductive factors (BMP-2). We further loaded this bioink with angiogenic and neurotrophic morphogens (VEGF and NGF), and precisely patterned these biomolecules, promoting the migration, organization and differentiation of human umbilical vein endothelial cells and human induced neural stem cells, respectively. Coculture conditions showed that the multiple morphogens and cell types promoted the osteogenic differentiation of human mesenchymal stem cells.

Finally, our bioink could be loaded with antibiotics, providing an encouraging solution for the prophylactic treatment of osteomyelitis in non-union fractures.

As cell-derived extracellular matrix (CDM) partially recapitulates native tissue niches, it enables the production of microenvironments with customizable properties. These can be processed into biomaterials with sustainable bioactivity and sufficient biological complexity to guide intricate tissue processes such as healing and regeneration. Nonetheless, low amounts of CDM that can be sourced in vitro, as well as the limited understanding of ECM biology are major limiting factors in the development and clinical application.

In order to engineer a biomaterial with enhanced pro-angiogenic properties, we have integrated the pro-regenerative ECM of mesenchymal stem cells (MSCs) with the heparan sulfate-mimetic dextran sulfate (DxS).

DxS aggregated and co-precipitated various ECM components during cell-driven ECM assembly, leading to an accumulation of a rich CDM with unique mechanical and topographical properties [1]. This DxS-ECM facilitated endothelial sprouting in vitro, significantly exceeding the effect of unmodified MSC-derived ECM (cECM) and collagen I. Implantation of these CDMs into full-thickness skin defects within mouse dorsal skinfold chambers demonstrated that DxS-ECM significantly enhanced functional re-vascularization and accelerated wound closure, as compared to cECM and collagen I.

Investigation of the molecular constitution revealed that co-precipitation of CDM with DxS resulted in an ECM with a qualitatively and quantitively different composition. Proteomics analysis further identified potential new players responsible for its mechanism of action.

In conclusion, we have created a CDM hybrid biomaterial with superior pro-angiogenic properties in vitro and in vivo. This biomaterial has the potential to serve as a highly effective treatment for ischemic diseases.

Articular cartilage-derived progenitor cells (ACPCs) offer new interesting avenues as a cell source to use for cartilage tissue engineering. Unlike mesenchymal stromal cells (MSCs), ACPCs do not have the tendency to differentiate into the hypertrophic lineage. This study aims to investiage the potential of ACPCs for cartilage tissue engineering and clinical application.

Cells were isolated from healthy (n=6, age 46-49, mean age 48) and osteoarthritic (n=6, age 41-82, mean age 62) human knee cartilage. ACPCs were isolated from the total cell population by clonal growth after differential adhesion to fibronectin. Cells were characterized by cell surface marker expression, growth kinetics, colony-forming efficiency, and multilineage differentiation. ACPCs were compared to full-depth chondrocytes derived from the same donors. Next, ACPCs were cultured in 3D pellets to investigate neo-cartilage formation.

Healthy and osteoarthritic ACPCs were successfully isolated and differentiated into the adipogenic and chondrogenic lineage, but failed to produce calcified matrix when exposed to osteogenic induction media. Both ACPC populations, as well as full-depth chondrocytes met the criteria for cell surface marker expression to define MSCs as determined by flow cytometry. Cartilage-like matrix production was successful in ACPC pellet cultures.

In conclusion, this study provides further insight into a progenitor cell population which is present in both healthy and osteoarthritic human articular cartilage. The populations show similarities to MSCs, yet the ACPCs did not produce calcified matrix under well-established osteogenic and mineralization culture conditions. Furthermore, ACPCs show potential for cartilage tissue engineering and possibly for clinical application, as a promising alternative to MSCs.

Cardiovascular disease is the leading cause of death and disability worldwide. Bioresorbable vascular stents are a highly anticipated transition from metallic stents, showing potential to negate latent complications while permitting restoration of vascular function [1]. Recent results with bioresorbable stents have seen little success largely due to a need for materials with improved mechanical and degradation characteristics [2].

Here, we show a preliminary comparative investigation into the use of graphene oxide (GO) to mechanically reinforce medical-grade poly(ε-caprolactone) (PCL) fabricated using both fused deposition modelling and melt electrowriting (MEW) toward use in patient-specific bioresorbable stent technology. The application of 3D scanning, modelling and printing opens avenues for manufacture of patient-specific treatments for complex lesions [3].

For the development of 3D printed tubular structures, medical grade PCL (Purasob® PC 12, Corbion Purac, Netherlands) was combined with graphene oxide at 0.1, 0.5, 1.0 and 5.0 wt%. GO was characterised with transmission electron spectroscopy, Raman, EDSX and AFM. A rheology-based model was used to calculate the extrusion parameters based on composite viscosity. Composites were loaded into a custom MEW printer and extruded through a 21 gauge needle (Nordson, Ohio, USA) at 90°C, with a voltage difference of 4.5 kV applied from the needle tip to the mandrel at a 5 mm working distance. Gcode was generated in Repetier Host 3D printing program (Hot-World GmbH & Co. KG, Willich, Germany). Pore angles of 20°, 60°, 90° and 120° were printed with five layers with a 4 mm pore area.

Juvenile nephronophthisis is an inherited renal ciliopathy, causing cystic kidney disease, renal fibrosis, and end-stage renal failure in children and young adult. Mutations in NPHP1 gene encoding nephrocystin-1 protein have been identified as the most frequent responsible gene and cause the formation of cysts in renal medulla. The disease mechanism of juvenile nephronophthisis is little known yet, so no effective medicines exist even today. Because Nphp1 mutant mice failed to recapitulate renal manifestations of nephronophthisis (Jiang et al., 2008), faithful disease models are required to dissect molecular pathogenesis. To develop disease models, which can lead to develop effective therapies for juvenile nephronophthisis, we established disease-specific hiPSC lines from juvenile nephronophthisis patients, carrying NPHP1 mutations. Juvenile nephronophthisis patient-derived hiPSC lines were generated from peripheral blood mononuclear cells of each juvenile nephronophthisis patient using episomal vectors carrying reprogramming factors under feeder-free culture conditions. Generated hiPSC lines formed typical human embryonic stem cell-like colonies in feeder-free culture conditions, and also showed the expression of self-renewal markers and carried a large deletion in NPHP1 gene. Furthermore, both juvenile nephronophthisis-specific hiPSC lines formed embryoid bodies in vitro and showed the pluripotency for three germ layers. Since the molecular pathogenesis caused by NPHP1 dysfunction remains unclear, these cell resources provide useful tools to establish disease models and to develop new therapies for juvenile nephronophthisis.

ENGINEERING OF INJECTABLE MULTIFUNCTIONAL POLYURETHANE-BASED HYDROGELS FOR THE ADVANCED TREATMENT OF HARD-TO-CLOSE WOUNDS

Rossella Laurano[P][1], Monica Boffito[1], Alice Zoso[1], Valeria Chiono[1], Gianluca Ciardelli[1]

Corresponding author's email: rossella.laurano@polito.it

To improve the hard-to-close wound treatment effectiveness and minimize side-effects on not-target tissues, the design of smart drug carriers locally releasing their payload in a controlled way is attracting widespread interest. The work was aimed at designing a multi-functional injectable delivery platform for wound treatment, overcoming the main limitations of traditional wound dressings, allowing shape-adaptability to defects through rapid post-injection gelation and controlled drug release kinetics. The aims were achieved by exploiting the versatile chemistry of polyurethane (PU) for the synthesis of multi-functional polymers and taking advantage of the alkaline characteristics of chronic wounds exudates when colonized by bacteria.
Specifically, PU amphiphilicity was ensured by selecting Poloxamer®407 as macrodiol; alkaline pH-responsiveness was introduced by plasma-treating PU powders to expose carboxyl groups (i.e., 5.3×10E18±0.6×10E18 units/g of polymer) while preserving PU molecular weight (Mn: 29±1 kDa) and hydrogel thermo-responsiveness (gelation within 7 minutes at 37 °C for 15% w/V concentrated systems). Hydrogel thermo-sensitivity was exploited to: (1) encapsulate drugs (e.g., Ibuprofen, 1 mg/mL) in the sol state, (2) tune hydrogel viscosity for its easy injection up to room temperature through G18 needles, (3) localize payload release, and (4) perfectly fill the wound cavity. On the other hand, hydrogel pH-responsiveness was explored to enhance drug release in the presence of alkaline exudate. Hydrogel was biocompatible according to ISO10993, and able to quickly change its internal pH (i.e., pHchange_5min=3.76 vs. 2) and release high drug amounts when incubated with alkaline buffer compared to an acid milieu (approx. 60% vs. 8% within 1 h).

Biomaterials and biomaterial functionalization are promising methods to support pancreatic islet viability post-transplantation in an effort to reduce insulin dependence for patients afflicted with diabetes mellitus type 1. Assessing how endogenously expressed pancreatic ECM proteins are affected by post-transplant-like hypoxic conditions may provide significant insights towards the development of tissue-engineered therapeutic strategies to positively influence β-cell survival, proliferation and functionality.

To better understand which ECM proteins may play a role in β-cell homeostasis, we investigated the expression of three relevant groups of pancreatic ECM proteins in human native tissue, including BM proteins, proteoglycans and fibril-forming proteins. In an in vitro hypoxia model, we identified that ECM proteins were differently affected by hypoxic conditions, contributing to an overall loss of β-cell functionality. The use of a COL1 hydrogel as carrier material mitigated the hypoxic impact on proteoglycans as well as fibril-forming protein expression, supporting β-cell functionality in hypoxia. The addition of endothelial cells (ECs) into the COL1 hydrogel improved β-cell response as well as the expression of relevant BM proteins. Our data show that β-cells benefit from a microenvironment composed of structure-providing COL1 with incorporation of paracrine signaling ECs to withstand the harsh conditions of hypoxia. Such hydrogels support β-cell survival and can serve as initial source of ECM proteins to allow cell engraftment while preserving cell functionality post-transplantation.

FUNCTIONALIZABLE AND MECHANICALLY TUNABLE BIOMATERIAL FOR EMB3D PRINTING OF SPATIOTEMPORALLY CONTROLLABLE PRE-VASCULARIZED TISSUES

Malin Becker[P][1], Maik Schot[1], Jeroen Leijten[1]

INTRODUCTION: Embedded 3D (EMB3D) printing is a promising approach to engineer complex tissues such as patterned or pre-vascularized tissue constructs[1,2]. However, the resulting tissue constructs are often mechanically weak, unable to form mechanical or chemical gradients, and lack on-demand tunability. Here, we report on the use of a dually crosslinkable dextran-based hydrogel as a bath for EMB3D printing, allowing for local on-demand functionalization and formation of spatial mechanical gradients.
METHODS: Dextran was functionalized with tyramine and biotin moieties to create a dually crosslinkable polymer[3]. Physically crosslinked embedding baths were created via biotin/avidin protein/ligand interaction. A gelatin based sacrificial bioink was extruded into the hydrogel using an Inkredible+ 3D printer. Covalent enzymatic or photo-initiated crosslinking of the printing bath was used to create mechanically robust tissues. The tissue's biotin moieties were subsequently used for on-demand mechanical or biochemical functionalization of the bulk and/or the channel surfaces.
RESULTS & DISCUSSION: Rheological characterization of the physically crosslinked bath revealed shear-thinning and self-healing properties that were highly suitable for EMB3D printing. Covalent crosslinking resulted in a 3-fold increase of the storage modulus of the hydrogels, which enabled the stabilization of printed channel networks, while diffusion of crosslinking agents from the ink resulted in controllable stiffness gradients in the bulk. Furthermore, the ink/bath interface allowed for one-step functionalization by loading the ink with biotin-coupled cell bioinstructive moieties.
CONCLUSION: We report on a novel and dually crosslinkable hydrogel suitable for EMB3D printing, which offers mechanical stability, mechanical tunability, with on-demand biochemical functionalization of pre-vascularized engineered tissues.

Keywords
EMB3D; vascularization; dual crosslink

Skeletal muscle is in charge of body locomotion and homeostasis. It is one of the most important energy reservoirs and plays an important role in several chronic diseases as diabetes and cancer. Drug discovery for muscle disease treatment is struggling due to structural and molecular differences between species, and to the lack of knowledge on the underlying mechanisms. Tissue engineering aims to simplify the in vivo systems and reduce the use of animals by recapitulating the physiological conditions of the muscle. To obtain mature fibers, muscle engineering requires tissue-mimicking matrices, high cell density of aligned cells, and proper external stimuli. In this work, we optimize the composition of a previously reported1 photocrosslinkable biomaterial for muscle development. We use bioprinting methods to ensure the fiber alignment and produce large numbers of engineered muscles in a simple, fast and automated way. We obtain tissue-like stiffness structures that recapitulate the native environment and induce muscle fiber differentiation on its own. Compared to 2D, the engineered muscles exhibit upregulated expression of differentiation genes without the conventional chemical stimuli, whose pattern suggests a shift from fast to slow fibers. Those 3D muscles present mature fibers with sarcomere formations and proved functionality. To that end, we activate and modulate the contraction of bioprinted muscles through electrical stimuli, and we present their response to different drugs during mitochondrial respiration tests using Seahorse technology. All in all, we present a scalable and easy-to-differentiate in vitro platform for muscle research with potential applications in atrophy-related diseases.

To reduce the need of revision surgeries of bone implants ascribed to loosening phenomena/implant instability, functional coatings are under investigation, requiring standard/reproducible procedures for their preclinical evaluation in a physiological-mimicking environment. In vitro bone tissue models represent a powerful tool for predictive in vitro screening, resulting in a reduction of animal experimentation in agreement with 3Rs principle.
In this perspective, this work was aimed at developing a 3D-printed bone tissue-like through micro-extrusion additive manufacturing of scaffolds from a purposely-engineered bio-ink. Bio-ink formulation was developed by combining gelatin methacryloyl (GelMA, 7%w/V) as polymeric component and inorganic rod-like nano-hydroxyapatite (nHA, 3%w/V) to mimic the bone mineral content. nHA addition did not alter bio-ink thermo-responsiveness as demonstrated by unchanged gelation onset temperature (i.e., 24°C) and kinetics. Differently, differences in the storage modulus before and after irradiation at 365nm (ΔG') showed remarkably higher values for GelMA/nHA compared to GelMA (i.e., ΔG'=5.3kPa vs. 3.7kPa), suggesting the role of nanoparticles as reinforcement filler. By exploiting ink thermo-responsiveness and photo-crosslinking ability, GelMA/nHA formulations were micro-extruded in mild conditions into model square meshed structures with high shape fidelity. Subsequently, printed geometry was refined to morphologically reproduce the cortical/cancellous bone tissues and to maximize cell response. 3D scaffolds (i.e., 25 layers in cylinder-shape constructs with 400 µm pore size) were mechanically characterized showing adequate properties for bone tissue engineering/modelling. Murine fibroblasts (3T3) were preliminarily included in the bio-ink to obtain cellularized constructs. Cell viability tests evidenced the absence of cell damages induced by shear stresses during scaffold fabrication.

The need of orthopedic implants increased in the last year due to the fact that people becomes older (ageing society). Currently, the long-term stability of orthopedic implants is challenged by two main reasons: generation of microparticles that activate inflammation and bone resorption and bacterial colonization. To overcome these challenges we developed a new coating system for titanium implants that on the one hand prevents denaturation of membrane proteins and bacteria adhesion and on the other hand is able to modulate inflammations and acts as a provisional extracellular matrix for osteoblasts to colonize. The first step is designed by an ultra-thin hydrogel coating based on carboxybetaine methacrylamide (CBMAA) that exhibits excellent antifouling properties and is biocompatible. Furthermore, the hydrogel contains mesenchymal stem cell-derived extracellular vesicles (MSC-EVs), which are released in a self-regulated manner in the presence of matrix metalloproteinases (MMPs) proportional to the inflammation conditions near the hydrogel. Subsequently, the hydrogel is degraded leaving space for the osteoblasts to generate their own extracellular matrix. Bacteria adhesion and biocompatibility tests were performed to check the antifouling properties of the hydrogel. Furthermore, different strategies were explored to link the MSC-EVs to our hydrogel coating. These results demonstrate that the combination of bacteria repellency with modulation of inflammation and promotion of osseointegration is a powerful tool to enhance the long-term application of hip implants.Acknowledgement. Clay nanoparticles offer a surprisingly rich array of opportunities for biomaterial design and regenerative medicine that are only beginning to be explored. In aqueous solutions nanoclay particles self-assemble into stiff gels upon contact with physiological ionic solutions. Upon implantation in the body, nanoclay gels provide bioactive environments, through the adsorption of proteins and ions that promote the invasion of cells. Due to their affinity for proteins such as growth factors, nanoclay gels can be applied to deliver, localise, enhance and even pattern activity of growth factors to initiate tissue regeneration. This talk will describe the development and application of nanoclays for growth factor delivery and regenerative medicine including recent work to translate this technology towards a therapy for bone fusion.

Silk fibroin, a protein derived from cocoons of Bombyx Mori silkworms, has recently been well-recognized in biomedical applications due to its excellent characteristics such as non-toxicity, non-immunogenicity, biodegradation and mechanical integrity. Our research group have been continuously investigating on the Thai silk fibroin-based scaffolds for tissue engineering and controlled release applications for a decade. Recently, we focused on the application of Thai silk fibroin-based materials as cell carrier and bioink of a 3D bioprinting technique. Various types of Thai silk fibroin-based hydrogel formulations have been developed. Gelation time, viscoelastic properties and biodegradation rate of the Thai silk fibroin-based hydrogels were characterized. Cell encapsulation efficiency and viability of Thai silk fibroin-based hydrogel bioinks were evaluated using mesenchymal stem cells and cell lines. Printability of Thai silk fibroin-based hydrogel bioinks was tested with an extrusion-based 3D bioprinter. The study elucidated the potential of Thai silk fibroin-based hydrogel bioinks for 3D bioprinting of tissue engineered constructs.

Gelatin is a popular material in the fields of tissue engineering and biofabrication as reflected by the high number of publications covering a plethora of chemical modifications(1). Herein, we report on different chemical modification strategies to tailor gelatin towards specific biofabrication applications. The first photo-crosslinkable gelatin hydrogel, gelatin methacryloyl (Gel-MA), originally developed by our research group was introduced around 20 years ago(2). Ever since, we investigated a number of different modification strategies to further promote the application potential towards various additive manufacturing technologies.

These strategies include further modification of gel-MA via the introduction of additional methacrylates to improve the resolution in multiphoton lithography (gel-MOD-AEMA)(3,4). Besides improving the resolution, also the writing speed and required energy to process a material using multiphoton lithography can significantly be improved by exploiting thiol-norbornene photo- chemistry 5,6 (gel-NB). Moreover, this gel-NB was successfully applied to encapsulate fibroblasts in a multiphoton lithography process with unprecedented cell viability (± 100%)(6). Furthermore, by combining gel-NB with a thiolated gelatin (gel-SH), micro-blood vessels lined with HUVECS could be generated within an adipose tissue-derived stem cell-containing hydrogel with unprecedented precision(7). Besides multiphoton lithography, the gel-NB/gel-SH system also proved promising for conventional deposition-based additive manufacturing for adipose tissue regeneration(8).

In summary, by tailoring the chemical modification of gelatin, it shows unprecedented processing capabilities when exploiting multiphoton lithography and conventional syringe-based biofabrication technologies. Furthermore, the materials could be tailored to serve a number of regenerative applications including adipose tissue(8), placental barrier(4), ocular applications(9), connective tissue(6) and blood vessel formation(7).

The surface chemistry of scaffolds for tissue regeneration can guide cells growth. In this study [1], we present a novel method to functionalize electrospun Polycaprolactone (PCL) scaffolds allowing the tuning of biomolecule superficial concentration by varying only one process parameter. The method is based on the deposition of NH2 functional groups starting form (3-Aminopropyl) triethoxysilane (APTES) as precursor by a novel Atmospheric Pressure Plasma Jet (APPJ) and by a successive selective covalent linking of these amines with a synthetic Human Vitronectin adhesive cue (HVP). The addition, in the peptide C-terminus, of an aldehyde group ensures the selective ligation by alkylimino-de-oxo-bisubstitution between the primary amine and HVP. By this method, we managed to alter the HVP surface concentration just varying the deposition time of the plasma process; this resulted in different surface coverage of the plasma coating, which in turn led to diverse amount of linked HVP. Coating stability, morphology and coverage was assessed by infrared and photo-electron spectroscopies and by electron microscopy. As a function of the coverage a variation on peptide concentration was revealed by Total Nitrogen method and confirmed by biological assays, which demonstrated an increase of human osteoblasts viability as a function of peptide concentration.

Pancreatic islet transplantation is a promising therapeutic advancement in the treatment of type 1 diabetes; however, a major obstacle remains in supporting cell function post-transplant. To identify possible ECM proteins for the functionalization of islet encapsulation devices, we investigated the presence of ECM in native pancreatic tissues and in our EndoβH3 pseudo-islet system. We identified the small leucine-rich proteoglycan decorin to be strongly co-localized with insulin-producing cells. Supplementation of decorin in the pseudo-islet cultures significantly increased the β-cell glucose response while also downregulating the ECM proteins involved in fibrosis. Furthermore, functionalization of a clinically-approved collagen type 1 (COL1) gel with decorin significantly increased insulin production in response to glucose. Our data proposes decorin as a therapeutic agent to support β-cell function and improve the efficacy of pancreatic islet transplants.

The cryopreserved mesenchymal stem cells (MSCs) can be used immediately as a treatment for spinal cord injury (SCI) emergency dogs. However, cryopreserved cells reduce their characteristics such as cellular viability and antioxidant properties. To solve this problem, we potentiated the characteristics of MSCs by heat shock (HS) treatment and further improved antioxidant capacity by heme oxygenase-1 (HO-1) overexpression. As a result of the PCR, these MSCs have increased gene expression related to stemness, anti-inflammatory, and antioxidant. Twelve SCI beagle dogs were randomly assigned into three groups. We injected intravenously HO-1-overexpressed and HS-treated MSCs (MSCs-HO-HS) and compared this group with HS-treated MSCs group, and MSCs group. MSCs-HO-HS group showed significant improvement in hind limb locomotion from one week as compared to other groups. Spinal cords were harvested at four weeks and used for histopathological analyses. MSCs-HO-HS group showed higher expression of neural marker (Nestin, β-III-tubulin) and also revealed less intervened fibrotic changes of the lesion and improved myelination. The results showed that HO-1 overexpressed and HS-treated on MSCs improved the properties of stem cells, further improving the hindlimb motor function and nerve protection seen in the application of existing MSCs. The stem cells are also thought to be useful for early treatment of SCI, given improved motor function from one week. In conclusion, the use of MSCs-HO-HS in SCI first aid is considered to help early neural sparing and further restore hindlimb motor functions.

Artificial polymers are widely used in tissue engineering due to their biocompatibility and biodegradation(1). Among them, one can cite poly(ε-caprolactone), PCL, poly(lactic) acid, PLA or polyurethane, PU. Despite their many advantages, the process of cell adhesion on their surface is still challenging and requires often some additional steps during the synthesis in order to incorporate some adhesive ligands or to render the surface more hydrophilic increasing its affinity for cell adhesion(2). All those steps are therefore time consuming and expensive. Herein, we provide a simple way to tailor the adhesion of two cell types namely, NIH 3T3 fibroblasts and Wharton's Jelly-derived mesenchymal stem cells (WJMSCs), by varying the isocyanate-to-polyol ratio during the PU synthesis which is also called the « isocyanate index » (NCOind). We demonstrate that above a given NCOind, all cell types can clearly adhere on the surfaces without any functionalization whereas no adhesion is possible below such threshold. We use both Wide and Small Angle X-ray Scattering (WAXS and SAXS) to correlate this phenomenon to the microstructure of the PU. A phase separation between polyols and isocyanate is shown while the evolution of the nature of the interface between each phase seems to correlate with the adhesive properties of cells(3). Finally, we produce a PU scaffold as a substrate for tissue engineering which allows for both cell adhesion and colonization. To conclude, this approach provides a simple and versatile tool to control cell adhesion onto PU surfaces which could be further used for medical devices or implants.

NEOCARTILAGE ASSEMBLY WITH ORGANOIDS IN VISCOELASTIC HYDROGELS

João F. Crispim[1], Keita Ito[P][1]

[1] *Eindhoven Technical University*

Corresponding author's email: K.Ito@tue.nl

Current regenerative therapies for cartilage have proved their success in clinics, however they are associated with several drawbacks that require resolution. Optimizing chondrocyte expansion and their in vitro assembly, can potentially reduce the time and costs of these therapies and at the same increase their clinical potential. In this study we developed a suspension expansion protocol for chondrocytes with the addition of notochordal cell matrix (NCM) as supplement. NCM is a matrix rich in collagen type II, GAGs and growth factors. This led to the formation of organoids, similar in composition and organization to cartilage, in large quantities and in a short period of time (12 days). Next, we encapsulated these organoids into alginate hydrogels with different viscoelastic properties to study how viscoelasticity of the matrix affects cartilage formation by the organoids. We observed that in the more viscoelastic hydrogel, the organoids grew and fused together leading to the formation of a homogenous tissue similar to native cartilage in composition and organization in contrast to the more elastic hydrogel formulations. When compared with the standard approach using single cells, encapsulation of organoids led to a higher proliferation, matrix deposition and superior tissue organization. The resulting neocartilage was mechanically superior and stable after 24 days of culture. This study describes a multimodal approach that involves chondrocyte expansion, organoid formation and their in vitro assembly into neocartilage which proved to be superior to the current standard approaches used in cartilage tissue engineering.

Mimicking the complex hierarchical structure of the extracellular matrix (ECM) has always been a major goal in tissue engineering (TE) approaches [1] [2]. Despite the great advances in biomaterial processing technologies, the main limitation concerns the resolution of the fibers, which hampers the reproduction of ECM.

Here, we combine Silk Fibroin (SF) [5], a highly potent biomaterial that intrinsically has the characteristics of making fibrous structures, with Electrohydrodynamic printing, an innovative 3D printing technique that allows patterning at micro and sub micro scale.

To fabricate these complex structures, Electrohydrodynamic printing applies a voltage between the needle and the collector screen to charge the polymer solution, with a consequent thinning of the fibers, making it possible to reach optimal resolutions for recreating the hierarchical and fibrillar structure of ECM [3] [4].

We have studied SF in its chemical structure to allow a better understanding of the structural and mechanical behaviour of the material before and after printing. We have demonstrated the printability of SF with Electrohydrodynamic printing and, just by tuning the rheological properties, it is possible to obtain straight fibers with a resolution of 10-20 mm. We have also demonstrated that these fibers can be physically crosslinked inducing the formation of b-sheets structure in the protein chain; after crosslinking the fibers are stable and don't dissolve in water.

SF is therefore proving to be an optimal material for this application and is gaining strong interest in soft tissue engineering.

Aging worldwide population demands new solutions to permanently restore damaged tissues, thus reducing healthcare costs. Stem cells are a promising alternative due to their differentiation potential into multiple lineages. Yet, better control over cell-material interactions is necessary to maintain tissue engineered constructs in time. In particular, it is crucial to control stem cell quiescence, proliferation and differentiation in 3D scaffolds while maintaining cells viable in situ. Here, we developed a biomimetic scaffold inspired by the mesenchymal stromal cell niche. The multi-compartment scaffold is composed of a hydrogel, aimed at maintaining cell quiescence, encapsulated on a proliferative electrospun cup that is surrounded by a 3D printed scaffold, aimed at differentiation via peptide sequences.

In vitro, cells encapsulated in alginate remained quiescent for a low concentration of RGD peptides bound to the hydrogel matrix. Cells seeded on electrospun meshes were able to proliferate and migrate through the entire mesh thickness, depending on the pore size and fiber diameter of the scaffolds. Cells seeded on the 3D printed scaffolds functionalized with osteogenic and chondrogenic peptides on a gradient manner were able to support cell differentiation, as measured by classical osteogenic and chondrogenic gene markers expression and protein secretion.

In vivo, the scaffolds showed to maintain biocompatibility. The gel compartment served as a pool of quiescent cells that were able to migrate and proliferate on the electrospun mesh. The 3D printed compartment appeared fully infiltrated by neo-tissue and served as a support for cell differentiation with large amounts of collagen and glycosaminoglycan deposition.

Engineering muscle tissue is challenging due to the limited degree of diffusion. To overcome this problem, the incorporation of a vascularized network is important. Therefore, a possible strategy is generating vascularized tissue-specific spheroids. The use of these microtissues is advantageous compared to single cells because of their high cell density and accelerated ECM production. When spheroids are combined with a hydrogel, a bioink can be obtained and used for 3D bioprinting. Vascularized spheroids were generated by seeding 7,5x10^5 endothelial cells, fibroblasts and mesenchymal stem cells (MSC) in a 200 µm-microwell system. Myogenic spheroids were generated by seeding 1,0x10^6 myoblasts, whether or not together with MSC and endothelial cells, in a 400 µm-microwell system. After cultivation in expansion medium, spheroids were exposed to differentiation medium. Subsequently, vascularized myogenic spheroids were generated by combining myoblasts, MSC and endothelial cells. To assess the effect of different hydrogel compositions, encapsulation experiments were performed in gelatin-methacryloyl and gelatin-norbornene. Morphology, ECM production and spheroid viability was evaluated.

Stable vascularized and myogenic spheroids could be obtained. Encapsulated spheroids remained viable and histology showed the presence of tissue-specific ECM components. Hydrogel composition had an effect on the morphology. Moreover, different pre-encapsulation stages of the spheroids determined the fiber alignment of the muscle tissue.

During this study it was demonstrated that both stable vascularized and myogenic spheroids can be obtained and encapsulated to use as a part of a printable bioink. Future work will investigate if the bioprinting of vascularized myogenic spheroids leads to functional muscle tissue constructs.

Nowadays, the main approaches to engineer vascularized tissues are to develop biomaterials combining with cell-based therapy to achieve rapid vasculogenesis, angiogenesis and anastomosis between engineered and host blood vessels. However, the thickness of engineered vascularized tissues in animals were still less than 1 mm, because the hydrogel becomes less permeable with increasing thickness. To overcome this challenge, a diffusion-based computational simulation was used to guide and optimize the geometry of hydrogel structures. Then, human white adipose tissue derived mesenchymal stem cells (MSCs) and human umbilical vein endothelial cells (HUVECs) were encapsulated into gelatin-based prepolymer and patterned into different kinds of three-dimensional (3D) hydrogel structures by photolithography micro-patterning technique. After subcutaneous implantation into mice, the cell-laden hexagonal structures can guide vasculogenesis and accelerated angiogenesis to form uniform distributed vascular networks in the large (diameter ≈ 2cm) and thick hydrogel (> 2 mm) within 7 days in normal and diabetic mice. Moreover, mice islets were integrated into this engineered vascular network, and the process of islet revascularization after transplant were reviewed. After 7 days, transplanted islets were anastomosed and integrated rapidly into the surrounding engineered vasculature, and thereby significantly increased the islet viability and function observed in conventional islet transplantation. In summary, we developed a novel micro-fabrication technique to generate large and thick vascularized tissue constructs and showed its improvement in islets function. This concept could serve as a platform technology for engineering other vascularized tissue or organs.

INDUSTRIALIZATION OF MESENCHYMAL STEM CELL DERIVED EXTRACELLULAR VESICLE MANUFACTURING

Bart Van Dijk$_P$[1]

[1] *Lonza senior scientist*

Corresponding author's email: bart.vandijk@lonza.com

Mesenchymal stem cells (MSCs) have shown promise in regenerative medicine and to treat autoimmune and inflammatory diseases. There is growing evidence that the immunosuppressing function of MSCs can be attributed to MSC-derived extracellular vesicles (MSC-EVs). Additionally, MSC-EVs can be used as a drug delivery system aimed at other diseases. In order for MSC-EVs to be used to treat patients, they must be produced according to good manufacturing practice (GMP), and comply with appropriate regulatory guidelines. Lonza is a partner in the EVPRO consortium, which aims to use MSC-EVs to counteract inflammation of hip revision prostheses. Within EVPRO, two manufacturing platforms are used, either multilayer culture flasks (2D) or hollow fiber bioreactor (3D). In the present study, a detailed gap assessment was performed of both approaches, investigating GMP compliance and scalability of the manufacturing process (i.e., procedures, materials, equipment, preliminary data, process scale, analytical testing).The main gaps identified are removing or substituting starting and raw materials, closing and de-risking the process, establishing an in-process and release testing strategy. Additionally, the 2D process has a scalability gap, as it will likely only be scalable up to phase 2/3 clinical studies. Although there are a considerable amount of gaps in the research processes, if addressed by process development, there are no gaps which could prevent transfer to a GMP facility. Next, Lonza will focus on closing these gaps to industrialize the MSC-EV manufacturing process, and transfer the process into a GMP-like setting. This project was funded by EU Horizon 2020 grant 814495-EVPRO.

The therapeutic efficacy of mesenchymal stromal/stem cells (MSCs) is increasingly attributed to its secretion of trophic factors, particularly 50-200nm small extracellular vesicles (sEVs) which include exosomes. We demonstrated in rat models of osteochondral defects and osteoarthritis that weekly intraarticular injections of MSC-sEVs (100µg) enhanced cell survival, proliferation, and matrix synthesis, while concurrently inhibiting cell apoptosis, inflammation, and matrix degradation to promote osteochondral repair. Using chondrocyte cultures, we attributed some of these cellular activities during EV-mediated joint repair to CD73-mediated adenosine activation of AKT, ERK and AMPK signalling. Additionally, we observed in our rat osteochondral defect model that EV-treated defects displayed a regenerative immune phenotype characterized by higher infiltration of M2 macrophages over M1 macrophages, with a concomitant reduction in pro-inflammatory synovial cytokines IL-1β and TNF-α. In a rabbit osteochondral defect model, we further optimized the number of injections and demonstrated that the combination of MSC-sEVs (200µg) and hyaluronic acid (HA) administered at a clinical practical frequency of 3 intraarticular injections were effective in promoting sustained and functional cartilage repair. Defects treated with MSC-sEVs and HA showed enhanced functional cartilage repair with progressive improvements in gross appearance, histological scores, and mechanical properties. By 12 weeks, defects treated with MSC-sEVs and HA composed mainly hyaline cartilage that are mechanically and structurally superior to HA-treated defects and demonstrated mechanical properties that approximated that of adjacent native cartilage. These findings provide the basis for development of a cell-free MSC-sEV therapy that can be escalated to a clinical protocol for joint repair in patients.

We are working on an open microwell islet delivery device that aims to maintain pancreatic islet viability upon implantation by stimulating revascularization. Here we report on the standardization, optimization and upscaling of an off-the-shelf beta cell delivery device made from clinically approved polyvinylidene fluoride (PVDF).

Devices showed and even distribution of microwells across the surface, with an average well diameter of ~380 µm, depth of 260 µm, and pore diameters of 50 µm at the bottom and 90x40 µm at the sides. A software application was created to upscale the delivery device towards human-sized implants. Rat islets showed to be both viable and functional after 7 days of in vitro culture in either mouse- or rat-sized implants. Human islets cultured in rat-sized implants showed improved functionality over free-floating control islets after 7 days of culture. Oxygen imaging was used to measure oxygen kinetics in individual islets during normoxia and hypoxia. Local oxygen levels were affected when islets were within 500 µm of one another. Moreover, in silico local oxygen level predictions seem to overlap with in vitro results.

PVDF is a suitable biomaterial for the production of an next version of the microwell islet delivery device. The combination of oxygen imaging and computational modelling offers insight into the optimal islet packing density within the implant, allowing simulation of several future implant designs. Finally, a software application was developed that allows determination of patient-specific implant dimensions and aids physicians to select which size off-the-shelf implant is most suitable for their patient.

Hyaluronic acid (HA) is an ideal initial material for preparing hydrogels, which may be used as scaffolds in soft tissue engineering based on their advantageous physical and biological properties. In the present study, two crosslinking agents: divinyl sulfone and butanediol diglycidyl ether were used to investigate their effect on the properties of HA hydrogels. As HA hydrogels alone do not promote cell adhesion on the scaffold, fibrin and serum from platelet-rich fibrin were combined with the scaffold, the aim was to create a material intended to be used as soft tissue implant that facilitates new tissue formation, and degrades over time. The chemical changes were characterized and cell attachment capacity of the protein containing gels was examined using human mesenchymal stem cells, viability was assessed using live-dead staining. FTIR measurements revealed that linking fibrin into the gel was more effective than linking SPRF. The scaffolds were found to be able to support cell adherence onto the hydrogels, and the best result was achieved when HA was crosslinked with divinyl sulfone and contained fibrin. The most promising derivative, 5 % DVS crosslinked fibrin containing hydrogel was injected subcutaneously into C57BL/6 mice for 12 weeks. The scaffold was proven to be biocompatible, remodeling, and vascularization occurred, while shape and integrity were maintained.

Stem cell (SC)-based therapies hold the potential to revolutionize therapeutics. They enhance the body's natural repair process, but 99.9% are currently suboptimal in safety and efficacy. The dearth of knowledge in the trajectory and state of SCs throughout treatment has prevented both troubleshooting and devising more optimal therapeutic strategies. Nanoparticles (NPs) are ideal to track SC behavior as they can be made multimodal, biocompatible and are easily modified. In our approach, we design NPs tailored for SC monitoring in the corneal regenerative therapy (CLSCT) by exploiting light imaging techniques. Mesoporous silica NPs can be readily multi-functionalized to achieve multimodality, enabling high-resolution positional imaging of SCs. Gold introduced into their cores allows optical imaging, whilst the addition of fluorescent probes into their silica matrices enables fluorescence imaging. Further, by adding fluorescent probes into the pores that are activated by reactive oxygen species (ROS), SC health and potency can be monitored. With such NPs endocytosed into limbal epithelial SCs, the native regeneration mechanism in CLSCT can be observed in real time. This research should not only enable us to more satisfactorily pre-process SCs, rendering this therapy more efficacious, but also influence the optimization of other SC therapies.

3D bioprinting is an interesting strategy to deliver pancreatic islets towards the human body. To date, only few groups directly 3D bioprinted pancreatic islets inside a hydrogel and assessed cell viability and function.[1-5] However, proper cell functionality was not observed, most likely due to impaired diffusion of insulin. We hypothesize that careful selection of a hydrogel with a relatively open network should lead to the effective diffusion of insulin from hydrogel-encapsulated islets. We studied the diffusion of fluorescently-labeled dextrans (resembling the size of insulin) through different alginate-based hydrogels using fluorescent recovery after photo bleaching (FRAP). In addition, rheology was used to determine the hydrogel mesh size. FRAP indicated that diffusion constants were highest for 1.5% UP alginate, which also showed to hold the largest hydrogel mesh size. Based on these results, INS1E cells (cell line), rat islets or human islets were 3D printed using an Ultimaker 2+ 3D printer modified with a Discov3ry past extruder. Cell functionality was evaluated at both day 1 and day 7, and compared against free-floating controls. All cell types demonstrated to be viable and functional, as the stimulation index exceeded 2. FRAP and hydrogel mesh size measurements are valuable tools to select promising hydrogel formulations for 3D bioprinting. Careful selection of hydrogel characteristics resulted in successful insulin secretion from 3D bioprinted pancreatic islets. We report for the first time on 3D bioprinted pancreatic islets and beta cells which maintain both viability and functionality. Future research will focus on upscaling technique towards a clinically relevant scale.

Carbohydrate-based porous scaffolds are promising biomaterials supporting cartilage regeneration. In this respect, their composition could be designed to face clinical challenges, i.e., articular load bearing, infections and oxidative stress due to inflammation. Herein, an innovative scaffold has been developed, combining raw materials belonging to different kingdoms of life. Indeed, gellan gum, a bacterial-derived carbohydrate, was blended with a beehive product (Manuka honey) with prominent antibacterial features. Moreover, resveratrol, a phytoalexin with powerful antioxidant activity, was loaded into the silica shells of diatoms, unicellular microalgae with cytocompatible features. We hypothesized that the gellan gum-based composite scaffold holds suitable mechanical properties to support mechanical loading during new cartilage formation, providing anti-infective and antioxidant properties through Manuka-honey supplementation and resveratrol release. The resveratrol-doped scaffold, chemically, morphologically, mechanical and pharmacokinetically characterized, was demonstrated to have mechanical properties in the range of that of natural cartilage (Young's modulus between 130 and 147 kPa), to be cytocompatible and able to promote chondrogenesis by preserving the cells maturation also within oxidative stress conditions by scavenging oxygen and nitrogen active species thus reducing oxidative stress. Resveratrol doping also contributes to enhance the antibacterial protective effect of the Manuka honey towards regenerating chondroblasts even in the presence of Staphylococcus aureus infection due to the ability to preserve the metabolically active cells.

Direct reprogramming of fibroblasts into induced cardiomyocytes (iCMs) represents a new promising strategy to restore cardiac functions after myocardial infarction. Recently, our group demonstrated that four microRNAs (miR-1, 133, 208 and 499, termed “miRcombo”), previously studied in mouse model, were effective in direct reprogramming of adult human cardiac fibroblasts (AHCFs) into iCMs [1,2]. Moreover, literature findings suggested that direct reprogramming efficiency increases for cells in three-dimensional (3D) culture substrates [3].

The aim of this work was to analyze the effect of miRcombo transient transfection on AHCFs cultured in 3D fibrin-based hydrogel (5 mg/mL) versus 2D culture plates. After 15 days culture, the expression of Cardiac Troponin T (cTnT), Myosin heavy Chain 6 (Myh6) and Cardiac Troponin I (cTnI) was higher in miRcombo-transfected AHCFs in 3D versus 2D cultures. Interestingly, cardiac markers were slightly upregulated for NegmiR-treated AHCFs in 3D versus 2D cultures, suggesting increased cell plasticity in 3D culture microenvironments.

Additionally, we demonstrated that cardiac markers were upregulated in miRcombo-transfected cells cultured in 2D plates coated with biomimetic natural polymers versus uncoated plates, suggesting that biochemical cues improve direct reprogramming efficiency. Hence, “biomatrix”, a cardiac extracellular matrix produced by AHCFs cultured in vitro [4] was included into 3D-fibrin hydrogels to recreate a cardiac-like microenvironment. Direct reprogramming efficiency of miRcombo-transfected AHCFs cultured in fibrin/biomatrix hydrogels increased as a function of biomatrix concentration (10-100 µg/mL).

This research was supported by BIORECAR project funded from the European Research Council (ERC) under European Union's Horizon 2020 research and innovation programme (grant agreement No 772168).

Stem cell therapies offer promising solutions to treat diseases or conditions for which few treatments exist. There has been interest in harnessing the potential of mesenchymal stem cells (MSCs) however, the clinical trials have been disappointing and inconsistent.[1,2] One of the major reasons for the failure of MSCs in clinical trials is that these cells trigger thrombotic activity upon infusion. The CD142 or tissue factor (TF)[3] expressed on the cell surface is believed to be a master regulator of thrombotic activity and the effect of TF knockdown on these cells were never investigated. In this study, we have engineered a novel pluronic-derived nanoparticle (PSS-NP) for delivering anti-TF siRNA. PSS-TF NPs were able to knockdown (KD) TF with ~75% efficiency without eliciting any toxic effects. The TF-KD MSCs significantly reduced the instant blood mediated inflammatory reaction in human whole blood model as evidenced by reduced platelet aggregation (~3 folds less compared to MSCs) and thrombin anti-thrombin complex formation when compared to the MSCs. Unexpectedly, TF-KD MSCs also enhanced the differentiation efficiency in osteogenic conditions as evidenced by increased mineralization as well as higher expression of genes related to osteogenesis (ALPL, BGLAP, DLX5). The TF-KD MSCs retained their immunosuppressive properties, as evidenced by the suppression of pro-inflammatory cytokines on M1 macrophages. However, the TF-KD MSCs displayed enhanced paracrine signaling when activated by endotoxins. We believe, the results of our study are of great importance and will bring a paradigm shift in performing stem cell-based therapies.

Mucociliary clearance (MCC) is an important mechanism of the respiratory system and depends on the globally unidirectional orientation of ciliary beating within the epithelium. For tissue engineered constructs of the respiratory tract it is essential to recreate a correct ciliary beating orientation. However, the unidirectional orientation is missing in current in vitro cultures. In this study, we established an in vitro bioreactor culture system to investigate the influence of mechanical stimuli to respiratory epithelial cells with regard to the global orientation of cilia.

For culture and stimulation, a bioreactor composed of two chambers separated by a PET-membrane was used. The bottom chamber was used for dynamic medium supply, the upper one for the culture and stimulation of human respiratory epithelial cells (HREs). Mechanical stimulation of cells occurred via airflow applied by a syringe pump. Bioreactor cultures with and without stimulation were compared to each other as well as to static controls.

The established bioreactor system enables HRE culture on a PET membrane with dynamic medium exchange and the use of laminar airflow to mechanically stimulate the HREs via defined wall shear stresses. Furthermore, it allows investigation of mucociliary transport using fluorescent microbeads. Immunohistochemistry is used to analyse cell polarization and the orientation of cilia.

Mechanical stimulation of HREs via applied airflow is believed to assist the airway epithelium in correctly orienting the cilia on a global scale. Achieving the unidirectional ciliary beating in vitro represents an important step for the creation of tissue engineered constructs with functioning MCC.

Induced pluripotent stem cells (iPSCs) differentiated to renal progenitors can self-organise into nephron-like structures when cultured in an air-liquid interface.[1] Although these organoids contain kidney-like structures, their maturity is limited.[2] Moreover, we previously identified an aberrant extracellular matrix (ECM) protein expression (type 1a1 collagen and alpha-SMA) that indicated a possible fibrotic programme. Therefore, making these kidney organoids unsuitable for kidney replacement for patients with chronic kidney disease. Previous results showed a reduction of these aberrant ECM expression when organoids were encapsulated in soft thiol-ene cross-linked alginate hydrogels (180 Pa) for 4 days instead of the air-liquid interface.

To further investigate the hydrogel properties related to this improvement of the renal phenotype, we designed a series of different dynamic covalent hydrogels with various relaxation times or stiffnesses, ranging from approx. 10^1 to 10^5 sec. and/or 100 Pa to 20 kPa respectively. We used cross-linkers that are dynamic under cell culture conditions, resulting in reshuffling of the cross-linker bonds when multiple groups are present.[3] This mimics the dynamic characteristics of the naturally occurring extracellular matrix. The formed kidney organoid were encapsulated in the series of hydrogels and cultured. Their phenotype and the expression of key extracellular matrix proteins was analysed to determine the role of relaxation time and stiffness on organoid culture. Preliminary results shows difference of cell types and ECM expression when encapsulated in a stiffer hydrogel. This study highlights the importance of carefully choosing the hydrogels properties and cellular response on these biomaterials within the regenerative medicine and organoid fields.

A large number of chemicals remain inadequately tested for their potential cardiotoxic effects. Current approaches rely on large animal models, with limitations in terms of cost and complexity. Support in cardiotoxicity evaluation could be obtained by 3D models effectively mimicking the cardiac tissue. Compared to 2D, 3D cell culture more accurately represents the real cell micro-environment, influencing the spatial organization of cell surface receptors involved in cell-cell and cell-extracellular matrix crosstalk, and providing physical constraints to cells, which affect signal transduction and cell behaviour. 3D cardiac models should replicate also the mechanical properties and chemical composition of the native tissue.

In this work we developed of an innovative poly(ester urethane) (PUR) scaffold mimicking cardiac tissue. The PUR was selected because of its elastomeric-like properties1. The porous scaffold was fabricated by thermally induced phase separation and then functionalized with fibronectin by plasma treatment. The success of fibronectin grafting was assessed via XPS analysis. SEM analysis showed a pore-aligned configuration, with mechanical properties and histoarchitecture resembling the myocardium. Biological characterization with fetal cardiomyocytes highlighted a stable viability for 14 days, including good beating activity and adhesion. The increased levels of phosphorylation of AKT and ERK1/2 ought to account for the prolonged cell survival and beating activity of cardiomyocytes cultured on scaffolds versus TCPs. The modulation of cardiac muscle (prepro-ET-1, MYH7, CTGF) and glucose metabolism (SLC2a1, PFKL) genes indicated a transition phase in cardiomyocyte maturation, with an initial evolution to an adult phenotype and a permanence of some fetal characteristics.

Hydrogel fibers are structurally and biologically useful devices for the fabrication of filament-like tissues and differentiation of stem cells [1, 2]. We established a cell-laden degradable hydrogel fiber through visible light-initiated crosslinking to differentiate stem cells and fabricate filament-like tissue [2]. The human adipose stem cells (hADSCs)-laden fibers were fabricated by cross-linking phenolic-substituted alginate and gelatin (Alg-Ph and Gela-Ph respectively) in an aqueous solution containing cells through irradiating visible light. The crosslinking of phenolic moieties was mediated by ruthenium(II) tris-bipyridyl dication (Ru(II)bpy and sodium ammonium persulfate (SPS) [2]. The encapsulated hADSCs proliferated and grew within cell-laden hydrogel fiber, and maintained their pluripotency ability the cells formed filament-like constructs. The filament-like tissues covered with an additional heterogeneous cell layer was made by degrading the fiber membrane using alginate-lyase after covering the fiber surface with vascular endothelial cells. Cellular viability preserved more than 90% during Alg-Ph and Gela-Ph hydrogel fiber fabrication and filament-like tissue formation until 18 days. These results demonstrate the feasibility of alginate-based hydrogel fibers obtained through the Ru/SPS-mediated crosslinking system and visible light irradiation for the engineering of filament-like tissues.

Human bone marrow mesenchymal stromal cells (hBMSCs) associated to biomaterials are currently used in clinic for bone repair. Although the safety of this treatment has been demonstrated in clinical trials, their kinetics of bone formation are heterogeneous (1, 2). Cells from several donors were amplified and grafted either subcutaneously or in-situ into an immunodeficient mouse model and our results indicate that the bone potentials of the cells is donor-dependent. To understand this heterogeneity, we focused on the hBMSCs behaviour and observed that hBMSCs with high bone potential were associated with higher cell survival. To determine their mechanism of action and understand how cell survival is controlled, an RNAseq analysis was performed at 8 hours, 1 and 2 weeks after engraftment. The greatest differences were observed at 8 hours and our results show that cells with reduced bone potential have higher levels of expression of pro-inflammatory cytokines. This is associated with an upregulation of murine neutrophil and NK-cell activation, indicating possible chemotaxis of the host immune system by cytokines secreted by transplanted cells. Differential activation of the host's innate immune system can play a major role in the long-term cell-survival. Neutrophil-depleted mice were used and 24 hours post graft, our results show better cell survival which is associated with an increase in bone formation. In conclusion, our results show that part of the heterogeneity of hBMSCs is due to their ability to regulate the inflammatory response, which has an impact on their survival and therefore their bone potential.

Hydrogels derived from natural substrates are emerging constructs for multifunctional microenvironment cell culture and tissue fabrication [1-4]. In this study different compositions of hyaluronic acid (HA) and chitosan (CH) with opposite charges fabricated. In order to increase the interaction between these components phenol moieties conjugated on backbone of HA (HAPH) and CH (CHPH), and the conjugated samples subjected to enzymatic crosslinking via carbodiimide-mediated condensation in the presence of horseradish peroxidase to make hybrid hydrogel scaffolds [1-3]. The physical characteristics of hydrogels including gelation time, enzymatic degradation and water contact angle of hydrogels decreased with increasing HAPH content. The rheological and mechanical properties of the hydrogels showed that moderate concentration of HAPH can have the best results in the hydrogel structure. Hydrogel morphology altered depending on the amount of incorporated HA in CH precursor hydrogel solution and their pore size destitution decreased with increasing HAPH. The cellular studies showed proper cell viability and proliferation for cells on optimum blend hydrogel surface compared with the neat hydrogels. Furthermore, the hybrid hydrogels demonstrated good characteristic for expression of cartilage tissue markers including Col2, SOX9 and ACAN and higher propensity of MSCs to differentiate into cartilage cells comparing to the control samples. Therefore, the results suggest the optimum hybrid hydrogel can provide superior biological microenvironment for chondrocytes in three-dimensional cartilage tissue engineering.

Introduction

Autologous chondrocyte implantation (ACI) is a procedure to treat cartilage defects; chondrocytes are isolated from an unaffected area of cartilage and are then expanded to be re-implanted to repair the defect site. Many aspects of this process are not optimized: in particular, monolayer expansion culture causes chondrocytes to de-differentiate, expressing mesenchymal or stem-like markers as: CD10, CD90, CD105, CD1661, collagen-I, collagen-II and versican. Repair tissue formed from these cells include undesirable fibrous extracellular matrix. We hypothesize the introduction of novel 3D cell expansion techniques (bioreactors) can reduce /eliminate de-differentiation and increase the cells therapeutic potency. To facilitate this investigation, we have developed a prognostic assay using FACS to characterize cell phenotype, enabling a rapid and high-throughput analysis of manufactured chondrocytes.

Methods

A literature review was conducted of the markers associated with chondrocyte isolation, culture, de-differentiation, and trans-differentiation.

Results

FACS markers of healthy chondrocytes, pericellular matrix and mature chondrons (CD 151, collagens II, VI, IX and aggrecan), hypertrophic chondrocytes (collagens I and X). Markers of de-differentiated cells include CD90 (mesenchyme), CD9 (osteochondroprogenitor)2, CD146 (chondroprogenitor)3.

Discussion & Conclusions

We have developed a FACS-based assay to qualify, quantify and characterize the cell types and sub-populations produced during chondrocyte expansion culture. This assay is novel as it identifies the level of de-differentiation under culture conditions and provides a ratio for immature (potentially reparative) chondrocyte/progenitor cells and the mature chondrocytes (surrounded by chondrons). This test allows for a high-throughput screening of cells manufactured under novel and improved bioreactor conditions.

Genetically engineering of mesenchymal stem cells (MSCs) has attracted great interest for osteoarthritis (OA) to enhance cartilage repair. We aimed to investigate the impact of MSCs overexpressing platelet-derived growth factor (PDGF-MSCs) or heme oxygenase-1 (HO-1-MSCs) on OA phenotype in chondrocytes and synovial cells and assess the in vivo efficacy by intraarticular injections in canine OA models. Canine chondrocytes or synovial cells were stimulated with lipopolysaccharide (LPS) to mimic the OA and then cocultured with MSCs, PDGF-MSCs, or HO-1-MSCs. We examined gene expression related to OA pathology; pro-inflammatory, extracellular matrix-degradative/synthetic, or pain-related factors. Furthermore, canine OA models were randomized into four groups: normal saline, MSCs, PDGF-MSCs, and HO-1-MSCs. We then assessed OA symptoms, radiographic OA severity, and serum matrix metallopeptidase (MMP)-13 before and after treatment. Overexpression of PDGF or HO-1 significantly reduced expression of proinflammatory factors, MMP-13, and nerve growth factor elicited by LPS, but increased that of aggrecan and collagen type 2 or tissue inhibitor of metalloproteinases (TIMP) in chondrocytes or synovial cells. Furthermore, co-cultured MSCs have exhibited a high expression of genes to maintain joint homeostasis. In vivo studies showed that OA symptoms were improved after the administration of all MSCs. Also, PDGF-MSCs elicited the most significant improvement of limb function and pain reduction. No remarkable significant difference was found in radiographic assessment and serum MMP-13 change. Targeting genetically modified MSCs focusing on PDGF and HO-1 is an effective strategy to treat OA, which suggests that PDGF-MSCs can be novel bioagents leading to greater improvement of OA symptoms.

Articular cartilage disease and injury result in restricted movement, pain and disability in advanced stages. Articular cartilage has a limited ability of self-repair and no known drugs currently exist that fully cure the damaged tissue. Several studies describe the use of tissue engineering tools to construct articular cartilage but most tissue engineered cartilage is made of a mixed cell population without considering the stratified nature of the original tissue. Therefore, we applied tissue engineering techniques to construct stratified cartilage to replace the damaged one. Freshly isolated bovine knee chondrocytes were 3D-cultured in biomimetic alginate sulfate hydrogels which induced their proliferation by 5-fold independent of gel stiffness, while maintaining the cartilage phenotype. Chondrocytes were subjected to different zonal stimuli such as oxygen tension and mechanical stimulations. The mechanical properties of the hydrogel were tested using a texture analyzer (Instron machine) and mechanical stimulations were applied to the whole system using a cell stretching system (STREX). The difference in oxygen tension applied to the system induced different cartilage phenotypes. Low oxygen promoted middle/deep phenotype and high oxygen promoted a superficial zone phenotype. The engineered layers will be bound together to form a single tissue. The stratified biomimetic knee cartilage tissue with phenotypically stable chondrocytes can be developed in vitro and can be used for therapy in case of injury or disease.

The cornea is a transparent avascular tissue which is responsible for refracting and transmitting light into the eye. About 90% of the cornea is composed of the stroma which exists of precisely arranged collagen fibrils. Between these collagen lamellae keratocytes can be found, which are mitotically quiescent cells.[1] In wound repair processes these keratocytes differentiate into a myo-fibroblastic phenotype. Lately, the idea of a bioengineered cornea has gained credibility in the field of ophthalmology. Synthetic hydrogels based on supramolecular moieties allow for material tunability by the incorporation of bioactive additives into the material which encourage the mimicking of the natural extracellular matrix.[2] In this project, we aim to modify bioactive additives with ureido-pyrimidinone (UPy) moieties to design an in-vitro hydrogel-based 3D stromal construct for encapsulation and recruitment of corneal keratocytes.

A collagen type I binding and an integrin binding peptide were synthesized and functionalized with UPy-moieties.[3] Additionally, dendritic structures were synthesized of the collagen binding peptide to mimic multivalent peptide presentation. Various combinations of these peptides were incorporated as bioactive additives within an UPy-based hydrogel. Activated human corneal keratocytes were encapsulated in the hydrogels and cultured for several weeks in 3D. Immunofluorescence revealed the expression of characteristic myo-fibroblastic cell markers: alpha-smooth muscle actin, and vimentin. Moreover, the hydrogels showed proliferated cells and cellular production of various collagen types.

We have successfully designed a 3D-hydrogelconstruct with biological properties that supported the encapsulation of activated keratocytes. Next, this project will be extended with studying the phenotype maintenance of encapsulated primary keratocytes.

INTRODUCTION: Low back pain affects 80% of the population at some point in their lives with 40% of cases attributed to intervertebral disc (IVD) degeneration. We have recently developed an ex vivo caprine IVD degeneration model that accurately represents the human condition [1]. Here we aim to utilise this model for testing the efficacy of our synthetic, Laponite® cross-linked pNIPAM-co-DMAc, injectable hydrogel (NPgel) [2] to halt or reverse degenerative processes.

METHODS: After establishing the ex vivo model [1], degenerate caprine IVDs were injected with NPgel (+/- mesenchymal stem cells) and subjected to a further 21 days of physiological loading within a bioreactor system. Histology, immunohistochemistry and FTIR imaging were performed subsequently to assess matrix and protein expression changes.

RESULTS: Histological staining identified catabolic matrix and protein expression in degenerated caprine IVDs, similar to changes observed during human IVD degeneration. The injection of NPgel increased the expression of healthy NP matrix proteins, such as aggrecan, and also decreased expression of catabolic factors IL-1β, IL-8, MMP3 and ADAMTS4 compared to degenerate discs that were not injected with NPgel.

DISCUSSION & CONCLUSION: The development of treatments for IVD degeneration is hindered using models which do not closely represent human IVD degeneration. Here we have established a reproducible, large animal model of IVD degeneration. Within which, NPgel halted catabolic processes and initiated regeneration of the IVD, indicating that in the future this may become a viable treatment strategy for IVD degeneration.

Natural extracellular matrix (ECM) has been used as a natural scaffold to improve the repair of numerous tissues (1-3). Decellular ECMs can induce and promote cellular fate such as proliferation and differentiation of the stem cells. The decellular matrix gelled by neutralization in the physiological conditions which prove the injectability of the produced scaffold. The transforming growth factor-beta (TGF-β) superfamily is a key mediator of MSC chondrogenesis. Here, we investigated the decellularized cartilage hydrogel containing alginate microsphere Loaded by TGF-β to the improvement of chondrogenic differentiation of human MSCs. The TGF-β encapsulated in alginate microspheres showed release times extending up to 6 days. Decellularized hydrogel seeded with MSCs and TGF-β containing microspheres developed comparable chondrogenic gene expression to constructs supplemented with TGF-β continuously in culture media or with hydrogel without any TGF-β, whereas constructs with TGF-β directly encapsulated in the ECM without microspheres had inferior properties. Histological studies also show the appropriate chondrogenic differentiation for the hMSCs in the test group. Also when these constructs implanted in defects that were prepared from the cow femur knee, constructs containing TGF-β microspheres resulted in superior cartilage matrix formation to groups without or with TGF-β added directly to the gel. This study demonstrates that the controlled local delivery of TGF-β is essential to neocartilage formation by MSCs and that further optimization is needed to avert the differentiation of chondrogenically induced MSCs towards a hypertrophic phenotype.

Nanotechnologies applied to the inner ear involve different applications, among which the development of drug delivery systems and the production of new materials useful to improve the efficiency of innovative cochlear implants. The purpose of this study was to examine the biocompatibility of different nanoparticles, lithium niobate, barium titanate and chitin nanofibers (nanochitin) on a cell line derived from an Immortomouse ™ organ of Corti, the OC-k3. These cells mimic the sensorial inner ear tissues because they express markers of hair and supporting cells and not those typical of neuronal cells. Cell viability, cell morphology, apoptosis and oxidative stress were tested on OC-k3 cells treated with nanoparticles up to 48 hours. The results showed that lithium niobate and nanochitin did not affect the viability of OC-k3 cells up to 48 hours. Further tests showed that all nanoparticles did not affect cell morphology, apoptosis and oxidative stress. Lithium niobate, barium titanate and nanochitin show a good biocompatibility on sensory cells, therefore they could be used to develop an innovative cochlear implant electrode based on a new piezoelectric nanomaterial obtained by combining these nanoparticles. This study was performed as part of the Italian Health Ministry project “New self-powered devices for cochlear stimulation based on piezoelectric nanomaterials” (RF-2011-02350464), the “4NanoEARDRM” project funded under the frame of EuroNanoMed III, and by the Italian Ministry of Education, University and Research (MIUR), Italy [grant n. PRIN-2010S58B38_004].

Globally, donor tissue falls far short of meeting demand for corneal transplants; currently less than 2% of patients in need receive a donor cornea. Synthetic alternatives to donor tissue are on the market, but these are a last resort measure due to their high risk of rejection. Additionally, these synthetic corneas do not allow the cells of the eye to repopulate the region. As a result, tissue engineers are focusing on creating materials which support corneal cell expansion and function. These materials are often very successful in this aspect, however fail to take into account factors such as optical transparency, refractive indices and the necessary mechanical characteristics to support surgical considerations such as suturing and intraocular pressure.

Here, we present a hybrid construct which takes these considerations into account. An optically clear hydrogel was combined with supportive patterned electrospun matrices to provide a construct capable of supporting both corneal cell expansion and function as well as surgical suturing and necessary pressure prerequisites. Several material combinations were tested with human corneal keratocytes and results validated using immunohistochemistry and qRT-PCR. Additionally, a novel mechanical characterization was performed to assess suturability of the construct.

Results indicate that these constructs hold promise for corneal transplant, providing an alternative to the shortcomings of synthetic corneas and the global shortage of donor tissue.

ACKNOWLEDGEMENTS: This research was performed under the framework of Chemelot InSciTe , as part of the EyeSciTe Consortium (Netherlands). Medace B.V. Maastricht provided equipment and research space.

Understanding the complex interactions between cells and nanoparticles has been one of the main objectives of nanomedicine since its dawn (1). The physico-chemical properties of nanoparticles have been studied over the past decades for improving the delivery of therapeutic anti-cancer drugs (2-4). Although significant, these efforts have produced poor clinical translation of nanoparticle-based therapies (5).

Therefore, a shift toward new paradigms, in which the inner molecular processes of the cells take the lead in the interpretation of bio-nano interactions, is desirable. In this context, the study of cell mechanics has emerged as a promising area of investigation (6). Indeed, the mechanical properties of cells have been recently proposed as new prognostic factors in cancer growth and dissemination (7). Mechanotargeting and mechano-therapeutics made their way through medical vocabulary as a new class of drugs and treatments targeting mechanically activated pathways involved in pathologies (8-9). By using nanoparticles with tunable size and surface coating, we demonstrate that the inhibition of Yes-associated protein (YAP) – a key protein of mechano-regulated Hippo pathway responsible for cell stiffness regulation (10) - affects nanoparticles uptake in cancer cells. Remarkably, nanoparticles internalization is independent of YAP inhibition in healthy cells, where its activity is less pronounced. In conclusion, our study represents a proof-of-concept that the internalization of nanoparticles in target cancer cells might be controlled by tuning cell mechanosensing pathways, ultimately improving the specificity of the nanotherapy.

Diabetes triggers chronic inflammation, declines the antibacterial action and angiogenesis leading to protracted wound healing. Bioactive glass manifested high regenerative efficacy when used in bone regeneration (1). This study aimed to assess the regenerative efficacy of novel bioactive glass nanofibers (BGnf) on surgically created alveolar mucosal wounds of the diabetic rabbit model. Glass nanofibers(500-900nm):(1–2mol% of B2O3, 68–69 mol% of SiO2, and 29–30 mol% of CaO) were synthesized via the sol-gel technique followed by electrospinning of the glass/polymer sol and heat-treatment of fibers at 700C(2). Fibers analysis broadcasted its amorphous, cross-linked structure and bioactivity. Following that, 12 healthy New Zealand rabbits were successfully subjected to chemical induction of type I diabetes. Two weeks after diabetes confirmation, two groups of bilateral elliptical maxillary mucosal defects (10 * 3.5 mm) were created. The defects of the experimental group were grafted with BGnf(n=12), while the other group was the control(n=12). To evaluate fibers regenerative efficacy, three different assessments (clinical, histological, and immune-histochemical) were performed at 1, 2 and 3 weeks' time interval(2). After 1 week, BGnf treated wounds showed complete wound regeneration with significantly high-level VEGF (14.08±3.88%) and collagen I% (6.12±0.49%) expression. Contrariwise, the control group showed suppurative exudates with inflammatory cell infiltration at lamina propria and lower VEGF(3.92±0.222%) and collagen I(3.88±1.934%) expression. After 3 weeks, VEGF and collagen I of BGnf group also recorded a higher expression than the control group. In conclusion, BGnf stimulates in- situ soft tissue regeneration, neovascularization and antibacterial action in the wet oral environment in diabetic patients.

Fiber mat containing cell interactive molecules offers the ability to deliver the cells and bioactive molecules in wound bed, which will help to achieve a high therapeutic treatment (1-3). In this study, co-electrospun hybrid of polyvinyl alcohol (PVA), chitosan (Ch) and silk fibrous mat was developed and their wound healing potential by localizing bone marrow mesenchymal stem cells (MSCs)-derived keratinocytes on it was evaluated in vitro and in vivo. The fabricated fibrous Ch-PVA + Silk hydrogels were characterized for their structural, mechanical and biochemical properties. The shape uniformity and pore size of fibers showed smooth and homogenous structures of them. Fourier transform infrared spectroscopy (FTIR) verified all typical absorption characteristics of Ch-PVA + Silk polymers as well as Ch-PVA or pure PVA substrates. The contact angle and wettability measurement of fibers showed that mats found moderate hydrophilicity by addition of Ch and silk substrates compared with PVA alone. The mechanical features of Ch-PVA + Silk fibrous mats increase significantly through co-electrospun process as well as hybridization of these synthetic and natural polymers. Higher degrees of cellular attachment and proliferation obtained on Ch-PVA + Silk fibers compared with PVA and Ch-PVA fibers. In terms of capability of Ch-PVA + Silk fibers and MSC-derived keratinocytes, histological analysis and skin regeneration results showed this novel fibrous construct could be suggested as a skin substitute in repair of injured skin and regenerative medicine applications.

TISSUE ENGINEERING OF THE TEMPOROMANDIBULAR JOINT CONDYLE: AN ANATOMICAL HISTOLOGICAL INVESTIGATION. THE DEPARTMENT OF MATERIALS, SCHOOL OF NATURAL SCIENCES, THE UNIVERSITY OF MANCHESTER, UK. A. FREED, M.O'BRIEN, J. GOUGH AND S. CARTMELL.

The temporomandibular joint (TMJ) is a complex joint which is made up of the articular disc and condyle (1). Temporomandibular disorders (such as clicking, locking, dislocation, and degeneration) affect 10.5 million people worldwide (2). The current gold standard for repair is surgery which carries risks, lengthy downtime and long-term pre/post assessments. Tissue engineering is a promising alternative for condylar repair and replacement. In order to regenerate the condyle, the anatomical structure needs to be understood. As current literature is limited in this area, this study investigates the anatomy of four rat condyles using histology.

Two rats were dissected (3). Haematoxylin and eosin (H&E), collagen type II, picrosirius red (PSR) and alcian blue (AB) stains were applied. The H&E stain identified the following four zones in the condyle; fibrous layer, proliferative layer, chondrocytic layer and the hypertrophic layer.

The PSR stain highlighted collagen in the condyle but showed no collagen type I or III. Collagen type II marker stain showed type II collagen present throughout the four layers of the rat condyle. The AB stain revealed sulphated acid mucopolysaccharides at 0.2M throughout all four layers. 0.5M highlighted strongly sulphated acid mucopolysaccharides present throughout all four layers. Keratan sulphate was strongly present in the fibrous layer at 0.9M.

The PSR stain showed no traces of collagen type I and scarce type III which challenges previous literature (1). The AB stain showed a variance of proteins throughout the condyle. These differences between human and rat tissue are currently being investigated further.

The aim of this study was to evaluate the bone regenerative capacity of a soft, load-transducing elastomeric scaffold; Poly(glycerol sebacate)(PGS) in surgically created palatal defects simulating a cleft palate condition in New Zealand white rabbits. A total of 18 rabbits were used. A palatal defect model was created posterior to the maxillary second incisors (n=8). After optimization, the final 5x2.5x4mm3 defect reaching to -but not perforating- the nasal mucosa was created in 11 rabbits; sham control (n=5) or PGS (n=6). Samples were retrieved after 4 and 8 weeks for CBCT, histological and histomorphometric analyses. Results showed that dimensions of the defect grafted with PGS showed significant reduction after 8 weeks, but sham defects showed a decrease in coronoapical dimensions but increase in mediolateral dimensions. Bone density (2096.4HU±83.62) and mean bone fill% (70.46±1.73) were significantly higher for PGS than sham defects (1807.51HU±25.10) and (57.55±4.90) at 8 weeks, respectively. These values showed increase for PGS from 4 to 8 weeks while they decreased for the sham group indicating advanced bone resorption. Histologically, PGS defects showed almost closure and preservation of the external contour. PGS scaffolds showed a clear enhancement of recruitment of osteoblasts and osteoclasts, significantly increased angiogenesis as well as enhanced osteoid matrix deposition. This study introduced a novel application for PGS in the maxillofacial region. Mimicking the osteoid matrix, it allowed the stimulation of recruited cells into an osteogenic lineage and dynamic bone remodeling while preserving contour and mid palatal suture anatomy which are crucial for cleft palate management.

Numerous studies clearly indicate the existence of a strong influence of physical and chemical cues in native extracellular matrix (ECM) on cell behavior. In particular, micro- to nanoscale topography features in the natural ECM can significantly affect cell morphology, adhesion, migration, proliferation and differentiation [1]. In order to study such spatially defined cell-matrix interactions and to help the formation of biologically functional tissue analogues in vitro [2], there has been an increasing demand for advanced cell culture platforms able to emulate native cellular environments.

A variety of techniques can be used to create micro/nanotopographies on planar substrates. Many studies have confirmed the advantages of such biomimetic substrates as compared to conventional flat cell culture-ware [3]. However, the integration of topographies onto non-planar, curved substrates, which reflects in vivo-like tissue geometry more closely [4], has not been fully investigated due to fabrication limitations.

To address these challenges, we developed an advanced fabrication process that allows us to create complex 3D substrates with both curvature and cell-scale or even subcellular features. Our process is based on an initial formation of micro- or nanotopographies on flat polymer films by conventional nanoimprint lithography and successive curvature formation by a solid-state forming process called 'microthermoforming' [3]. This allows to transform pre-structured planar thermoplastic polymer films into curved substrates which have radii milli- or micrometer range, or at a smaller scale. The developed substrates are expected to better mimic complex in vivo architectures and to provide engineered cell culture substrates for various tissue engineering applications.

ORGAN CULTURE AND BIOREACTORS FOR ASSESSING BIOMATERIALS FOR TISSUE REGENERATION

Mauro Alini[P][1]

[1] *AO Research Institute*

Corresponding author's email: mauro.alini@aofoundation.org

Advanced biomaterials and tissue engineered constructs have been developed to improve tissue repair; nevertheless, their clinical translation has been hampered, also by the lack of reliable in vitro models suitable for pre-clinical screening of new implants and compounds mimicking the in vivo situation.

Tissue regeneration is strongly influence by the mechanical properties and behavior of biomaterials, which can be completely different when tested in "isolation" or in a biological context. Therefore, it is important to evaluate the performance of such advance biomaterials in in vitro models, which reproduce closely the in vivo tissue status.

To such end, we have developed several complex organ models (cartilage, intervertebral disc, bone, etc.) which include, not only the tissue part, but the tissue is cultured within a bioreactor, reproducing loading patterns similar to the in vivo microenvironment. Here, we will focus on bioreactor systems that transmit a mechanical stimulus, as this is a key parameter in the homeostasis of various musculoskeletal tissues, such as bone, cartilage, tendon, and intervertebral disc.

By testing regenerative therapies under conditions that are closer to the ones encountered in vivo, bioreactors can provide a useful screening tool and standardization opportunities for the evaluation of various biomaterials, but as well as cell types, drugs, or tissue engineered products. This will allow to reduce the number of samples for the final in vivo evaluation, allowing the 3R philosophy approach to be implemented.

Durable and non-immunogenic tissue-engineered heart valve replacements are not yet commercially available. Thus, a better understanding of developmental and regulating mechanisms of cardiovascular tissues is essential to develop new implant materials. Moreover, cardiovascular tissue transplants or tissue-engineered grafts need to be monitored before transplantation.

Towards this aim, Raman microspectroscopy and multiphoton imaging were established as marker-independent, non-destructive techniques for quality assessment of cardiovascular transplants. Allogenic and xenogenic cryopreserved heart valves as well as different tissue-engineered polymer scaffold-based heart valve grafts were implanted in sheep models and explants of different timepoints were analyzed by single-point Raman spectroscopy, Raman imaging as well as multiphoton imaging. Transplanted cryopreserved heart valves, were analyzed in regards to tissue integrity and immunogenicity. Moreover, quantitative monitoring of interstitial cryoprotectant concentrations was performed for quality control. In scaffold-based TE heart valves, Raman imaging was applied to investigate structural changes over implantation time and in different leaflet regions. In addition to marker-independent localization of scaffold and tissue structures such as collagen fibers, nuclei or fibrin, this technique allows for a detailed molecular analysis based on specific Raman signatures. Thus, implants could be analyzed in regards to biomaterial degradation and collagen maturation on a molecular level.

Raman analysis combined with multivariate data analysis tools allowed for the determination and characterization of structural extracellular matrix changes, tissue infiltration and formation, scaffold degradation and real-time quantification of residual cryoprotectants.

This work affirms the potential of Raman techniques for future applications in in situ quality assessment in cardiovascular implants.

Osteoporosis is a degenerative disease caused by an imbalance between bone formation and resorption, leading to bone weakening and fractures. One of the affected areas is the pelvis whose fractures are not treated since they require extensive interventions and long recovery. Here, we fabricated an injectable electrospun scaffold made of type I collagen incorporating mesoporous bioactive glasses (MBG) and nano-hydroxyapatite (nano-HA) to promote bone regeneration. Collagen was extracted from rat tails and scaffolds were fabricated using electrospinning. First, different solvents were evaluated and the collagen quality was investigated after fabrication via SDS-page and circular dichroisms. Then, MBG and nano-HA were incorporated from 5wt% to 15wt% and the mats were evaluated in terms of mechanical properties and cytocompatibility. Last, scaffolds were produced using direct writing electrospinning (DWESP), focusing the jet to a point to create 3D scaffolds. Grid and concentric pattern were fabricated, searching for the design that could hold the pressure when injected to the fracture. The ideal solvent resulted to be acetic acid:water, whereas PBS20x:ethanol and acetic acid:ethyl acetate:water did not allow the complete collagen dissolution and therefore were not processable. The resulting scaffolds had a fiber diameter of ~200 nm and the presence of collagen bands was confirmed by SDS-page. MBG and nano-HA were incorporated after sonication up to 15wt%. The two DWESP designs were optimized by varying diameters and dimensions testing also their injectability. In conclusion, collagen could be dissolved and spun successfully through electrospinning and DWESP with or without nanoparticles to be injected into osteoporotic fractures.

Electrospinning is a versatile technique to produce nano and micro scale fibrous scaffolds for tissue engineering and drug delivery applications. This research aims to demonstrate that hyaluronic acid-chitosan (HA-CS) nanoparticles can be electrospun together with a mixture of polycaprolactone (PCL) and gelatine (Ge) using a portable device to create scaffolds for tissue repair. A range of polymer solutions of PCL and Ge at different weight/volume concentrations and ratios were electrospun and characterised. Fibre-cell interaction (F11 cell line) was evaluated based on cell viability and proliferation. Three polymers (8% w/v at 85:15 and 70:30 PCL:Ge ratio, and 10% w/v 50:50 PCL:Ge) were selected and electrospun into different fibre arrangements: random or aligned. HA-CS nanoparticles were synthesised and characterised, and used to functionalise the selected electrospun fibres (8%, 70:30). The optimal dosage (1x10^-2 mg/ml) of NPs was determined using a cytotoxicity assay, prior to embedding these into the fibres as either surface modification or blend. Fibres with blended NPs delivered a higher cell viability than unmodified fibres, while those NP-coated fibres resulted in a higher cell proliferation (72h) than the NP-blended ones. These biocompatible scaffolds allow cell attachment, maintain fibre arrangement, promote directional growth, and yield a higher cell viability.

Despite the considerable volume of research into the biology and regenerative potential of MSC, the lack of suitable models that recapitulate the in vivo situation has led to poor clinical translation1. Decellularized constructs have the ability to present tissue-specific ECM components in their native organization.

In this work, three different constructs, i.e. 2D matrix, 3D scaffold and hydrogel, were optimized as meaningful in vitro models that allow studying the influence of microenvironmental cues on MSC. A 2D decellularized cell-derived matrix was obtained by 10 or 21 days cultivation of human MSC followed by incubation with high-pH detergent solution and DNase. A 3D bioscaffold was produced by EDTA-based decellularization and decalcification of human femoral heads2. A translucent 3D hydrogel was obtained by pepsin digestion of decellularized bone powder followed by neutralization at 37°C for 1h. Removal of DNA was confirmed by nuclei absence observed on histological sections. Preservation of specific bone ECM-related proteins was analyzed by SDS-Page and immunostaining (particularly strong presence of preserved collagen-I was observed for all models). The ultrastructure of models was investigated by SEM and/or microCT, confirming preservation of the native ECM architecture. Resazurin assay and FACS analysis of recovered cells showed sustained MSC viability. Osteogenic differentiation seemed to be promoted by the models, as observed by alizarin-red staining and gene expression analysis. Future studies will investigate how the different complexity of models affects stemness and mechanosensing in MSC, providing insights in the influence of these microenvironmental cues on the regenerative potential of MSC.

Introduction:

Idiopathic Pulmonary Fibrosis (IPF) is characterized by aberrant extracellular matrix (ECM) deposition and remodeling, which orchestrates cellular responses to the fibrotic microenvironment[1]. Decellularized lung ECM-derived hydrogels resemble the mechanical properties[2] of native decellularized tissues, potentially providing a 3D model mimicking native cell-ECM interactions. We aimed to characterize this 3D human lung microenvironment model, with respect to stiffness and viscoelastic properties, in the presence and absence of primary human lung fibroblasts.

Materials & Methods:

Lyophilized powders of decellularized IPF and control lung matrices (pool of 6 patients) were pepsin digested, and formed to hydrogels seeded with control primary lung fibroblasts (n=4 donors), and cultured for 14 days. Stiffness and viscoelastic relaxation were measured by Low-Load Compression Testing[2] (20% strain).

Results:

IPF hydrogels were stiffer than controls (1.84 ± 0.33 kPA vs 1.37 ± 0.35 kPA), and became even more stiff when cell-seeded (1.91 ± 0.37 kPA) in contrast to controls which became softer (1.09 ± 0.27 kPA). Time to reach 100% viscoelastic relaxation was shorter in cell-seeded compared to native hydrogels for both IPF (19.14 ± 3.17 vs 41.6 ± 37.66 seconds) and control (11.44 ± 6.55 vs 22.21 ± 19.59 seconds).

Conclusion:

The mechanical properties of the ECM hydrogels were modified by fibroblasts, while in turn the ECM microenvironment altered cellular responses. These data suggest that higher stiffnesses and altered relaxation patterns of the ECM could contribute to the fibrotic response in IPF by instructing the cells. Fibroblast-seeded ECM-derived hydrogels can provide more insight on cell-ECM interactions in IPF.

The molecular mechanisms for tissue regeneration and wound healing are not yet well understood. Limited success of clinical trials indicates that a crucial aspect of the growth factor wound healing strategy is the effective delivery of these polypeptides to the wound site. A meta-analysis approach in which genetically clear the role of each gene and protein or signal pathway can help to overcome the limitations associated with the application of recombination growth factor proteins. Studies point to the synthesis of factors within the chronic wound environment that could have deleterious effects on the repair process. So, the understanding of how damage or loss of tissue can be reconstructed is one of the biggest challenges in biomedical research and facilitating reconstruction. In this paper, we use a bioinformatics approach and network theory for more accurately and better understanding the genetic underpinnings of wound healing mechanisms.We begin by selecting some literatures related genes in human wound healing in Gene Expression Omnibus to obtain the genes involved in this process and deduce the protein-protein interaction network from them. Then, we analyze the network to rank the genes associated with wound healing according to topological properties and find the hub genes among them. Finally, we perform a method to find the most important biological pathways in GO and KEGG. The findings, including gene expression analysis, confirm how a network-based bioinformatics method is able to classify candidate genes for analysis, thus accelerating the understanding of molecular mechanisms and assist for discovery of potential goals.

AN INNOVATIVE, BIOMATERIAL-BASED DELIVERY SYSTEM FOR THE ANGIOGENIC GROWTH FACTOR VEGF

Matthias Schumacher$_P$[1], Debby Gawlitta[2], Pamela Habibovic[1], Sabine H van Rijt[1]

A limiting factor in clinical bone augmentation is sufficient neovascularization. A promising strategy to tackle this problem is the targeted release of pro-angiogenic growth factors (GFs) from the employed implant. One prominent example is the vascular endothelial GF (VEGF) that can enhance and pattern vascularization [1]. In this context, mesoporous bioactive glasses (MBGs) have been proposed as versatile GF carriers because of their intrinsic characteristics: a large surface area resulting from their highly ordered porosity on the mesoscale, as well as high degradability and bioactivity [2]. However, to date strategies to immobilize GFs on MBGs are solely based on electrostatic interactions – which are poorly controllable in terms of adsorption as well as release kinetics, and may deteriorate protein conformation and activity. Herein, we propose MBGs decorated with VEGF-binding peptide as novel biomaterial/GF-delivery system for bone augmentation applications. MBG was synthesized according to established protocols [2] and surface-functionalized with reactive amine groups using alkoxysilane chemistry [3]. Then, a peptide sequence known to specifically bind VEGF based on [4]) was covalently coupled to the amine functional groups. Both the degree of amine functionalization as well as the amount of immobilized binding peptide could be controlled. Finally, binding efficacy and specificity for VEGF as well as release kinetics and biological activity of the complexed GF were studied.

Taken together, the proposed system appears as promising new strategy to immobilize the pro-angiogenic factor VEGF on a highly biocompatible and bioactive biomaterial and deliver it into a bone defect without impairing its biological potency.

Zinc was described as the 'calcium of the twenty-first century' as consequence of its promising applications in bone tissue regeneration. This element can play an important role in stimulating the osteogenesis and mineralization and suppressing osteoclast differentiation [1]. In this study, new bioactive ZnCl2-doped sol-gel materials were designed to be applied as coatings onto titanium. The materials were synthetized through the sol-gel method using methyltrimethoxysilane and tetraethyl-orthosilicate as precursors and increasing amounts of ZnCl2. The coatings were physicochemically characterized through SEM, FTIR, NMR, hydrolytic degradation, Zn2+ release, contact angle and roughness measurements. Cytotoxicity, ALP activity, gene expression (ALP, RUNX2, RANKL, RANK, iNOS) in vitro testing were performed in MC3T3-E1 osteoblasts; and TNF-α, IL-1β, TGF-β and IL-4 gene expression and TNF-α cytokine secretion in RAW264.7 macrophages. The effect of Zn on the adsorption of human serum proteins onto the material surface was evaluated through nLC-MS/MS.Homogeneous coatings with a controlled Zn2+ release were obtained. The materials were no cytotoxic. Moreover, the addition of Zn increased the gene expression of ALP, TGF-β, and RUNX2 in the osteoblasts. A higher IL-1β, TGF-β, and IL-4 gene expression and a reduced TNF-α liberation were measured in macrophages. Proteomic results showed changes in the adsorption patterns of proteins related to immune, coagulative and regenerative functions, in a Zn dose-dependent manner. Overall, the developed coatings could improve bone regeneration capacity in a Zn dose-dependent manner, as well as exert an anti-inflammatory effect. Furthermore, a correlation between movements in protein adsorption patterns and cellular response was established.

CARTILAGE ORGANOID FORMATION FROM 3D CULTURE OF CHONDROCYTES AND NOTOCHORDAL CELL MATRIX

Autologous chondrocyte implantation is a clinically used technique to regenerate articular cartilage in focal defects, however it faces the challenge of chondrocyte dedifferentiation during 2D expansion in vitro. Previous research has shown that adding porcine notochordal cell matrix (NCM) to the culture medium induces proliferation and matrix production of bovine chondrocytes in alginate beads[1]. Besides, NCM is rich in proteoglycans and collagen type II, important cartilage matrix components. Therefore, it was hypothesized that adding NCM to a 3D chondrocyte culture provides the cells with a cartilage-like matrix to attach to, while also inducing proliferation. Healthy bovine and osteoarthritic human chondrocytes were cultured in spinner flasks (5*10^4 cells/ml) for 12 days with/without 1 mg/ml NCM. Adding NCM resulted in increased proliferation of the chondrocytes (5.6- and 3.9-fold for bovine and human, respectively) compared to the control group without NCM while viability of >90% was maintained throughout the culture period. It was observed that cells attached to the NCM as well as to each other. The organoids kept growing over time, reaching up to 500µm in diameter by day 12. Immunohistochemistry of NCM cultured organoids showed the presence of proteoglycans, collagen type II and VI, and cartilage-marker Sox-9, confirming the chondrogenic phenotype and the presence of an interterritorial and pericellular matrix within the organoids. This work shows the potential of using NCM supplementation in chondrocyte culture, as it leads to proliferation and organoid formation without compromising the phenotype of chondrocytes as in standard 2D expansion protocols.

One of the persisting challenges in articular cartilage regeneration is the inferior quality of repair tissue and lack of integration with the surrounding cartilage, leading to suboptimal load distribution and degeneration of the surrounding cartilage. Culturing chondrocytes with porcine notochordal cell matrix (NCM) has been shown to form organoids containing collagen type II and proteoglycans. The present study hypothesizes that this might improve cartilage tissue formation and integration in short-term cartilage repair. In this study, this novel approach will be compared to an autologous chondrocyte implantation-like procedure using 2D expanded chondrocytes and Tisseel fibrin sealant. Chondrocytes derived from human tissue of patients undergoing total knee replacement (TKR) surgery (n=5) were expanded in spinner flasks supplemented with 1 mg/ml NCM, forming cartilage organoids, and in traditional 2D culture conditions for 12 days. Osteochondral explants (Ø 10mm, 5 per donor) were isolated from tissue of six different TKR subjects and a Ø 6mm chondral defect was created in the center of each explant. Explants were cultured in a double-chamber culture platform in which cartilage and bone compartments are separated to allow for supplementation of tissue-specific medium. Organoids and 2D cultured chondrocytes were implanted into the defects using Tisseel fibrin sealant (10^6 cells/80µl) and the constructs were cultured for 28 days. Characterization of the organoids in the spinner flasks before implantation shows the presence of proteoglycans, collagen type II and Sox-9. Analysis of the biochemical content as well as histological and immunohistochemical appearance of the cultured constructs after 28 days is pending.

Mulberry (Bombyx mori, BM) and non-mulberry (Antheraea assamensis, AA) silk have been used in diverse tissue engineering applications, yet a detailed immune response towards these biomaterials is largely unknown. Here we present a detailed macrophage phenotype and host response towards BM, AA, and blend of BM and AA (BA) silk in comparison with extracellular matrix (ECM) scaffolds (liver ECM and small intestinal submucosa-SIS), and polypropylene (PP) mesh. Host remodeling events, including cell infiltration, macrophage activation, foreign body multinucleate giant cells (MNGC) response, vascularization, and collagen deposition have been evaluated following biomaterial implantation in rat partial-thickness abdominal wall defect model. AA and SIS elicited a pro-inflammatory response at 14 days that transitioned to an anti-inflammatory response by 35 days. All biomaterials showed higher cell infiltration on day 14, and BM, AA, and BA maintained higher cell infiltration at 35 days. LECM and SIS showed fewer MNGC compared to defect only and PP mesh, and AA showed significantly fewer MNGC than BM, BA, and PP mesh on 35 days. In addition, the activation profile of murine bone marrow-derived macrophages (BMDM) was assessed in vitro after treatment with degradation products of biomaterials. AA treatment stimulated a higher arginase:iNOS ratio compared to BM, BA, SIS, and pepsin in naive BMDM, and significantly increased Fizz1:iNOS ratio compared to BM, BA, LECM, SIS, and pepsin in pro-inflammatory challenged BMDM. The outcomes of the present study provide an improved understanding of macrophage-mediated events associated with the source of silk biomaterial, which would aid in tissue engineering applications.

Due to its similarities to the natural extracellular matrix's structure and dynamic rearrangement, dynamic or supramolecular biomaterials have been of increased interest in the field of regenerative medicine. Although mesh-size and diffusion in fixed hydrogel networks are vastly investigated [1, 2], less research has focused on the effect of dynamic hydrogels on the diffusion of key nutrients and toxins.

Nutrient diffusion is important to maintain viable cells within the biomaterials. Moreover, when active cellular transport of molecules is required, this dynamicity should not interfere. This is for example important when these biomaterials are implemented in the design of tubular epithelial cell dialysis devices or kidney replacement (with organoids) for patients with chronic kidney disease[3]. With more than two million patients depending on dialysis with no possibility for kidney transplantation, many different strategies are investigated for the design of dialysis devices and organoid growth [4, 5] capable of toxin transport abilities, which conventional dialysis does not possess.

Here we sought the optimal mesh-size and diffusion properties by employing a variety of dynamic hydrogel systems with different mesh-size and cross-linking strategies. The diffusion coefficients for various protein sizes were determined. Renal tubular epithelial cells (sourced from adult stem cell derived 'tubuloids'[5]) were cultured on these hydrogels. The effect of the hydrogel's dynamicity on diffusion and cellular uptake of toxins were investigated to determine the required diffusion properties for optimal uremic toxin diffusion.

The lack of a hemocompatible blood-material interface represents a major challenge for implanted synthetic biomaterials that are in direct contact with blood [1]. The optimal way to meet such a pivotal hemocompatibility requirement is to create an endothelial lining at the implanted blood-material interface [2], ideally through in situ endothelialization. This requires i) implanting a biomaterial with specific characteristics to recruit and interact with circulating cells that can form a functional endothelium directly in the body [3], and ii) targeting the most favorable cell source for in situ endothelialization. The source of cells recruited in such a process has been under investigation, with the main focus on circulating endothelial progenitor cells (EPCs) [4,5]. However, EPCs represent a very small fraction of the peripheral blood (0.002%-0.01%) [6]. Growing evidence suggests that the more abundantly present monocytes (CD14+) have a strong potential to differentiate into endothelial-like cells, thereby contributing to endothelium formation on implanted artificial surfaces [7].
Here, we focus on designing and testing novel material surfaces to recruit and differentiate circulating monocytes for implant endothelialization. To this end, a supramolecular biomaterial based on hydrogen bonding units is functionalized via a modular approach [8,9] with a heparin binding peptide, to subsequently bind heparin and VEGF to the material. Current testing of the material in blood and under hemodynamic loading will tell the efficiency to recruit angiogenic monocytes and their ability to differentiate into EC like cells to form of a protective monolayer against thromboembolic events on blood-contacting supramolecular implants.

CO-CULTURES IN 3D PRINTED SCAFFOLDS FOR CARTILAGE REGENERATION FOR CRANIOFACIAL RECONSTRUCTION

Steven Posniak$_P$[1], Gordon Wallace[1], Johnson Chung[1], Xiao Liu[1]

[1] *University of Wollongong*

Corresponding author's email: sp695@uowmail.edu.au

INTRODUCTION:In the field of regenerative medicine, cartilage regeneration and craniofacial reconstruction remains a challenge as traditional methods are unable to adequately replicate the native cartilage tissue [1]. This study investigates an extrusion bioprinting approach to mimic and replace injured craniofacial cartilage.

METHODS:The 3D-BioplotterTM (EnvisionTEC, Gladbeck, Germany) was employed for bioprinting. Scaffolds were printed with the dimensions of 5mm*5mm and heights of 1mm. BM hMSCs were purchased from Lonza and primary chondrocytes were acquired from patients with consent. The hydrogel GelMA/HAMA was used with a ratio of 5:2 (w/v) containing 0.03% LAP. Scaffolds were printed with BM-hMSCs and chondrocytes at a density of 2 million cells/ml using BM-hMSC:Chondrocyte ratios of 1:0, 3:1, 1:1 and 0:1 through an 18G nozzle. Scaffolds were examined after 1-, 21- and 35 days. Photocuring was performed by utilizing 405nm visible blue light for 60 seconds. Scaffolds were characterized via immunostaining, DNA content analysis and qPCR.

DISCUSSION & CONCLUSIONS:MSCs and chondrocytes have numerous advantages and disadvantages when used for cartilage regeneration [2]. By combing these cell types, the disadvantages can be alleviated and produce an improved cartilage-like extracellular matrix. Additionally, this combination of bioprinting and cells successfully creates an environment that produces natively-similar chondrocytes which can potentially be used for craniofacial reconstructions.

ACKNOWLEDGEMENTS:The authors wish to acknowledge funding from the Australian Research Council (ARC) Centre of Excellence Scheme (CE140100012), support of the Australian National Fabrication Facility (ANFF) – Materials Node. Professor Gordon Wallace acknowledges the support of the ARC through an ARC Laureate Fellowship (FL110100196).

Human adipose tissue is an attractive and abundantly available source of adult stem cells applicable in regenerative medicine and tissue engineering. Several companies developed systems aiming for a closed, sterile, safe and reproducible cell isolation process. However, many of these systems are based on enzymatic digestion with collagenase, which is the most expensive part of the isolation process, complicates regulatory authorization and may have negative impacts on cell potency and efficacy. The aim of this study was to test a newly developed non-enzymatic device called Biomicromill (BMM) that mechanically, in a non-enzymatic way homogenize the fat tissue for the enrichment of therapeutic cells for autologous clinical applications. Our new BMM device was compared to other non-enzymatic (shaking and cutting) and standard enzymatic isolation methods regarding cell yield, viability, ATP content and the presence of regenerative cells, subpopulations and differentiation potential into the adipogenic, osteogenic, chondrogenic and vasculogenic linage. After BMM isolation mature adipocytes were separated whereas regenerative cells were enriched regarding specific subpopulations such as endothelial progenitor cells (CD45-/CD31+/CD34+), pericyte-like cells (CD45-/CD31-/CD146+), and supra-adventitial adipose-derived stromal/stem cells (ASC) (CD45-/CD31-/CD146-/CD34+). BMM showed higher cellular ATP levels and stronger adipogenic, osteogenic and chondrogenic differentiation potential compared to cells isolated by enzymatic and the other tested non-enzymatic isolation methods. Cells derived by BMM showed the potential to form tube-like structures in a fibrin clot system. Here we tested a new cell enrichment device, which is able to reveal therapeutic cells of high quality without use of enzymes for immediate clinical application.

Our objective is to study the potential of human dental stem cells from the apical papilla (SCAP) as a therapeutic tool for the repair of spinal cord injury. SCAP are less studied than other MSC but our recent results indicate that they possess a yet non-explored therapeutic potential. Combined with the fact that they are easy to obtain, isolate and expand1, and in consequence cheap to produce, SCAP have a high translational potential.

We recently showed that SCAP decrease the expression of pro-inflammatory markers in activated microglia and support remyelination of spinal cord organotypic sections by protection of oligodendrocytes and stimulation of their progenitor differentiation, notably via the secretion of activin A2. We also observed that when seeded on pharmacologically active microcarriers (PAM)3 or subjected to a pro-inflammatory stimulus (unpublished data), SCAP expression of immunomodulatory molecules increased (PGE2, IDO-1, TSG-6 and IL10, activin A, TSG-6 and VEGF, respectively).

Injecting SCAP seeded on PAMs loaded with brain derived neurotrophic factor (BDNF) in a rat spinal cord contusion model3 or implanting a whole apical papilla in a rat hemisection model4 resulted in a significantly improved locomotor function. To further understand how SCAP could stimulate the repair of the spinal cord, RNAseq analysis is ongoing on human apical papillae retrieved 24h after their implantation in a rat spinal cord hemisection model.

Our research contributes to uncover the high therapeutic potential of SCAP and to better understand by which mechanisms they can stimulate tissue repair.

Traumatic cartilage lesions can cause progressive degeneration of joint tissue and consequently osteoarthrosis. Current cell-based therapies mainly use chondrocytes to fill the defects without adding bone cells. The aim of this study was to evaluate the influence of osteoblasts on the differentiation of chondrocytes to develop a co-culture technique for optimal formation of the bone-cartilage part as transplant for deep cartilage lesions and possibly osteoarthrosis.

Human primary chondrocytes and osteoblasts isolated from knee joints were cultivated in vitro as 3D microtissues in cell-repellent plates for two weeks. For further two weeks, bone- and cartilage-like microtissues were co-cultured in close contact to one another. Cartilage-like microtissues alone served as differentiation control. The differentiation degree was evaluated via immunohistochemistry (IH) to detect bone- and cartilage-specific markers and histology to visualise typical glycosaminoglycans (Safranin O, Alcian blue) and calcium deposits (von Kossa) on cryosections.

As demonstrated by IH and histological analysis, expression of cartilage-specific markers as well as collagen type I was observed in cartilage-like microtissues after the first two weeks of culture. Co-cultured cartilage-like microtissues showed less collagen type I and II as well as Sox9 expression compared to cartilage-like microtissues cultivated alone. Bone-like microtissues in co-culture exhibited collagen type I and proteoglycan synthesis as well as calcium deposits.

This study suggests an influence of bone-like microtissues on collagen synthesis of cartilage-like microtissues by modulating Sox9 expression of chondrocytes. Further optimisations of the co-culture technique are necessary to improve the differentiation degree of both the bone and cartilage part of the microtissues.

Harnessing the potential of embryo-like structures (ELS) – i.e., 3D aggregates of pluripotent stem cells that resemble particular stages and/or regions of early (human) embryogenesis – whilst remaining within the parameters of responsible innovation will require mapping out the ethical and policy challenges raised by their research use. In so doing, this study identified challenges on three levels.

On a conceptual level, it is unclear whether human ELS qualify as human embryos. Large discrepancies across international definitions of the human embryo lead to equally discrepant positions regarding the conceptual qualification of ELS, either a priori ruling out the possibility of them qualifying as embryos or ultimately comprising epistemological uncertainty with regard to their qualification.

Equally undetermined is whether and the extent to which ELS can have moral status. On a normative level, the challenge thus becomes determining whether ELS could come to develop features of moral concern, how these features translate to specific biological markers, processes and structures, and the degree of moral value they confer. Deliberations of this kind are important to pursue in order to determine if and to what extent ELS research could present a morally preferable alternative to animal and/or human embryo research.

Finally, on a policy level, the challenge becomes developing policies capable of safeguarding against the particular intricacies of ELS research. The fact that scientists may be increasingly able to bypass morally relevant stages or events in ELS showcases the urgency of rethinking the foundational paradigms of contemporary ethical and legislative embryo protective frameworks.

INTRAPERICARDIAL INJECTION OF HYDROGELS DERIVED FROM DECELLULARIZED CARDIAC EXTRACELLULAR MATRIX LOADED WITH MESENCHYMAL STROMAL CELLS AND THEIR SECRETOME: A NOVEL PROPOSAL OF THERAPEUTIC APPROACH TO CYTOSTATICS-INDUCED DILATED CARDIOMYOPATHY

INTRODUCTION: Intramyocardial injection (IM) of hydrogels containing stem cells, their secretome or both, may hold promise to treat dilated cardiomyopathy (DCM). This, however, may lead to adverse outcomes related to the trauma of the IM injection and poor conductibility of the biomaterial. Additionally, DCM is a multichambered disease, which demands a treatment setup that reaches the entire heart. We hypothesized that the intrapericardial injection of hydrogels derived from cardiac decellularized extracellular matrix (dECM) loaded with adipose tissue-derived stromal cells (ASC) and their secretome (conditioned medium, CMed) dampen or reverse the progression of DCM. METHODS: DCM was induced in rats through ten weekly intraperitoneal injections of doxorubicin (cumulative dose: 18mg/kg). In week five, the animals were divided in intrapericardial treatments (2ml/kg): 1) saline, 2) dECM hydrogel and 3) dECM hydrogel loaded with ASC and their CMed. ASC concentration was 20 million per mL while 100x concentrated CMed in hydrogel were used. Non-treated, healthy rats, were used as controls. Interstitial myocardial fibrosis was determined by Sirius Red and hemodynamic parameters were determined by pressure-volume loops. RESULTS: Interstitial myocardial fibrosis was reduced in ASC/CMed-treated animals compared to saline controls ($p=0.0139$). Ejection fraction and cardiac work efficiency were improved in the ASC/CMed-treated rats compared to saline ($p=0.0151$ and $p=0.0655$, respectively). Treatment with sole dECM hydrogel did not reduce fibrosis nor improve hemodynamic parameters. CONCLUSION: The intrapericardial injection of dECM hydrogels loaded with ASC and their secretome warrant a novel therapeutic possibility by improving ventricular hemodynamics and reducing cardiac remodeling in doxorubicin-induced DCM.

Glycans play a key and dynamic role in regulating cellular functions and behaviour, including cell-cell and cell-ECM communication, signal transduction and molecular recognition. They are tethered to the extracellular matrix (ECM) components as poly- or oligosaccharides and on cell surface, where most of receptor are N- or O-glycosylated. Many cell development events, including cell adhesion, growth, migration, differentiation, host-pathogen interactions are associated with changes in oligosaccharide structures.[1][2] The study of differential ECM glycosignature effect is limited today by the lack of glyco-tools able to resemble both, glycan and proteins identities. Here in this work a panel of differential glycosylations were developed on collagen type I and gelatin, in order to characterize the effect of both glycosignature and ECM proteins motifs. The biomolecular interaction of glycoconjugate ECM mimetics were tested on solid-phase assays for the interaction with Siglec-9, Siglec-10 and DC-SIGN, carbohydrate-binding proteins expressed at extracellular level and with immunomodulatory functions. Preliminary studies on soluble and 3D structured glycoconjugates polymers were performed to validate a combinatorial platform to study and tailor cell fate for tissue engineering and in vitro cultures.

Introduction: Successful biomimetism requires exquisite design of engineered tissues. Fibre-reinforcement of hydrogels is able to overcome their inherent mechanical weakness, but introduces cues, affecting the functional outcome, especially in high-anisotropy tissues as the myocardium. Here, we generate human cardiac tissues, and apply computational modelling to optimize fibre reinforcement for the desired functionality.

Methods: Uniaxial and biaxial mechanical tests were employed. hiPSC-cardiomyocytes (CMs) were embedded in matrigel, casted on MEW-PCL fibres and cultured for 28 days. Gene-expression, structure (IF) and functionality (optical mapping) were assessed and compared with conventionally-cultured hiPSC-CMs in 2D. This information was used to generate computational electrophysiological models to investigate the impact of the MEW-PCL fibres on the activation pattern of hiPSC-CMs.

Results: Fibre mechanics dominated the properties of the composites. hiPSC-CMs formed microtissues and were able to survive and contract for 4 weeks. Gene expression highlighted an increased maturity, with fibres aligning CMs, which redounded in faster conduction velocities. In silico simulations revealed a high impact of the composite's pore size on the velocity of electrical propagation. Maximum local activation time (LAT) was 51 ms and increased up to 71 ms for pore sizes of 100 µm and 700 µm. Simulation of 2D-cultured hiPSC-CMs led to maximum LAT values of 350 ms due to the loose coupling of the cardiomyocytes.

Conclusion: Composite systems matured, at structural, gene-expression and functional levels. Simulations provided insight on the impact of the MEW-fibres on the activation pattern of hiPSC-CMs, and open the way for the fabrication of tailored human cardiac tissues.

Human in vitro bone remodeling models can potentially facilitate the investigation of physiological bone remodeling while addressing the principle of replacement, reduction and refinement of animal experiments (3R). Physiological bone remodeling follows a specific sequence of events: activation, bone resorption by osteoclasts, reversal, and bone formation by osteoblasts [1]. Current in vitro models typically use osteoblast-osteoclast cocultures to study cell-cell interactions in two dimensions. As such, cell-matrix interactions and their temporal organization are often neglected. To enable the investigation of cell-matrix interactions and to mimic the sequence of these interactions in vitro, a bone-mimetic template is required [1, 2]. Here, we aimed at developing such a template, inspired by bone's extracellular matrix composition and organization. Using silk-fibroin as an organic matrix, poly-aspartic acid (pAsp) to mimic the functionality of non-collagenous proteins [3], and 10x simulated body fluid as mineralization medium [4], we were able to prepare mineralized silk fibroin films and scaffolds. By using pAsp in the mineralization medium, mineral precipitation in the medium was inhibited and mineralization of the organic matrix (both films and scaffolds) was enhanced. The surface of the mineralized films and scaffolds was covered with a layer of mineral crystals. This mineralization led to an improved young's modulus both at the nanometer and millimeter scale. After cell seeding, scaffold remodeling was tracked with micro-computed tomography over a period of 6 weeks. The use of this template for in vitro bone remodeling models enables the investigation of cell-matrix interactions and their sequence, characteristic for physiological bone remodeling.

MECHANICAL CONSTRAINTS FOR ECM REORGANIZATION IN A 3D IN VITRO MYOCARDIAL INFARCTION MODEL

Ignasi Jorba$_P$[1], Dylan Mostert[1], Carlijn Bouten[1]

[1] *Department of Biomedical Engineering, Eindhoven University of Technology, Eindhoven, the Netherlands - Institute for Complex Molecular Systems, Eindhoven University of Technology, Eindhoven, the Netherlands.*

Corresponding author's email: i.jorba.masdeu@tue.nl

After myocardial infarction (MI) tissue suffers from a massive loss of cardiomyocytes (CMs), together with a loss of extracellular matrix (ECM) organization, leading to an impairment of the coordinated contraction. Current approaches for myocardial regeneration mainly focus on enhancing the number of contractile cardiomyocytes to the damaged area, without taking into account the restoration of ECM anisotropic organization. Recent findings show that ECM organization can be controlled by the mechanical environment, such as cyclic strain. Here, by using a 3D cardiac model developed previously in our laboratory [1], we propose that changing on demand the strain pattern of the tissue will induce ECM remodeling to anisotropic organization. A co-culture of iPSC-CM and primary cardiac fibroblast will be seed in a collagen I and Matrigel hydrogel to mimic the biological, biochemical environment of MI tissue. By locally modifying the stiffness of the hydrogel we will alter the strain pattern of the beating tissue. The platform is based on flexible micropillars that allows tissue contraction force measurements. Additionally, the platform is compatible with confocal microscopy to visualize ECM remodeling and cell orientation. The results of the study will contribute to design strategies to reorganize ECM after MI.

Chondrogenically primed mesenchymal stem cells (MSCs) have been shown to form bone in vivo through the endochondral ossification pathway, representing a potential off- the-shelf allogeneic option for bone repair. The aim of this study is to investigate the ability of chondrogenically primed paediatric MSCs (pMSCs) to form bone in vivo and determine its persistence within an allogeneic immune system.21 day chondrogenically differentiated human pMSCs were subcutaneously implanted in immunodeficient IL2Rγ-/-RAG2-/- mice. Mice received an intraperitoneal injection of allogeneic human Peripheral Mononuclear Blood Cells (PBMCs) 3 weeks before implantation or 8 weeks after. uCT scans were performed at either week 3, or 8 and 12 post-implantation. Blood, bone constructs and femurs were analysed. No significant differences in the volumes of the bone constructs were detected at weeks 8 and 12. Human T cell infiltration was observed in the constructs at weeks 3 and 12 post-implantation, with a predominance of the CD4 subtype at week 3 and of the CD8 at week 12. On this time point, bone-forming cells of human and mouse origin were identified. No significant changes in the levels of circulating human CD45 cells were detected in the blood of the humanized animals. Our results show that bone derived from chondrogenically primed pMSCs can persist in the presence of a mismatched immune system without the development of significant immune responses. In this process cells from host and donor sources play a role. These findings illustrate the potential of pMSC-derived bone constructs for clinical use in an allogeneic setting.

INTRODUCTION: 3D bioprinted vascular grafts represent a promising alternative for the replacement of small-caliber blood vessels (SCBV). We evaluated the use of a vascular decellularized extracellular matrix (dECM) based bioink as a biomaterial for 3D bioprinting of the tunica media of SCBV. METHODS: Vascular (aortic) dECM-based solution was used in the present study. Upon warming to 37ºC, the solution turns into a hydrogel. Differentiation of ASC to smooth muscle cells (SMC) on the hydrogel was induced with 10ng/mL of TGF-β1 and SM22α used as a differentiation marker. A combination of the hydrogel and 10 million cells/mL was used as bioink for 3D bioprinting of the tunica media layer of SCBV in an extrusion-based 3D bioprinter using the freeform reversible embedding of suspended hydrogels (FRESH) method. The morphology of the 3D bioprinted tissue construct was evaluated after 24 hours, 7 days, and 21 days with Masson's trichrome staining. RESULTS: The hydrogel drove spontaneous (without TGF-β1) differentiation of ASC to SMC. The staining of 3D bioprinted SCBV evidenced the maturation of the construct along the time. At 24 hours, ECM hydrogel containing cells shows a porous pattern, becoming more compact the longer the construct is cultured. At 21 days, a well defined compact cell-rich vessel wall characterizes the construct. CONCLUSION: Bioinks based on vascular dECM hydrogels offer cells a microenvironment mimetic to the native tissue, spontaneously differentiating ASC to SMC, and supporting 3D bioprinting of the tunica media layer of SCBV, representing a promising alternative for the manufacturing of vascular grafts.

Inflammation and hypertrophic differentiation are key processes that dampen stable hyaline cartilage development from mesenchymal stem cells (MSCs). Accumulating data suggest these processes are also involved in the progression of osteoarthritis, leading to the modification and degradation of cartilage extracellular matrix. Therefore, the aim of this study was to identify a novel target for osteoarthritis (OA) and cartilage tissue engineering, associated with chondrocyte hypertrophy and inflammation.

To identify targets, we combined previously published microarray data sets from both mice and human origin [1-2-3]. Combination of datasets revealed candidate targets, among which the Ephrin receptor A2 (EphA2), a tyrosine kinase receptor, was the only new target identified.

EphA2 was found to be upregulated in the hypertrophic compared to the proliferative zone of the murine growth plate and in human OA versus healthy cartilage. In chondrogenically-differentiated human MSCs, the EphA2 activity inhibitor ALW-41-27 dose-dependently reduced the hypertrophic markers COL10A1, ALPL, IHH and the catabolic enzymes MMP3 and MMP13. Additionally, EphA2 inhibition did not influence glycosaminoglycan nor Collagen-II deposition, suggesting that the effect of ALW-41-27 was mainly targeting the hypertrophic differentiation. Similarly, in OA chondrocytes, ALW-41-27 reduced the expression of COL10A1, MMP3 and MMP13, but also significantly decreased the production of nitric oxide and IL-6 when the chondrocytes were stimulated with the inflammatory factor TNFα.

These results identify EphA2 to be associated with osteoarthritic cartilage, chondrocyte hypertrophy and inflammation. Based on our data, ALW-41-27 may constitute a new approach for OA treatment by limiting hypertrophy and inflammatory pathways in resident articular cartilage chondrocytes.

Breast cancer is a major public health issue, whose morbidity and mortality are increasing across the world. Surgical resection is the most widely used and preferred therapy in clinic. However, surgical resection cannot completely eliminate all the cancer cells and may result in cancer metastases and recurrence. Moreover, surgical resection is always accompanied with large breast defects that are difficult to self-heal. It is strongly desired to design a bifunctional material for effective breast cancer therapy and breast reconstruction. In this study, bifunctional composite porous scaffolds of gold nanorods (AuNRs) and gelatin with well controlled pore structures were prepared by introducing AuNRs into the porous matrices of gelatin and using ice particulates as a porogen material. The composite scaffolds had large spherical pores with good interconnectivity, which were beneficial to cell adhesion and distribution in the scaffolds. The composite scaffolds showed high photothermal conversion effect, whose photothermal temperature could be modulated by the amount of incorporated AuNRs, NIR laser power intensity and irradiation time. The composite scaffolds exhibited excellent photothermal ablation capacity of breast tumor cells in vitro and in vivo. When hMSCs were cultured in the cmposite scaffolds, the cells adhered and proliferated throughout the scaffolds. The composite scaffolds enhanced formation of lipid vacuoles and expression of adipogenic genes (CEBPA, PPARG, LPL, FABP4 and FASN). The results indicated the AuNRs-gelatin composite scaffolds had a bifunctional property for simultaneous photothermal ablation of breast cancer cells and adipogenic differentiation of hMSCs.

As key regulators of host immune response, macrophages can determine the success of biomaterial transplantation. Macrophages are responsible not only for the inflammatory reaction by M1 but also for the process of constructive remodeling of degradable biomaterials by M2 macrophages. Here we used an in vitro approach to evaluate the polarization of primary human monocyte-derived macrophages (MDM) into M1 or M2 in response to the porcine decellularized nasal septal cartilage (DNSC).

MDM were cultured in the presence of DNSC, or two types of porcine-derived biomaterials for reference. The response of MDM was monitored during a 6-day culture period by microscopy and flow cytometry, as well as for secretion and gene expression of inflammatory factors.

Initially, DNSC induced an M1-like inflammatory response, as seen by the increased production of TNF-α, IL-1β, and IL-6 by MDM. By the end of the culture period, the secretion of M1-factors reduced, while production of the M2-specific cytokine, CCL18 increased. Furthermore, the increase of the M2-specific marker, CD206 was observed on DNSC. Overall, we observed a mixed reaction of MDM to the DNSC. However, the initial pro-inflammatory reaction could be effectively antagonized by IL-4. Moreover, preloading of DNSC with IL-4 markedly reduced the production of M1 factors and induced an early polarization of MDM towards M2, as evidenced by the increase in CCL18 gene expression.

Overall, DNSC induced a mixed M1/M2 response in MDM. However, the functionalization of DNSC with IL-4 effectively antagonized the M1 component of the immune response.

Recent advances in biomaterials science are increasingly focused on (re)search for next-generation soft tissue regeneration solutions. Hydrogel-based materials are becoming a focal point to address many tissue engineering requirements, possessing exceptional biocompatibility, with tailorable shape, structure and mechanical properties, as well as infinite possibilities drug delivery. The widespread antibiotics use has led to aggravated resistance issues in many bacterial strains, so the focus is increasingly shifted towards alternative antibacterial solutions such as silver nanoparticles (AgNPs). In this work, we have developed novel composite materials based on poly(vinyl alcohol)/chitosan (PVA/CHI) and poly(vinyl alcohol)/chitosan/graphene (PVA/CHI/Gr) hydrogels with silver nanoparticles obtained through green in situ constant-voltage electrochemical synthesis. The obtained AgNPs' properties, sizes and size distributions were examined using UV-visible spectroscopy, dynamic light scattering and transmission electron microscopy. In vitro swelling and silver release kinetics were monitored in the simulated physiological conditions (pH7.4, 37 °C). The obtained release and swelling isotherms were fitted with several theoretical models that helped discern the mechanisms of these processes. Tensile testing was carried out to examine the composites' mechanical behavior and elasticity – important properties for soft tissue engineering materials. Finally, the excellent antibacterial activity of the obtained silver/poly(vinyl alcohol)/chitosan (Ag/PVA/CHI) and silver/poly(vinyl alcohol)/chitosan/graphene (Ag/PVA/CHI/Gr) hydrogels against Staphylococcus aureus and Escherichia coli was confirmed quantitatively by colony counting method, and their non-toxicity was verified towards two model fibroblast cell lines (MRC-5 and L929) utilizing the MTT assay. Through thorough characterization, the obtained nanocomposite hydrogel materials were identified as strong candidates for active antibacterial soft tissue engineering materials.

Osteoarthritis (OA) is the most common debilitating joint disease, and its treatments remains mainly symptomatic. There is a tremendous need for the study of the onset, progression and treatment of OA through in vitro joint disease models, of particular interest for drug screening prior to undertake preclinical studies. To this end, 3D bioprinting allows the custom creation of biomimetic structures using cell-laden hydrogels as bioinks. However, bioinks tend to be mechanically weak and collapse after extrusion.

In this work, we developed an injectable hyaluronic acid (HA)-based hydrogel using an innovative, dual dynamic/non-dynamic covalent crosslinking strategy. By varying the molecular weight (100-300 kDa) and concentration (1-3% (w/v)) of HA, we successfully obtained 3D printable stable viscoelastic hydrogels with a large range of mechanical properties (80 to 1000 Pa for G’ at 1 Hz). Using L929, a murine fibroblastic cell line, we demonstrated the excellent cytocompatibility of the newly designed viscoelastic hydrogels, with a high proportion of viable cells (95% after two days), and an increased metabolic activity and DNA content over time, suggesting a cell proliferation. The chondrogenic differentiation of human mesenchymal stromal cells (hMSCs) encapsulated in these gels was further evaluated over 28 days. The gene expression of a panel of chondrogenic markers, including type II-collagen, aggrecan and SOX9, was evaluated by real-time PCR, followed by the histological analysis of a glycosaminoglycan-rich extracellular matrix.

Together, our results highlight the potential of a new class of injectable hydrogels to bioprint OA models and drive chondrogenic commitment of hMSCs in vitro.

There is an increasing demand for the development of safe, reliable, and long-lasting orthopedic devices for skeletal tissue engineering. Hydroxyapatite (HAP) has lately gained a lot of attention as a coating material for bone implants. Poor mechanical and antibacterial properties of HAP can be surpassed by introducing other components to the composite – graphene (Gr) and silver. Graphene is expected to improve the coatings' mechanical properties and to ensure a better interconnected composite structure.Well-known antibacterial effect of silver in bacterial infections treatments makes it a logical choice for composite coating production. In this work, the electrophoretic deposition (EPD) technique was successfully used for obtaining HAP and biocomposite HAP/Gr, Ag/HAP, and Ag/HAP/Gr coatings on Ti plates. Single-step cataphoretic EPD was performed from ethanolic suspensions. Obtained coatings exhibited uniform surface without cracks, as demonstrated by FE-SEM analysis. Elastic, plastic, and fracture response of coatings' surfaces was investigated using the nanoindentation test. HAP/Gr and Ag/HAP/Gr coatings exhibited higher hardness and lower penetration depths i.e. they were more resistant to indentation as opposed to their counterparts without graphene. Substantial improvement was achieved and values of mean reduced elastic modulus were increased up to 50 %. Antibacterial activity was monitored against Staphylococcus aureus and Escherichia coli bacterial strains and pointed to the strong antibacterial capacity of the silver-containing coatings (Ag/HAP and Ag/HAP/Gr) within first 3h post-incubation. Based on these results, Ag/HAP/Gr composite coating electrodeposited on titanium exhibited strong antibacterial properties and favorable mechanical properties making it a promising candidate for bone implant materials development.

Potato virus X (PVX), a filamentous biocompatible plant viral nanoparticle with more than 1200 potential sites for targeted molecule exposition, is a novel nanocomposite for hydrogel-based materials, which often require functional molecules to mimic extracellular matrix in bone tissue engineering. Here, PVX was genetically modified to precisely present highly concentrated mineralization- and osteogenesis-associated peptides in a local area, individually. These engineered viral nanoparticles (VNPs) were laden in agarose or agarose-collagen blended hydrogels at a concentration lower than other studies by two orders of magnitude. The effectiveness of enriched peptides on VNPs was proven and compared with free peptides and VNPs presenting only 10% and 30% functional peptides. Osteogenic induction analyses of mesenchymal stem cells, including alkaline phosphatase activity, Alizarin red staining and gene expression, showed significant increases when under the stimulation of VNPs. An attachment of VNP to cells was observed under confocal microscopy, illustrating a stimulation of biomimetic peptides in close proximity of the cells. The release of VNPs in hydrogels was quantified and more than 80% of VNPs remained inside after several culturing procedures. Cell containing VNP-laden hydrogel solutions were further used to develop a bone substitute via drop-on-demand bioprinting technology. Printing repeatability was high, demonstrating a suitable solution as a bioink. Cell viability and cell-VNP distribution in bioprinted hydrogels were monitored with fluorescence microscopy and 2-photon laser scanning microscopy, respectively, and osteogenesis was once again evaluated. Overall, this study demonstrated that PVX nanoparticles are excellent candidates for hydrogel nanocomposites in bioink development and bone tissue engineering.

INTRODUCTION

Cardiovascular side effects are major drawbacks of oncological drugs, like doxorubicin (Dox), as leading to late onset cardiomyopathy. Dox can impact activity of cardiomyocyte mitochondria, causing oxidative stress (1). We showed that the human fetal amniotic fluid-stem cell (hAFS)-conditioned medium (hAFS-CM) exerts remarkable pro-survival effects on Dox-exposed cardiomyocytes in vitro (2). Here we compare hAFS and human adult adipose tissue mesenchymal stromal cells (hMSC) paracrine potential in a Dox-derived cardiotoxicity murine model.

METHODS

hAFS were isolated from left over amniotic fluid of diagnostic amniocenteses; hMSC were obtained from liposuction aspirates. hAFS and hMSC were preconditioned under hypoxia (1% O2) for 24h to enrich their cell-conditioned medium (CM). A Dox-cardiotoxicity mouse model (3) was employed to investigate long-term hAFS-CM and hMSC-CM effects. Functional activity of cardiomyocyte mitochondria was also evaluated via in vitro confocal and biochemical analyses.

RESULTS

hAFS-CM and hMSC-CM inhibited body weight loss and improved myocardial function in the cardiotoxicity mouse model ($p<0.01$). The treatment with hAFS-CM and hMSC-CM partially reverts the impairment of mitochondrial complex I activity, oxygen consumption, and ATP synthesis induced by Dox ($p<0.0001$). Moreover, both treatments recover about 25% of the dysfunction of catalase and glutathione reductase ($p<0.001$), determining a reduction of lipid peroxidation. hAFS-CM and hMSC-CM preserved mitochondria organization and metabolism in injured cardiomyocytes ($p<0.0001$).

CONCLUSIONS

Both hAFS and hMSC can be appealing paracrine source to be exploited for preserving cardiomyocyte mitochondria function. Further analyses are ongoing to profile molecular candidate(s) in their secretomes to define the optimal formulation for future therapeutic strategies.

Four million surgeries are performed annually to treat bone defects using either bone grafts or synthetic substitutes rendering it the second most transplanted tissue worldwide [1]. Given the drawbacks associated with auto- and allografts, synthetic scaffolds mimicking the composition, architecture and properties of the native extracellular matrix are gaining increasing interest [2]. These biophysical cues are hereby converted into biochemical cues through mechanosensitive pathways that regulate cell behaviour [3]. The establishment of vascularisation however is one of the current challenges especially in critically sized bone defects [2,4]. Therefore, the aim is to develop a biomimetic hydrogel scaffold mimicking the bone osteoid in which proper vasculature is induced. Thiol-ene step-growth photocrosslinking was herein selected to enable superior control, homogeneous network formation and lower radical concentrations compared to traditional chain-growth systems [5]. More specifically, norbornene-functionalised gelatin/hyaluronic acid systems were combined with thiolated gelatin to function as cell-interactive crosslinker thereby forming networks with mechanical properties capable of triggering either osteo- or angiogenesis. The modification degree of these systems was characterised through proton nuclear magnetic resonance spectroscopy and an ortho-phthalic dialdehyde assay. Furthermore, in-situ photo-rheology, swelling and gel fraction experiments were used to evaluate the obtained networks. Moreover, in vitro quantification of angiogenesis was performed through a tube formation assay using human umbilical vein endothelial cells. Finally, osteogenesis was quantified through the production of alkaline phosphatase, the presence of calcium deposits and osteogenic gene expression of encapsulated adipose-derived stem cells. The results showed that networks could be created which can stimulate angiogenesis and osteogenesis.

Keywords

Osteogenesis; Angiogenesis; Thiol-ene crosslinking

THE DISTORTION OF MEW PATTERNS BY 3D COLLECTORS: INVESTIGATION, QUANTIFICATION AND CORRECTION

Integrating melt-electrowriting (MEW) with other fabrication technologies, such as extrusion-printing or bioprinting, offers tantalising possibilities for multi-scale bio-manufacturing.[1] However, to fully realise these goals, we must overcome new challenges arising when performing MEW upon 3D, rather than 2D, collectors.[2]
While planar or mandril collectors induce an electrohydrodynamic acceleration only in the vertical direction, 3D-collectors produce an additional, horizontal, force pulling fibers towards the 3D-object. Here, we report our investigation of how this force distorts MEW patterns around and atop 3D collectors.

As a model system, we used hemispherical collectors (various sizes and compositions) placed upon a conducting 2D-substrate. We quantified deviation of fibers from their intended positions as a function of (i) distance, r, from the hemisphere, (ii) the surface area, SA, of the hemisphere, (iii) the nozzle height, h. We found that the horizontal acceleration, and therefore the horizontal force, is directly proportional to: 1/r^5, SA^2 and h^2 respectively. In light of these data, we consider the physical origins of the horizonal acceleration, concluding that the distortion force is likely of dielectrophoretic, rather than an electrophoretic, origin.

Following this, we derived a simple model which estimates fiber deviation in such systems, and we use an optimisation algorithm to calculate tool-paths which account for these deviations. Finally, we validated how g-code produced by this algorithm effectively corrects the distortion effect, restoring our ability to create well-defined MEW patterns near and atop hemispherical collectors.

This study is a step towards understanding the complexities of MEW on non-planar collectors, towards multitechnology biofabrication.

Due to the rising numbers of people diagnosed with heart insufficiency, the clinical relevance of the development of new long-lasting and reliable biomimetic materials for functional heart implants is higher than ever. Native porcine pericardium currently acts as the gold standard despite the drawbacks of the intensive decellularisation processes involved therein. To provide an alternative that mimics the non-linear mechanical properties of porcine pericardium, we aim at developing a novel biomimetic electrospun hybrid consisting of polyurethane and collagen as part of a cardiac support system for patients with left ventricular heart failure.

Therefore, high molecular weight isocyanate-free polyurethanes (Mw = 14.000 - 26.000 g/mol) were synthesized by the transurethanisation reaction of dimethylhexane-1,6-diyldicarbamate and polycarbonate diols. The chemical structures of the polymers were characterized by NMR and FTIR spectroscopy, DSC and GPC. Consecutively, they were evaluated on their biocompatibility and electrospun into fibrous scaffolds with fibre diameters in the submicron range, as shown by SEM analysis.

Collagen could be successfully dissolved in gentle solvents and used to establish an electrospinning process with native murine collagen Type I. Morphological analysis was performed with SEM, after which a quality control based on SDS-PAGE and non-invasive and non-destructive imaging methods, such as Raman was deployed to assess whether collagen can be processed without denaturation. The latter is especially relevant, as the impact of conventional electrospinning solvents on the structural integrity of collagen is controversially debated.[1]

BIODEGRADABLE LAMINARIN MICROGELS FOR BIOMOLECULES RELEASE

Edgar Castanheira[P][1], Tiago R. Correia[1], João M. M. Rodrigues[1], João F. Mano[1]

[1] *CICECO – Aveiro Institute of Materials, Department of Chemistry, University of Aveiro*

Fabrication of polymeric matrixes for controlled release have been extensively explored for tissue engineering applications. Systems based on biopolymers exceed conventional polymers in biocompatibility, biodegradability and cost efficiency[1]. Thus, natural polysaccharides are commonly used in tissue engineering due to their biological properties. Biodegradable carriers based on bioactive marine polysaccharides have been reported, however these materials are often based on charged or high molecular weight (HMw) biopolymers[2]. Hence, HMw polymers creates higher density matrixes, diminishing nutrient diffusion, while charged polymers may establish unspecific interactions. Herein, we introduce biodegradable and biocompatible microgels synthesized from laminarin, a low Mw marine polysaccharide with great biological activity (e.g. immune modulation). Within this work[3], controlled size microgels were synthesized from novel modifications to laminarin through a click chemistry mild process that do not interfere in living cells encapsulation. Furthermore, microgels has a controlled release, achieving a burst of 40% release after 24h and a continuous release (7% per day) over 5 days. Additionally, full degradability of the microgels in physiological conditions was achieved after 11 days. Live/Dead assays have shown no significant cellular death after 24h to concentrations up to 100 µg/mL. Moreover, with an assessment of morphology, no membrane and neither nucleus seemed to have been disturbed. Our results indicate that the developed biodegradable microgels are biocompatible when in culture with hASCs while presenting a controlled release. Concluding these biomaterials are promising platforms for cellular differentiation due to easy incorporation of biomolecules (e.g. dexamethasone), full degradability and sustained release over a long period of time.

CONTROLLING BLOOD COAGULATION IN SUPRAMOLECULAR VASCULAR ACCESS GRAFTS VIA FEEDBACK-RESPONSE MECHANISMS

Boris Arts[P][1], Patricia Dankers[1]

[1] *Eindhoven University of Technology*

Corresponding author's email: b.arts@tue.nl

Currently 1 in 1000 people in Europe suffer from end-stage renal disease and require hemodialysis[1]. Hemodialysis is a medical procedure to remove waste products from the blood where the blood circulation of the patient is directly connected to a dialysis machine, often, via a vascular access graft (VAG). The primary failure of VAGs are due to its low patency rates (the time the graft remains open), primarily caused by thrombosis due to poor hemocompatible properties of the material. Several studies showed that coating the inner lining of the graft, e.g. with heparin, improves the patency rate[2,3]. However major concerns are expressed regarding the long-term efficacy of those coatings. Hereto the aim of this study is to improve the hemocompatibility of these grafts by controlling blood coagulation through a feedback-response mechanism.

Here we make use of bisurea (BU)-based supramolecular polymers. BU motifs can self-assemble via hydrogen bonding resulting in dynamic crosslinks embedded in a soft amorphous polymer phase. Bioactive molecules, e.g. peptides, can be functionalized with BU and mixed in through a modular approach to implement specific properties in the material[4].

In our approach heparin is conjugated to the surface of our VAG model materials via a BU-modified thrombin cleavable peptide (TCP). When in contact with whole blood the enzyme thrombin is designed to cleave the peptide causing heparin to be released (response). In turn heparin can form an inhibitory complex with anti-thrombin, naturally present in blood, thereby inhibiting thrombin activity and decreasing heparin release (feedback).

Mesenchymal stem cells (MSCs) are promising cells to treat skeletal related diseases because of their (multi)differentiation capacity. However, one of the limitations that reduces their therapeutic use is cellular senescence, a state in which cells stop proliferating, while still metabolically active. By acquiring a specific senescence-associated secretory phenotype (SASP), senescent MSCs can contribute to tissue degeneration and chronic inflammation, also via the modulation of cellular metabolism. The transcription factor TWIST1 is suggested to play a role in cellular senescence, since its expression is reduced in slow proliferating MSCs and we previously demonstrated that high TWIST1-expressing MSCs have an enhanced expansion capacity [1-2]. The aim of this research is therefore to determine the role of TWIST1 in regulating cellular senescence and cellular metabolism of MSCs.

Here, we demonstrated that silencing TWIST1 in MSCs increased the occurrence of cellular senescence (siTWIST1-induced senescent MSCs). These siTWIST1-induced senescent MSCs had a different SASP profile compared to irradiation-induced senescent MSCs, and characterized by lacking of IL8 and IL6 expression. In addition, metabolic evaluation performed by the Seahorse XF apparatus showed that both siTWIST1-induced senescent and irradiation-induced senescent MSCs had a higher oxygen consumption rate compared to control cells, while siTWIST1-induced senescent cells had a lower extracellular acidification rate compared to the irradiation-induced senescent MSCs. Overall, our data indicate how TWIST1 regulation influences senescence in human MSCs, highlight the importance of TWIST1 as potential target for tissue engineering approaches and show that siTWIST1-induced senescent MSCs are characterized by a specific SASP and metabolic state.

Keywords

Senescence; Cellular metabolism; TWIST1

Motile bioactive Embedding baths based on biomaterial hydrogel particles.

Wet hydrogel supensions have been used as 3D bioprinting support baths in order to bypass the challenges emerging from non-optimal rheological properties of bioinks(1-2). The materials used as suspensions, were usually chosen based on their ability to behave as low yield stress fluids, in order to achieve high quality printing within them(3).However hydrogel suspensions consisting of hydrogel microparticles, are a class of metamaterials on their own accord, and thus can offer a wide variety of options for tissue engineering by allowing the cells to interact with the suspension(4–7).

We fabricated granular metamaterials from popular hydrogel formulations, namely Alginate, GelMa, and Collagen-Agarose. The transition from uniform hydrogel constructs to wet granular suspensions of particles in the range of 50-200µm, enabled embedded 3D printing. We assessed the different microparticles as embedding baths by printing within them, and asessed their bioactivity compared to their continuous hydrogel counterpart.

When optimized, the suspensions allowed smooth muscle cells to manipulate the macro-shape of the embedding bath during culture. By testing different cell concentrations of Smooth Muscle Cells (SMC) and Human umbilical vein endothelial cells we observed that the change of the macroshape was also significantly affected.

Materials with this property to change their shape driven by cell contractility-based compaction, have been called kinomorphs(8) and thus we have discovered a way to induce kinesiomorphia to conventional biomaterials.

Surgical repair of skull bone defects is often performed using patient-specific polymeric or metallic implants.(1) These implants, however, have poor osseointegration ability, and their life-long fixation is dependent on osteosynthesis screws.(2) We developed alternative porous implants using additive manufacturing (AM), combining a biodegradable polymer with an osteoconductive calcium phosphate ceramic. In this study, we have examined the osteogenic differentiation and tissue formation capacity of bone marrow-derived human mesenchymal stromal cells (hMSCs) on these implants. Porous poly(ethyleneoxide terephthalate)/poly(butylene terephthalate) (1000PEOT70PBT30) 3D scaffolds without or containing 30, 40 or 50 weight% beta-tricalcium phosphate (TCP), produced using 3D fiber deposition, were used. The scaffolds were seeded with hMSCs and cultured in basic or mineralization medium. On days 1, 14 and 28, the constructs were analyzed for DNA content, tissue formation, alkaline phosphatase (ALP) activity, and osteopontin and osteocalcin secretion. hMSCs cultured on the scaffolds showed similar cell growth on all scaffold types. hMSCs produced ALP, osteopontin and osteocalcin. However, we observed minimal tissue formation throughout the porous scaffolds in all conditions after 28 days. We did not detect differences in hMSCs osteogenic differentiation on the scaffolds upon increasing TCP content. This might be due to limited degradation of the polymer carrier in vitro, resulting in limited exposure of the TCP phase to the cells, which is required to support MSCs osteogenic differentiation.(3) In the near future, we plan to further validate the scaffolds using hMSCs and investigate the effects of adding TCP using in vivo models.

DEVELOPMENT OF FULLY-POLYMERIC ELECTRIC LEADS FOR BIOELECTRONICS

The use of metals as electric leads in bioelectronics, such as pacemaker leads, can be a common point of device failure (1,2). Conductive elastomers (CE), composites of conductive polymers (CP) and elastomers, are a promising alternative for bioelectronic applications. Their capacity to be soft, flexible and MRI compatible make them an exciting avenue for the fabrication of fully-polymeric electric leads.In this study, gel-based CEs were explored for the fabrication of electric leads. Gel-CEs consist of a CP gel system embedded in an elastomeric matrix. The gel forms continuous conductive pathways throughout the CE composite. This enables use of low CP contents, helping to preserve the mechanical properties of elastomeric matrix. Thus, a fabrication route for a gel-CE 1mm diameter wire was developed. First, poly(3,4-ethylenedioxythiophene):poly(styrene sulfonate) (PEDOT:PSS) was thermally gelled into a hydrogel which was subsequently lyophilised twice. The aerogel was then embedded inside a matrix of solvent-casted polydimethylsiloxane or radically polymerised polyacrylamide. Scanning electron microscopy/energy-dispersive X-ray spectroscopy (SEM/EDS) confirmed the inclusion of continuous PEDOT:PSS network within the matrices. SEM study showed that the second lyophilisation step increased gel's pore size, which is deemed as a major factor in development of a uniform matrix. However, occasional pores were observed in the material. Overall, the study has shown the feasibility of reproducible gel-CE wire fabrication with different types of matrices. Thus, the method potentially offers a whole group of mechanically robust and electroactive materials for small-scale bioelectronics, which properties can be specifically tailored with gel and matrix materials choice and modification.

DESIGN AND INVESTIGATION OF AN IN VITRO 3D GLIOBLASTOMA PERIVASCULAR NICHE

Rosalyn Hatlen$_P$[1], Padma Rajagopalan[1]

Glioblastoma (GBM) is the most deadly form of brain cancer, with a median survival time of 15 months1. One migration mechanism suggested for GBM cells is movement along blood vessels, in an area labelled the perivascular niche (PVN)1. Investigating how GBM and endothelial cells interact in the PVN may provide a deeper understanding of this cancer.

Our goal was to design a 3D in vitro model of the PVN. We assembled hydrogels composed of Type 1 collagen or a hyaluronic acid-gelatin mixture (Hystem-C®). While collagen is not prevalent in brain tissue, it is present in GBM tumors and can be relevant within elastic moduli similar to the brain. Since hyaluronic acid is found in the brain matrix, Hystem-C® mimics this chemical composition1.

Layered 3D hydrogels were prepared in glass-bottom tissue culture well plates. First, a thin collagen gel containing fluorescent beads was deposited, followed by a layer of collagen I or Hystem-C®. After gelation, a fibronectin-coated coverslip of LN229 (human glioblastoma) or human umbilical vein endothelial cells (HUVECs) was placed atop the stacked gels. For co-cultures, the second cell type was seeded around the coverslip.

HUVECs were cultured up to 14 days. HUVECs began to form connections around day 7 and by days 10-14, 3D connectivity was observed. LN229 migrated through the gel by day 6. We are currently investigating changes in migration and directionality in mono- and co-cultures of these cells. In the future, we aim to include macrophages and astrocytes to obtain a comprehensive understanding of the PVN.

Titanium (Ti) and its alloys have a long history as biomaterials for skull bone repair.(1) However, Ti (alloys) generally do not allow firm osseointegration.(2) Bioactive coatings can be applied, but it is difficult to obtain a homogenous coating.(3) We recently developed 3D porous implants from a Ti alloy and a CaP ceramic using additive manufacturing. This study analyzed the capacity of bone marrow-derived human mesenchymal stromal cells (hMSCs) towards osteogenic differentiation and tissue formation on these implants. Porous Ti6Al4V 3D scaffolds without or containing 5 or 10 weight% beta-tricalcium phosphate (TCP) were used. Upon culturing hMSCs on the different scaffolds for 14 or 28 days in basic or mineralization medium, cell metabolic activity, DNA content, tissue formation, alkaline phosphatase (ALP) activity, and osteopontin and osteocalcin secretion were analyzed. hMSCs cultured on the scaffolds remained metabolically active and showed a similar proliferation profile on all scaffold types. hMSCs produced ALP, osteopontin and osteocalcin. Additionally, we observed tissue formation throughout the porous scaffolds in all conditions after 28 days. No significant differences in ALP activity or osteocalcin and osteopontin secretion of hMSCs and tissue formation were observed between scaffolds without and with different amounts of TCP. This is in contrast with previous studies, showing that the addition of CaP typically increases the levels of ALP activity, osteocalcin and osteopontin.(4) Further in vitro studies as well as in vivo testing of the Ti-TCP scaffolds will be used to better understand the effect of the individual components and structural characteristics on the biological response.

Abdominal hernia is one of the most common conditions worldwide and the use of prosthetic meshes is now largely accepted as gold standard of the surgical strategy. Mesh design is a crucial point to define the properties and surgical outcomes of the implant1. The choice of mesh materials and manufacturing methods influence mesh biocompatibility, mechanical properties, porosity, and degradation rates. This work aims to develop a multicomponent hernia mesh device able to enhance the integration of the polypropylene (PP)-based hernia mesh thanks to the presence of a nanostructured biomimetic substrate able to improve cell attachment and new tissue formation. A commercial polypropylene (PP) hernia mesh was coated with a nanofibrous membrane based on polycaprolactone (PCL) and gelatin (Gel) through the electrospinning technique. Resulting PCL-Gel nanofibers were homogeneous and defect-free, with an average diameter of 0.15±0.04 μm, and well retained their morphology even after 28 days of incubation in physiological conditions. The presence of Gel decreased PCL hydrophobicity, while it slightly influenced mechanical properties. The biocompatibility of the coated PP meshes was assessed by seeding and culturing BJ human fibroblasts on the device, up to 7 days. After 24 h, cells adhered to the nanofibrous substrate, and after 72h their metabolic activity significantly increased demonstrating cells proliferation. The absence of detectable lactate dehydrogenase in the culture medium indicated that no necrosis induction occurred. Hence, the developed nanostructured coating provided the PP mesh with chemical and topographical cues similar to the native extracellular matrix thus enhancing mesh integration in the abdominal wall.

3D bone models remain of significant interest for the study of diseases associated with the skeletal system. Current approaches seek to use living organisms as bioreactors, however these do not address the 3Rs initiative. We detail a novel animal-free three-dimensional model for drug screening against bone pain, printing human bone marrow stromal cells (hBMSCs) and induced pluripotent stem cell-derived Nociceptors (iPSC-NCs) to fabricate a 3D platform to study the pathophysiological interaction of these cells.

An innovative clay-based biomaterial ink (bone ink), as previously established [1], was used to print hBMSCs. A low-polymeric fraction gelatin methacryloyl – Matrigel (GelMA-Ma) ink (neuro ink) was developed and characterised for the printing of the iPSC-derived nociceptors. Extrusion of the bone and neuro inks was tested on polydimethylsiloxane (PDMS) flow-focusing microfluidic chip using high-speed imaging (Photron-UX100) to determine the ideal extrusion parameters at 5 and 8 µl·min-1, respectively. Harnessing the ability of the microfluidic chip to rapidly switch between the bone and the neuro bioinks, hBMSCs and iPSC-NCs were printed serially, which critically demonstrated viability and functionality after printing, staining positively for alkaline phosphatase and expressing TRKA and CGRP, with limited expression of NEFH and RET. Significantly, the mechanical disruption of the neuro portion impaired functional transmission of neuro-signalling, confirming the ability to imitate the neural damage.

In conclusion, we demonstrate the functionality of a bone-neuro model able to recapitulate the complex skeletal innervation and to simulate /modulate the neural network, illustrating the potential of the model using novel therapeutic agents for bone pain studies.

The regeneration and replacement of soft tissue and research of appropriate donor tissues is increasingly important in an aging society. In this in vitro project the adipogenic differentiation of human adipose stem cells (ASCs) on sponge scaffolds made of silk fibroin was investigated to examine the optimal differentiation process for producing a fat tissue graft.
Human ASC were seeded with a number of 2x105 cells in 100 µl medium on fibroin sponge scaffolds and were stimulated towards adipogenic differentiation using 1 ml differentiation media based on High Glucose Medium supplemented by various concentrations of FBS (0%, 1% and 2%) and either rosiglitazone (5,6 µM) or Cremophor® EL (300 µM). On days 0, 3, 5, 7, 10 and 14 the Presto-Blue conversion indicated cellular vitality. The media supernatants were collected after 10 and 14 days and were analysed by ELISA. The scaffolds were cryosectioned and taken for histological staining methods. A 2D plate culture served as control.
Presto-Blue increased over the course of the experiment, indicating cell proliferation. Furthermore, ELISA indicated increased secretion of adiponectin and leptin. Adipogenically differentiated cells were also detected by immunohistochemical staining. We found 1% FBS and Cremophor® EL is the optimal culture setting.
Our experiments showed that silk fibroin sponge as a scaffold for an adipogenic differentiated cell culture can be produced by the addition of 1% FBS and Cremophor® EL, which could enable implantation of fatty tissue grafts in vivo.

This study aims to fabricate extracellular-like multilayers using glycosaminoglycans with capability to bind BMP-2 specifically in order to control osteogenic differentiation of cells by biocompatible release systems.

Native chondroitin sulfate (CS) and its oxidized form as polyanions were combined with collagen I as polycation to form multilayer coatings on model materials with getting advantage of the intrinsic cross-linking formed between oxidized CS and Col I to improve multilayer stability and affect the release of BMP-2. 50:50 mixture of native and oxidized CS was also studied. The myoblast cell line C2C12, which can differentiate into osteoblasts was seeded on 10 µg/mL BMP-2 loaded multilayers. Cell adhesion, osteogenic differentiation and BMP-2 release were investigated.

C2C12 cells cultured on the multilayers showed that BMP-2 loaded, oxidized CS multilayers promoted an osteogenic differentiation that was even higher than the positive control, when 10 µg/mL BMP-2 was added directly to the medium. Interestingly, the BMP-2 had synergistic effect on cell adhesion and spreading. BMP-2 in oxidized CS multilayers was successfully loaded to the layers, sustainably released over time and affected cell differentiation more than the soluble BMP-2.

The results show that oxidized glycosaminoglycans multilayers are useful as reservoirs for BMP-2* in which the intrinsic cross-linking affected BMP-2 release, improved multilayers stability due to the resulting stiff surface compared to the native ones, supported cell adhesion and subsequent differentiation. This can pave the way for coating implants and scaffolds for repair and regeneration of bone fractures.

This work was supported by the International Graduate School AGRIPOLY.

Muscular dystrophies are a group of genetic diseases characterized by progressive skeletal muscle weakness and degeneration. The intra-arterial injection of in vitro cultured mesoangioblasts, mesenchymal cells located on the vessel walls, holds potential for an effective stem cell therapy. The mesoangioblasts extravasate from the vessel through the vessel walls into the surrounding muscles, where they form healthy muscle fibers and compensate loss of muscle strength and mass. The Interreg-project GYM – Generate Your Muscle aims to develop an autologous stem cell therapy as a novel treatment for muscular dystrophies. In our subproject we aim to develop a 3D-bioprinted in vitro-vessel-on-a-chip model for the investigation and improvement of mesoangioblasts homing. Biofabricated functional vessel substitutes are used for the investigation of extravasation properties of injected mesoangioblasts under dynamic conditions with higher biomimicry than conventional migration assays under static conditions. The fabrication of the models combines extrusion with drop-on-demand-printing of cell-laden hydrogels. Thereby, a perfusable channel with a confluent endothelial cell layer with or without an adjacent smooth muscle cell layer (arterioles and capillaries, respectively) embedded by an extracellular matrix containing fibroblasts is fabricated. Cytokines, such as TNF-α or SDF-1, are included to replicate and improve the underlying migration mechanism of mesoangioblasts through the endothelial cell layer. The rheological and mechanical properties of different hydrogels combinations (gelatin, fibrinogen, thrombin, collagen) are evaluated concerning their suitability for bioprinting, facilitation of cell viability, proliferation and mesoangioblasts extravasation. As the project has just started, we will present our study design and the data obtained so far.

In the last decades, scientific evidence has highlighted how glycans and glycan-specific binding proteins play a key role as bio-information carriers in both pathological and physiological processes. The glycosignature of ECM is particularly important to control the cell fate during these processes. Glycans are expressed in the ECM as polysaccharides in glycosaminoglycan (GAGs) and proteoglycans (PGs) and as oligosaccharides in glycoproteins. To closely mimic the ECM in 3D structures, several polysaccharides or oligosaccharides have been employed1,2; however the availability of many commercial glycans founded in human ECM are limited by the source or the synthetic effort needed for the production. The selection of polysaccharide mimetics derived from alternative sources is a valid solution for the development of ECM glyco-components. An example of polysaccharide with high biomedical potentiality is chitosan, a linear polysaccharide formed by β-1,4-linked d-glucosamine (GlcN) and N-acetyl-d-glucosamine (GlcNAc) epitopes. Chitosan is FDA approved and it has outstanding properties such as excellent biodegradability, biocompatibility, and antimicrobial activity.3 Here in this work, to mimic the ECM hybrid structure, chitosan has been employed as polysaccharidic component and conjugate with modified gelatin using click chemistry.4 The selected glycoconjugate polymers have been employed as hydrogel for 3D U87 spheroids encapsulation and 3D bioprintable material. The obtained 3D cultures were fixed and its tissue sections were studied by matrix-assisted laser desorption/ionization mass spectrometry imaging (MALDI MSI) to characterize the effect of differential glycosignature and stiffness in 3D cell cultures.

Primary Open Angle Glaucoma (POAG) is a leading cause of irreversible blindness globally. The main risk factor for POAG is increased intraocular pressure (IOP), due to cellular dysfunction and fibrosis in the eye's drainage structures; the Trabecular Meshwork (TM) and Schlemm's Canal (SC), leading to an inability to control fluid outflow and IOP. The mechanisms which lead to TM/SC cellular dysfunction are still not fully understood, and there is a lack of reliable TM/SC models to accurately mimic the disease pathology. The aim of this project is to design and develop a novel 3D model of the TM/SC which can accurately model POAG.

Initially, we defined the co-culture conditions for the model using transwell inserts. To achieve this, media composition and hydrogel matrix components were investigated. TM cells are embedded in varying concentrations of type 1 collagen hydrogels, defining the correct stiffness required and SC cells are cultured on the underside of insert. Basic media (DMEM, 10%FBS and 2mM of L-glutamine) is used to culture both cell types. TGFβ-2 is added to the TM/hydrogel utilising a novel PODS® technology, releasing TGFβ-2 over 3 weeks. This release profile mimics the pathological TGFβ release within the eye, as seen in POAG.

We have demonstrated that TGFβ-2 release from the PODS® led to alterations in TM cells by producing increased alpha-SMA and fibrillogenic proteins. This resulted in an increase in the overall stiffness of the TM/hydrogel. In conclusion, our novel 3D co-culture represents more accurately the TM/SC dysfunction seen in human POAG.

Skin friendly soft materials have attracted a lot of interest as sensors for biomedical signals tracking and information recording as well as antibacterial systems. In this frame, polymeric biomaterials classified as hydrogels have several features which make them perfect choices for these applications, such as high-water content, softness, biocompatibility, tunable mechanical properties, and similar physical properties to living tissues.

In this work, metal nanoparticles, i.e., silver nanocubes, were added to poly(N-isopropylacrylamide)-based hydrogel precursor in order to obtain a thermoresponsive composite system with enhanced antibacterial and electromagnetic properties. Moreover, the introduction of a poly(ethylene oxide) – poly(caprolactone) electrospun mat into the hydrogel composites creates a compatible environment for homogenous hydrogel coating, while providing mechanical and structural properties to the final system.

Systems consisted of two outer layers of composite hydrogel, and one inner layer of electrospun mat were polymerized by UV light for a short time, obtaining a compact and stable device. Chemical, morphological and optical tests were performed to investigate the structure of each layer and the properties of the whole construct, as well as the possibility to activate the platform functions by light. The synergetic effect of photothermal-responsivity, antibacterial and electromagnetic properties of the composite material was investigated, revealing that the proposed platform is a potential candidate as an antibacterial organic molecule sensor (e.g. glucose).

Osteoarthritis (OA) is a disabling joint disorder causing articular cartilage degeneration. The use of secretome derived from bone mesenchyme stromal cells (BMSCs) represents a novel therapeutic strategy for OA. We characterized cells, secretome, extracellular vesicles (EVs), and EVs micro RNAs of hBMSCs grown in XFS compared to platelet lysate (PL), and conventional fetal bovine serum (FBS) culture system. We investigated also the therapeutic potential of conditioned media (CM) and EVs in an in vitro model of OA. We observed that XFS and PL promoted enhanced growth and viability of hBMSCs compared to the FBS medium. The secretome of these cells showed involved in homeostasis, wound healing, and angiogenesis, as well as a marked production of EVs. The biological effects of the CM and EV derived from hBMSC cultivated in XFS, and FBS-based medium was tested on IL-1α treated hACs to mimic the OA environment. We observed that under inflammatory condition hACs are able to recruit and internalize more MSC-derived EVs, especially those derived from cells cultured in our XFS system. Treatment with CM and EVs derived from XFS-cultured hBMSC inhibited IL-1α-induced expression of IL-6, IL-8, and COX-2 by hACs compared to FBS-based conditions. Moreover, hBMSC-EVs exerted a significant chondroprotective effect when pre-treatment of hACs was performed 3h before the induction of inflammation. We are currently testing the biological validity of hBMSC-EVs grown in PL medium on the same OA in vitro model. In conclusion, we develop an innovative Cell-free Extracellular Vesicle (EV)-based therapeutic approach for modulation of OA.

Hepatocyte polarity maintenance and functional maturation in in vitro cultured hepatocytes are primary goals to acquire major liver-specific functions. To endeavor this, the unique microenvironment with regulated pore size and mechanical stability supporting the varied cell-matrix interaction is crucial. In this study, three dimensional (3D) in vitro liver model were fabricated by blending silk fibroin and liver ECM in different ratios, and cultured with primary rat hepatocytes to accomplish the hepatocyte polarity. Physicochemical characterization like FESEM, FTIR, mechanical strength, integral stability, etc. was performed to understand the morphology and structural transition in the scaffolds. Cell proliferation and gene expression analysis of liver-specific functional markers including albumin, cytochrome P450 2E1, cytochrome P450 1A2, HNF 4α, α1 antitrypsin, SOX 9, and fibronectin revealed a significant difference in the expression pattern among variants of silk liver ECM blend scaffolds. Biochemical estimation of synthetic proteins and immunofluorescence staining analysis is in line with the gene expression analysis. Accordingly, the scaffolds are arranged in perfusion bioreactor mimicking the native liver lobule zone-specific functions, and long-term culture supported functional polarity in terms of synthetic proteins (albumin), ECM deposition (fibronectin, desmin), and bile canaliculi (cytokeratin 18). In this study, physicochemical attributes of silk liver ECM blend scaffolds established a unique pattern of functional hepatocyte polarity in each scaffold variant. Further, perfusion culture enabled maturation and functional polarity maintenance mimicking the native liver. As a whole, the in vitro model will find potential applications in bioartificial liver devices.

Defects of the auricle affect physiological and psychological well-being of patients. To date, reconstruction techniques of the auricle, despite their effectiveness, are limited because of donor site morbidity, high risk of complications and surgical complexity. Innovative tissue engineering techniques based on decellularization may be reliable alternatives for treatment of pathological conditions affecting the auricle.

The aim of this study was to develop a biocompatible decellularization protocol to obtain an engineered auricle. The study involved the construction of a scaffold based on cell-free extracellular matrix to be repopulated with autologous stem cells, allowing the regeneration of the organ and avoiding the rejection reaction. Rat auricles were harvested and perfused through a bioreactor. The efficiency of decellularization was evaluated based on specific parameters. Cell loss was evaluated by hematoxylin and eosin, DAPI stains and DNA quantification. The absence of muscle fibers was evaluated by Masson's trichrome stain and the extracellular matrix preservation by Alcyan blue, van Gieson's trichrome, Weigert and PAS stains. The biocompatibility of grafts was assessed by an indirect cytotoxicity assay. The study identified an efficient decellularization protocol, able to remove epithelial, glandular and muscle tissues, leaving no visible nuclei but preserving elastic fibers, collagen and glycoproteins. The glycosaminoglycans content was slightly reduced. The protocol resulted both reproducible and biocompatible. In conclusion, a protocol allowing the decellularization of the auricle and preserving the extracellular matrix was developed in our study, representing a first step to obtain an efficient, implantable and clinically useful engineered auricle, devoid of immunogenicity.

Inorganic-organic composites with calcium phosphates (CaP) and biocompatible polymers have a great interest in the field of bone tissue engineering. Mechanical properties, degradation behavior and cell material interaction are the most affected characteristics resulting from the addition of inorganic materials to polymeric hydrogel networks.

In this we report developed in situ precipitation synthesis for the production of hyaluronic acid (HA)/CaP composite strong hydrogels (90 mg/mL HA) and their biomechanical properties, analyzed with a new model-free method. We have observed significant non-linear effect of CaP concentration from 0 to 60% vol. on both invariant stiffness and viscosity, as well as differences of the properties at frequencies between 0.1-20 Hz. Results indicate that a careful adjustment of the in situ precipitated CaP in these hydrogels is required to tailor biomechanical properties for chosen clinical application.

This work was partially supported by COST Action MP1306 "NEWGEN".

A combination of increasing liver disease incidence and a shortage of donor organs available for patient treatment has led to a need for liver 'organoids'; lab created environments which mimic the in vivo extracellular matrix [ECM] niche and support the survival and function of hepatocytes.

A combination of biological materials supported by electrospun polymer scaffolds has demonstrated the ability to influence hepatocyte function, and with this in mind we created multidimensional scaffolds for liver tissue engineering. Several approaches were taken – decellularized human liver ECM, drug derived ECM and synthetic production of specific ECM proteins.

Scaffolds were fabricated by combining electrospun polymer matrices with each of the biofunctionalization approaches. Human hepatocytes were assessed for their response using scanning electron microscopy [SEM], mechanical and biochemical quantification, histology, and gene expression analysis. Additionally, drug derived ECM:polymer scaffolds were validated using gold standard primary human hepatocytes.

Results demonstrate that this novel approach of combining the most promising of techniques from the field of liver tissue engineering produces scaffolds capable of influencing hepatocyte function, with alterations in cell survival, albumin production and gene expression demonstrated in each multidimensional environment.

Creating multidimensional scaffolds provides a method of creating tailored, consistent environments for liver bioengineering and the investigation of cell matrix interactions and is a step on the path to providing lab grown organoids for patient transplant.

Neural tissue engineering (NTE) investigates the fabrication of bioengineered scaffolds, able to reproduce biomimetic microenvironments of the nervous system. Successful substrates combine morphological, electrical and biochemical cues to enhance cells guidance and, in turn, neural activity. Although a proper interface between substrates and electronics is necessary to achieve neural electrical stimulation and recording, current solutions (like microelectrode arrays) usually do not integrate electrodes with NTE substrates. In this study, we propose printing of electronics (PE) as a novel manufacturing technology to develop in-vitro NTE bioelectrical scaffolds with combined neural alignment. A feasibility study on the additive manufacturing aerosol jet-based technique is presented for in-situ printing of conductive patterns onto biomimetic scaffolds. The direct writing Aerosol Jet® Printing has proven ability in PE for electrical applications (like sensors, electrodes, interconnects,…) and microstructures production (resolutions ≥10 µm) [1],[2]. It is also able to deposit various inks (conductive, dielectric and biological solutions, viscosity range [1-100] mPas) on 2D, 3D and flexible substrates [3]. Process parameter evaluation is reported to assess the printability of a silver nanoparticle (AgNPs) ink and a poly(3,4-ethylenedioxythiophene)polystyrene sulfonate (PEDOT:PSS) ink on electrospun and micro-structured scaffolds, respectively. The printed conductive patterns show electrical resistances of R(AgNPs)~140 Ω and R(PEDOT:PSS)~280 Ω (line length~1 cm, thickness~40 layers). The printability process results more stable on the micro-structured substrates due to lower electrical dispersion and uniform surface. Furthermore, the biocompatibility tests on both substrates show a higher cell viability on PEDOT:PSS. Data concerning AgNPs toxicity indeed show a dose-dependent behaviour, according to the literature.

Epithelial ovarian cancer is one of the leading causes of death from gynecological malignancies in the western world. It is often diagnosed at an advanced stage with peritoneal metastases present because of the non-specific nature of the presenting symptoms. To improve treatment outcome, intraperitoneal (IP) chemotherapy has been added to the standard treatment modality since IP chemotherapy can achieve higher locoregional drug concentrations, while avoiding systemic toxicity.
As peritoneal adhesions are a very common complication after surgery, it hampers the uniform drug distribution in the peritoneal cavity, thereby reducing the efficacy of intraperitoneal chemotherapy after cytoreductive surgery.

Low endotoxin spheroid gelatin microspheres (MS) were prepared and crosslinked with genipin (GP-MS). The degree of crosslinking allowed to tailor the degradation rate of GP-MS, hence their residence time. In vivo studies in mice showed excellent biocompatibility, distribution and degradation characteristics of GP-MS. It was shown that the used low endotoxin gelatin-based MS are a promising strategy to prevent postoperative peritoneal adhesions.

Next, GP-MS were loaded with paclitaxel (PTX) and were retained within the peritoneal cavity from several days up to weeks depending on their degree of crosslinking. PTX release was sustained over time with an initial burst release followed by a slow release. Further, the MS decreased viability of ovarian cancer cells in a time- and concentration dependent manner. These data suggest that low endotoxin gelatin-based MS can be a promising IP drug delivery system to prevent recurrent ovarian cancer.1
Future work focuses on optimization of the formulation by testing different crosslinkers.

The bottom-up assembly of spheroids is a promising biofabrication alternative to generate functional tissues of clinically-relevant size. The use of spheroids as building blocks is often challenging due to the formation of dense structures with hypoxic regions that negatively impact cells viability and/or function, which may ultimately result in deficient scaffold-host integration and implant failure. Herein, patch-like constructs composed of optimized vascularized spheroids showing ability to generate capillary-like endothelial sprouts are described and proposed as a promising bottom-up approach for tissue engineering.

Spheroids with mesenchymal stem/stromal cells (MSC) and outgrowth endothelial cells (OEC) were generated [1]. MSC-to-OEC ratio and spheroids maturation time were tested for optimal OEC survival/organization. Spheroid-based patches were formed loading cells (1:1 ratio) into a square-shaped microwell agarose-mold and allowing them to aggregate into a single structure for 18h. Single spheroids and/or patches were analyzed for: size, metabolic activity, cell/ECM organization, sprouting potential and surface stiffness.

The 1:1 cell ratio enabled the production of spheroids with optimal OEC retention and organization into vascular-like structures, stabilized by endogenous ECM, both interstitial and basement membrane-like (at the periphery of vascular structures). Maturation time influenced spheroid sprouting ability, with 1-day-old spheroids showing extensive OEC sprouting, as opposed to matured spheroids that presented significantly inhibited sprouting. Spheroid-based patches had consistent square shape and size and exhibited similar sprouting potential to individual spheroids.

Spheroid-based patches stand out as a promising tool for building scaffold-free vascularized 3D constructs for tissue engineering in a bottom-up assembly approach.

Cardiac tissue engineering applications require electrically conductive platforms to transmit electrical impulses throughout damaged region of myocardium [1]. Concurrently, cardiac patches should ensure sufficient mechanical properties to preserve their mechanical integrity under physiologically relevant stress levels [2]. Besides, a porous microstructure is essential to provide requisite surface area for cellular functions, while allowing nutrient, waste and oxygen transport with the surrounding tissues [3]. Furthermore, biodegradability of a cardiac patch is another requirement to prevent a secondary surgery [4]. To address all of the aforementioned requirements, we fabricated electrically conductive biodegradable silk fibroin (SF)/carbon nanofiber (CNF) scaffolds to be used in cardiac tissue applications. Detailed characterization of physicochemical, mechanical, electrical and structural properties of the scaffolds as well as their biodegradation characteristics were assessed. Results revealed that incorporation of CNFs into porous SF matrix led to similar mechanical and electrical properties to that of heart muscle tissue and provided a control over its degradation through altering fabrication parameters. A potential secondary bonding mechanism was proposed to explain the interactions between SF polypeptides and CNFs that resulted in enhanced scaffold properties. Moreover, degradation dependent property changes of SF/CNF nanocomposites were investigated to simulate their time dependent performance in vitro. Biological properties of SF/CNF nanocomposites were also assessed using induced pluripotent stem cells (iPSCs). Enhanced viability, metabolic activity and cardiomyogenic differentiation of iPSCs on SF/CNF nanocomposites revealed their potential for use in cardiac tissue engineering applications.

Implantable devices have been developed for alternative treatment for various diseases such as cardiovascular disorders, skeletal diseases, chronic pain and diabetes. However, the interplay between the surface of implants and the immunological response can lead to implant failure. In this study, 2 types of synthetic polymers, Polyvinylidene fluoride (PVDF) & ChronoFlex, were tested to be potential biomaterials for future subcutaneous transplantation. A marker-independent approach via Raman Microspectroscopy was employed to monitor foreign body response (FBR) after subcutaneous implantation in regards to extracellular matrix (ECM) proteins such as collagen I and III, as well as alpha-smooth muscle actin. Principal component analysis (PCA) was performed on the Raman spectral data. Differences in the Raman bands representing amide I and III, phenylalanine, and hydroxyproline were identified, which indicated structural changes in collagen I between the two biomaterials that were not detectable by picrosirius red staining. The promising analytical approach provides a more sensitive and efficient way to characterize the ECM of the fibrotic capsule and a non-invasive tracking method to examine the progress of fibrosis.

DEVELOPMENT OF A HYDROGEL – BASED MICROFLUIDIC MODEL OF LYMPH NODE TRANSFORMATION

Corrado Mazzaglia$_P$[1,2]

[1] *University of Cambridge*

[2] *MRC cancer unit*

Corresponding author's email: cm986@cam.ac.uk

Lymph nodes (LNs) are organs of the immune system that maintain homeostasis and trigger primary immune responses. However, in many solid tumours, LNs are also a major site of metastasis, which accounts for about 90% of cancer-related deaths [1]. LNs that are downstream of a tumour and directly drain tumour-derived factors, go through a process of transformation, which may prime the organ for metastasis, and critically, may impair the development of effective anti-tumour immune responses. We still know relatively little about the processes driving these LN changes and how they disrupt immunosurveillance from early stages of cancer. As in vivo models do not easily permit us to follow events longitudinally or to finely manipulate the environment, we set out to create a microfluidic system that incorporates in vitro and ex vivo components to model LN transformation in a controlled, tractable system. The system is designed to enable monitoring of tissue remodelling in real-time, and permits cell retrieval at the experimental end-point to detect changes at a genetic and surface marker level. In summary, this model, integrating molecular and biophysical cues in a dynamic 3D environment, allows us to more comprehensively profile the mechanisms that contribute to LN transformation, immune modulation or therapeutic responses in tumour draining lymph nodes (TDLNs) such as immunotherapy.

Our previous studies have proved that moderate-intensity treadmill exercise can alleviate OA in rats, but the underlying mechanism of exercise therapy needs further research. The Wnt/β-catenin signaling pathway can regulate the effects of mechanical stimulation on cartilage cells and healthy joints, and there is a delicate balance between the occurrence and development of OA. Based on this, we speculate that Wnt/β-catenin signaling pathway is involved in exercise therapy for OA. In order to verify this conjecture, we applied mechanical stimulation to the joints of OA modeled rats through a treadmill and injected activators BIO and inhibitors IWP-2 of the Wnt/β-catenin signaling pathway into the joint cavity of the rats to interfere with Wnt/β -catenin signaling pathway. OA development was examined using the gait test, histological and immunohistochemical analyses, micro-computed tomography (micro-CT) analysis at 4 weeks and 12 weeks after injection. We found that both the BIO and IWP-2 groups significantly improved gait and inhibited cartilage destruction and osteophyte formation at 4 weeks, but there was no significant change at 12 weeks. These investigations revealed that Wnt/β-catenin signaling pathway involved in the effect of mechanical stimulation on OA is time-dependent. Once it cannot be maintained, Wnt/β-catenin signaling pathway cannot participate in the process.

Regenerative medicine and cell therapy represent a breakthrough change in paradigm in healthcare. For efficient cell adhesion, proliferation, morphogenesis and differentiation, scaffolds should properly mimic natural in vivo microenvironments and offer local conditions needed for regulation of cellular functions. Here we present a novel biocompatible scaffold for multi-dimensional cultures of cells, providing a cell culture matrix that supports cells growth in a proper fashion, capable of inducing cell morphologies resembling the true cell (tissue) morphology, preserving the metabolism, receptors activation and protein expression in a way which resembles the true situation in vivo [1].

We consider the action of these highly anisotropic nanoceramic scaffold to result in automechanoinduction of cells due to their own interaction with the substrate, without application of external forces or specific culture media, leading to changes in cells behavior, structure, functionality, and morphology. This has been demonstrated on hMSC and cancer cells reactions as well as for inflammatory markers downregulation in PMBC. Such scaffolds might present a new tool for cell studies using non-biological autostimulation.

This work was supported by Prototron Foundation (Estonia) and Estonian Research Council.

Cell-assembled extracellular matrix (CAM) has been used to produce vascular grafts without exogenous materials. [1-3] While these completely biological vascular grafts performed well in clinical trials, the in vivo remodeling and inflammatory response of this truly “bio” material has not yet been investigated. In this study, human CAM yarns were implanted subcutaneously in nude rats to investigate the innate immune response.

The impact of processing steps relevant to yarn manufacturing was evaluated (devitalization, decellularization, gamma sterilization, and twisting). We observed that all yarns were still present after six months, and were integrated into a non-inflamed loose connective tissue with a CAM tissue repopulated by fibroblastic cells and blood vessels. Two weeks after implantation, yarns caused minor peripheral inflammation except for gamma sterilized yarn that triggered a more intense host response dominated by M1 macrophages. Yarn mechanical strength was decreased two weeks after implantation except for the more compact “twisted” yarn. While the strength of other yarns appeared stable after initial remodeling, the gamma-sterilized yarn continued to lose mechanical strength over time and was significantly weaker than devitalized (control) yarns at six months.

This is the first study to formally demonstrate that devitalized human CAM is very long-lived in vivo and does not trigger a sustained degradative response but, rather, is very slowly remodeled. This data supports a strategy to produce human textiles from CAM yarn for regenerative medicine applications where a scaffold with low inflammation and long-term mechanical properties are critical.

Material associated infections are devastating complications in orthopedics. The “Race for the surface” with the osteointegration of the material can be influenced by surface properties and local antibiotic delivery. This study aimed at the development and in vivo testing of a porous titanium surface loaded with gentamicin.

The surface of titanium K-wires was laser structured, metal silver particles were embedded in the titanium dioxide layer, the pores were loaded with gentamicin, and the surface was mechanically tested. Biocompatibility and infection prophylaxis were assessed in rat osteointegration and infection models. K-wires were implanted in rat femura and the integration was analyzed by mechanical testing and histology. For infection prophylaxis, Staphylococcus aureus was inoculated and the bones were analyzed by histology and microbiology.

The pores revealed an amphora-like shape and the surface structuring was mechanically stable. Gentamicin loading revealed an adjustable loading capacity with a burst release within one hour. The in vivo study showed a good biocompatibility of the Porous and Genta-loaded K-wires with significantly better osteointegration compared to the CTRL. The Genta-loaded K-wires significantly reduced the bacterial colonization and the signs of osteomyelitis.

This porous surface modification shifts the “Race for the surface” in favor of the osteoblast. The mechanical stable amphora-like pores can be loaded with the required antibiotics. Due to the fast gentamicin release, the surface is protected from bacterial colonization without compromising biocompatibility and osteointegration. This approach enables for the production of “off-the-shelf” orthopedic implants with surface modification and loading with the antibiotic just prior to implantation.

The cross-talk between cell-matrix plays a pivotal role in tissue regeneration and off-late, conducting polymers have been inducted as alternatives for studying such interactions. However, close study reveals that incorporation of conducting polymers comprises stability of fabricated scaffolds. Herein, the study demonstrates a process to impart structural anisotropy with incorporation of Polyaniline (PANi) as conductive material, in silk fibroin (SF) loaded electrospun nanofibrous scaffold balancing scaffold stability as well as inducting opportunity to investigate cell-matrix interaction towards tissue regeneration. Blend of varying wt% of PANi was prepared with SF/Polycaprolactone (PCL) solution to electrospun stable scaffolds and SEM micrographs revealed that incorporation of PANi didn't affect fiber morphology and smooth beadfree nanofibrous scaffold with narrow fiber distribution from 150 nm to 250 nm was obtained by incorporating upto ~ .3 wt% of the conducting polymer. Further study with FTIR confirms presence of PANi in the composite scaffold while XRD demonstrated semi crystallinity. Surface analysis suggest moderately hydrophobic behavior ~ 115o, surface roughness of .075 µm, and mechanical study portrayed a young's modulus of ~ 30 MPa and nanoindentation presented an average modulus of 1.8 GPa. In vitro study with human dermal fibroblast (HDF) illustrated excellent compatibility profile of scaffold thus confirming mechanical stability of the scaffold for potential regenerative application. The successful incorporation of PANi in an optimized nanofibrous scaffold exhibited prospective opportunity to fabricate scaffold with plausible electrical conductance for regulating cell-cell and cell-matrix behavior towards enhanced tissue regeneration.

Human tissues derived from pluripotent stem cells ("human organoids") revolutionize in vitro disease modeling by providing multicellular architecture and function that are strikingly similar to those in vivo. This new and innovative technology, however, still lacks enough throughput and reproducibility to enable high-throughput screening (HTS) of compounds due to cumbersome organoid differentiation and maturation processes and difficulty in dispensing cells in hydrogels. Here, we overcome these challenges by developing "miniature three-dimensional (3D) bioprinting" technology and associated pillar and perfusion plate platforms for human organoid culture and analysis. High-precision, high-throughput, small-scale stem cell printing and encapsulation techniques were demonstrated on pillar plates (384PillarPlate and 36PillarPlate), which were coupled with a complementary deep well plate (384DeepWellPlate) and a perfusion well plate (36PerfusionPlate) for static and dynamic organoid culture. Bioprinted cells and aggregates in Matrigel were differentiated and matured into liver and intestine organoids on the pillar plate for in situ functional assays. The entire organoids on the pillar plate were permeabilized, fixed, stained with primary and secondary antibodies, and cleared with tissue clearing solutions simultaneously for in situ whole organoid imaging without the need for cryosectioning. The flexible pillar and perfusion well format connected by microchannels and reservoirs made it easy to change growth media for organoid culture without the use of bulky pumps and tubes. The pillar/perfusion plate platforms compatible with standard 384-well plates and HTS equipment such as automated fluorescence microscopes and microtiter plate readers could be adopted in current drug discovery efforts.

Cardiovascular disease is one of the major causes of mortality across the world [1]. Synthetic vascular grafts (SVG) and autograft vessels are the current treatment modalities. SVGs are able to successfully substitute for large vessels but are ineffective for small diameter vessels (<6 mm) [2] due to compliance mismatch and thrombogenicity. While autografts remain the gold standard they are limited by supply and anatomical variability issues.

To address this, we utilised melt electrowriting (MEW) [3] to successfully fabricate planar MEW scaffolds with five different fibre orientations mimicking the range of collagen architectures of native vessels. Optical microscopy and scanning electron microscopy were used to investigate morphological characteristics of the fibrous scaffolds. Strips of native vessels and synthetic scaffolds were subjected to tensile testing, both in the circumferential and longitudinal directions, to compare the mechanical behaviour. Results demonstrated control over the mechanical response of the constructs resembling the typical j-shape curve of native tissue. Preliminary biological studies demonstrate good cell viability , and ECM deposition after 21 days.

After identifying the most suitable MEW substrate in terms of mechanical response, smooth muscle cells (SMC) differentiation, and ECM deposition, a tubular MEW based SVG with an anatomically inspired architecture will be used to recapitulate the vessel wall and address the issues currently associated with compliance mismatch.

Hydrogel design for cell encapsulation is a booming field of research. While many crosslinking strategies have been proposed, most of them require external stimuli or catalysts, are not entirely bioorthogonal, or have inherent limitations (e.g., limited stability, slow gelation rate). Thus, hydrogels that would be fully tunable, fast-gelling, biocompatible and, yet, easy to synthesize and use, remain to be designed. We hypothesized that using the strain-promoted azide-alkyne cycloaddition (SPAAC) as a crosslinking mechanism would allow the synthesis of versatile polysaccharide-based hydrogels, addressing all design criteria and offering new opportunities.

We first investigated the development of SPAAC hyaluronic acid (HA)-based hydrogels. HA components were easily synthesized in single-step reactions from commercially available compounds. Mixing two HA components together, we successfully obtained hydrogels under physiological conditions. Optimizing the HA molecular weight, substitution, component ratio and polymer content, we designed tunable hydrogels that form within seconds to minutes, with stiffness tunable over orders of magnitude (0.5 to 40 kPa). Shrinking, swelling or non-swelling hydrogels could be obtained. All of these HA-based gels were stable over months under physiological conditions, and yet could be degraded enzymatically within hours to days. We further showed that SPAAC crosslinking could be easily applied to other polysaccharides, as a most versatile platform for hydrogel design.

Using a model cell line, we demonstrated excellent viability (> 90%) via live/dead confocal imaging, and investigated the effect of 3D encapsulation on metabolism and proliferation. These materials are now being investigated for a breadth of applications, spanning from organoid culture to bioprinting.

The evolutionarily conserved composition of ECM, and its critical role in the response to tissue injury, provide a compelling rationale for its use as an inductive biomaterial to promote tissue repair. However, gaps in our understanding of the compositional properties of ECM limit our ability to design and fabricate ECM biomaterials that fully capitalize upon their therapeutic potential. Although proteomic analyses have provided a detailed profile of ECM-associated proteins, the effects of incorporated (phospho)lipids and (extracellular)RNA on matrix biology, and the host tissue response, are largely unknown. Herein we show that matrix-bound nanovesicles (MBV) are an integral component of ECM bioscaffolds, and are enriched in miRNA and pro-resolving lipids with potent immunomodulatory activities. Using RNA sequencing and redox lipidomics to characterize the molecular cargo, we show that MBV are a distinct class of extracellular vesicle. We report that high levels of lysophospholipids, bioactive molecules important for wound healing, are a characteristic feature of MBV – and of the parent ECM by extension. Our results suggest that during wound healing, hydrolases release free MBV lipid mediators from their esterified into phospholipids forms, thereby augmenting their anti-inflammatory properties. The findings of the present study have significant clinical implications. Given their nanometer size, MBV can be utilized in clinical applications that would be otherwise untenable for planar ECM sheets. Delineation of the MBV immunomodulatory cargo may now allow for new perspectives on ECM-based therapeutics, especially in the design and manufacturing of biomimetic microenvironments, and the development of therapeutic strategies for advancing tissue engineering

Spheroids combining human dermal fibroblasts (HDF) and endothelial cells (EC) embedded in a fibrin gel may act as micro-sized centres for de novo dermal tissue formation, providing a promising injectable modular approach for skin wound healing. Herein, spheroids of HDF and endothelial progenitors (OEC, outgrowth EC) were generated under xeno-free (XF) conditions to analyse: cell organization and extracellular matrix (ECM) composition/mechanics in HDF-OEC spheroids; the effect of spheroids maturation stage on OEC sprouting potential and secretion of angiogenesis-related proteins; and the dynamics of endothelial tubulogenesis and dermal tissue formation from fibrin-embedded XF spheroid units.

Spheroids combining HDF (neonatal foreskin) and OEC (umbilical-cord blood) were generated and maintained in EGM-2MV(Lonza) or XF-medium (MCDB131 with Plastem® and growth factors)[1]. Spheroids were characterized for size, metabolic activity, cell/ECM organization, cell proliferation and secretome.

Within XF spheroids, OEC rapidly segregated, forming a surface monolayer and some central clusters, which eventually sprouted generating primitive networks at the core. While secretion of angiogenesis related proteins increased, endothelial sprouting potential decreased with maturation stage (1 vs.7 days). Upon fibrin-embedding, OEC (from day 1) rapidly sprouted into the gel, assembling into tubular-like structures. These sprouts organized into robust vessel-like networks, stabilized by endogenous basement membrane proteins, with impressive anastomosis between neighboring spheroids. Outward migrating HDF were highly proliferative, stained positively for vimentin and synthesized abundant amounts of interstitial ECM.

Altogether, these findings highlight the suitability of fibrin-embedded HDF-OEC spheroids as tissue-forming units for skin repair.

INTRODUCTION: In osteoarthritis (OA), increased cytokine production creates a positive feedback loop, activating “anti-chondrogenic” signaling pathways, which contribute to cartilage destruction [1, 2]. Delivery of siRNA provides potential for manipulating the OA microenvironment, creating conditions more conducive to stem cell recruitment and chondrogenic differentiation. This study describes the combining of a cell penetrating peptide (GET) [3] with a biomaterial scaffold, allowing for controlled delivery of siRNA in a therapeutic manner.

METHODS: siRNA targeting the NF-κB pathway complexed with GET was delivered to hMSCs and PCR was used to assess downstream chondrogenic mediators. GET-p65 siRNA formulations were incorporated into previously optimised porous coll-HyA scaffolds and scaffold architecture and particle retention were assessed using SEM and release assays. Assessment of 3D in vitro culturing of hMSCs on gene-activated scaffolds, transfection efficiency and activity of downstream mediators was carried out.

RESULTS: siRNA delivery (2D) prevented activation of the NF-κB pathway, attenuated downstream catabolic mediators and restored chondrogenic activity. SEM imaging and release assay highlighted successful retention of GET-siRNA nano-complexes within the scaffold architecture. hMSCs seeded on gene-activated scaffolds (3D) in the presence of inflammatory cytokines further demonstrated successful silencing and a subsequent reduction of downstream “anti-chondrogenic” mediators at Day 3 and 7.

DISCUSSION & CONCLUSION: Successful development of an advanced gene-activated scaffold delivery system allows for manipulation of the OA microenvironment through the silencing of the NF-κB pathway, corroborating previous results observed in 2D, and the creation of an environment more conducive to stem cell recruitment and beneficial for chondrogenic differentiation.

Introduction:

There is growing evidence that cell behavior such as migration and viability can be significantly influenced by external electric fields (EFs). Some of the behavior is thought to be closely related to wound healing.

This study aimed at investigating the effect of EFs on the migration as well as cell viability of HaCaT cells (a skin-derived cell line), as these are key steps of wound healing.

Method：

We built a set-up that was able to maintain a stable temperature and pH. EFs of 200mV/mm were introduced into the cell culture environment. Scratch-assays were performed to observe cell migration. The area of the scratches was evaluated every 12 hours for a total of 48 hours. Cell viability was evaluated by assessing mitochondrial activity using resazurin staining and total protein content was evaluated using Sulforhodamine B assay on days 1, 4, and 7.

Results:

When compared to the control group, the migration of HaCaT cells which received EFs increased significantly, after 48 hours, the EFs group had a 2.2-fold increase in migration($P < 0.001$) compared to the controls. After 7 days, the changes in cell viability, measured as the area under the curve, also showed a statistically significant difference ($p < 0.05$).

Conclusion:

The results of our study demonstrate that EFs have a positive effect on HaCaT cells migration and viability, two processes crucial for wound healing. Our findings suggest EFs can accelerate wound healing and thus could play an important role in the treatment of complex wounds.

Alcohol consumption is a well-known risk factor for major health conditions and can be attributed to ~3 million deaths per year worldwide[1]. Yet, there is opposing evidence in the literature for the association of alcohol consumption and osteoarthritis (OA).Three authors independently reviewed observational studies that assessed the association between alcohol use and OA. 1877 articles were assessed and 29 were selected. Cochran's Q and I2 test was calculated for heterogeneity, and fixed/random effects models were used accordingly. Meta-regression was performed via a restricted maximum likelihood approach.Of 29 included studies, 10 were cohort, 16 were cross-sectional and 3 were case-control, comprising 25192 subjects in total. Meta-analyses reported an odds ratio (OR) of association between any alcohol consumption and OA of 0.79 (0.68-0.93), suggesting a protective effect. OR of weekly consumption or more was 0.79 (0.65-0.97); no significant association was found with other patterns of consumption. Alcohol consumption was negatively associated with radiographic diagnosis (0.83 (0.70-0.98)), hand OA, knee OA, North American ethnicity and female gender. High degrees of heterogeneity was observed. During confounder analysis, grouping by unadjusted data resulted in an OR of 0.70 (0.55-0.89) but disappeared when analysing adjusted studies.Whilst weekly or more frequent alcohol consumption was negatively associated with the presence of OA, this association was abolished after confounder adjustment, due to lack of longitudinal exposure in study design, inclusion criteria for subjects and absence of confounder adjustment. Therefore, this meta-analysis provides evidence to dispel notions that alcohol use may protect against OA.

HUMAN STEM CELL-BASED SKELETAL TISSUE ENGINEERING: BIOFABRICATION AND DEVELOPMENT OF MICROJOINT TISSUE CHIP

Rocky Tuan$_P$[1]

[1] *The Chinese University of Hong Kong*

Corresponding author's email: rt_vcoffice@cuhk.edu.hk

Degenerative joint diseases, e.g., osteoarthritis, contribute to physical disabilities. Current treatments for osteoarthritis, e.g., anti-inflammatory drugs, provide only short-term pain relief. Tissue engineering/regenerative medicine, encompassing translational application of cells/scaffolds/biological signals, is a promising approach to repair damaged/diseased tissues to restore joint function/mobility. Adult mesenchymal stem cells (MSCs), e.g., from bone marrow and adipose, with multi-lineage differentiation potential, including chondrogenesis, are a promising cartilage repair cell type. A critical component to successful cell-based cartilage tissue engineering is a biocompatible/differentiation-supportive biomaterial cell-carrier scaffold. We have recently custom-designed photocrosslinked hydrogel scaffolds capable of live cell encapsulation during fabrication, with excellent cell retention/viability/differentiation, and generated robust cartilage/bone tissue constructs. Optimized scaffolds also allow controlled delivery of chondroinductive biofactors and anti-hypertrophy agents to improve the quality of the MSC-derived engineered cartilage. Custom-designed, cell-encapsulated constructs may be formed in-situ for joint cartilage re-surfacing, potentially amenable to minimally invasive, arthroscopic procedures. We have recently applied 3D-printing and a custom-designed microbioreactor to fabricate an MSC-derived, biphasic microtissue analogue of the osteochondral junction of the articular joint. This osteochondral microphysiological system is currently being used, coupled with additional tissue constructs simulating the infrapatellar fat pad (adipose) and synovium, as a joint tissue chip (microJoint) with a synovial fluid component, to model in-vitro osteoarthritis pathogenesis, e.g., exposure to pro-inflammatory agents, and to study biological and pharmacological influences on osteochondral health. The microJoint is being used as a human cell-based platform to screen for disease-modifying osteoarthritis drugs as well as to identify the cellular/molecular targets of osteoarthritis-associated pain. FROM MOLECULAR CONSTANTS TO MACROSCOPIC MECHANICS: TUNABLE OXIDIZED ALGINATE HYDROGELS USING MIXED DYNAMIC CROSSLINKERS

Francis LC Morgan[P][1], Matthew B Baker[1], Lorenzo Moroni[1]

[1] *MERLN Institute for Technology-Inspired Regenerative Medicine*

Corresponding author's email: f.morgan@maastrichtuniversity.nl

Recent advances in mechanobiology have highlighted the importance of ECM viscoelasticity in determining cellular responses to their local environment.(1) This has introduced new challenges for the rational design of hydrogels targeting specific cellular niches as both viscous (stress relaxation) and elastic (stiffness) mechanical properties must be balanced. Dynamic covalent chemistry (DCvC) is promising for this problem as the crosslinks are reversible, providing access to time-dependent viscoelastic properties. Notably, we can leverage the molecular constants associated with the reversible crosslinking reaction (Keq, k1/k-1) to modulate the stiffness and stress relaxation of a hydrogel. Here we use hydrazone and oxime crosslinks (secondary aldimines) exhibiting different molecular constants, and mixtures thereof, to tune the stiffness and stress relaxation of biocompatible oxidized alginate hydrogels. Maintaining a constant 2 wt% polymer content and total crosslinker concentration of 1 mol. equiv., we were able to tune the stiffness from 0.5 - 3.0 kPa and the stress relaxation from 10^3 s to 10^5 s by varying only the ratio of hydrazone to oxime crosslinks. While we investigated oxime and hydrazone in this work, any secondary aldimine undergoing a reversible reaction in aqueous conditions is a viable crosslinker. Indeed, varying the structure of the crosslinker changes the associated molecular constants,(2) thus giving access a wider range of mechanical properties. This broad basis for bottom-up hydrogel design is of interest for targeting viscoelastic properties of specific cellular niches, mechanobiological studies requiring fine control of mechanical properties, and as an accessible and flexible platform for designing dynamic networks.

INVESTIGATING THE MECHANISM FOR THE PRO-TENOGENIC EFFECT OF TENDON EXTRACELLULAR MATRIX ON HUMAN ADIPOSE-DERIVED STEM CELLS

INTRODUCTION: To address the challenges of tendon repair [1], our group previously developed a urea-based, non-enzymatic approach to prepare a soluble tendon derived ECM extract (tECM), which exhibited strong pro-tenogenic effects on human mesenchymal stem cells (hMSCs) [2]. The goal of this study is to elucidate the mechanism of the pro-tenogenic bioactivity of tECM by characterizing the active components.METHODS: tECM and human adipose-derived stem cells (hASCs) were prepared as previously described [3]. tECM fractionation was performed via either enzymatic digestion (i.e., pepsin, collagenase, hyaluronidase, chondroitinase) or size-fractionation (i.e., high-performance liquid chromatography (HPLC) in the presence of various chaotropic agents). The effects of fractionated tECM on hASC tenogenesis were assessed as previously described [2,3].RESULTS: tECM enhanced hASC proliferation and pro-tenogenic differentiation compared to fetal bovine serum (FBS) or commercial bovine collagen type I solution (Col 1, Advanced BioMatrix, USA) culture. The pro-tenogenic activity of tECM was significantly compromised by pepsin digestion, which digested tECM non-collagenous components, compared to other enzyme digestion groups. Our initial size fractionation methods via HPLC were unsatisfactory as small molecular weight tECM components (< 100 kDa) could not be separated and further technical optimization will be required.CONCLUSIONS: Our key findings include: (1) tECM is highly bioactive on hASCs, i.e., stimulating proliferation and enhancing tenogenic differentiation; and (2) non-collagenous tECM proteins are likely important active factors responsible for the tECM pro-tenogenic bioactivity [2,3]. Identification of these tECM biofactors will further support ECM-based tendon repair.ACKNOWLEDGEMENT: CUHK startup fund (TUAN) and CUHK Direct Grant (2018.092, WANG).

Mesenchymal stem cells (MSC) have a distinctive property of 'homing', where they migrate to sites of injury and tumor microenvironments [1,2]. This property has brought an exciting opportunity to use them for cancer cytotherapy [3]. However, the literature reports have paradoxically shown either pro- or anti-tumor effects of MSC in vitro [3,4]. This inconsistency could be attributed to the fact that the majority of the studies were conducted on conventional 2D in vitro models that do not ideally mimic the actual tumor environment [3]. In this respect, physiologically-relevant 3D tumor-on-chip in vitro models are a viable alternative in helping obtain better clarity regarding the potential of stem cells in anticancer therapies [5]. Here, conditioned medium from human amniotic membrane mesenchymal stem cells (AMMSC-CM) or hyperthermia-treated AMMSCs (heat-AMMSC-CM) was utilized to create indirect co-culture conditions, either co-culture or heat-co-culture, respectively, for collagen-embedded lung adenocarcinoma (A549) cells in a PDMS-based microfluidic device. The A549 cells established into multicellular tumor spheroids over five days of cell culture. The AMMSC-CM resulted in significant growth and proliferation of tumor spheroids. Remarkably, heat-AMMSC-CM led to both reductions in the diameters of spheroids formed and cell proliferation. The medium containing anticancer peptide P1 was found to be the least cytotoxic to co-culture of tumor spheroids as compared to monoculture or heat-co-culture groups. AMMSCs, contrary to the previous reports claiming their tumor-inhibiting potential, exerted tumor-enhancing effect on tumor cells. This study highlighted the growing importance of developing microfluidic 3D tumor models for the testing of stem-cell-based anticancer therapies

Age-related macular degeneration (AMD) affects millions of people worldwide and leads to blindness [1]. AMD is caused by age-related changes in Bruch's membrane (BM) and in the retinal pigment epithelium (RPE). Current therapies are unable to restore tissue functionality. So far, tissue engineering strategies for BM regeneration have focused on the fabrication of flat scaffolds. We propose a novel electrospinning approach to develop a hemispherical biomimetic BM substitute.
We designed a rotating collector with an innovative customizable device to fabricate hemispherical scaffolds composed of Bombyx mori silk fibroin (BMSF) and polycaprolactone (PCL). We investigated scaffold surface morphology, thickness, mechanical properties, and in vitro cytocompatibility with ARPE-19 cells.
Hemispherical scaffolds with randomly orientated nanofibers were successfully produced. They displayed a thickness of 40 µm, an average fiber diameter of 370±101 nm, a fiber packing density of 49.25±1.2%, and a Young's modulus of 13±3.6 MPa. Cells were viable after 5 days of contact with the scaffolds.
The obtained scaffolds mimic the BM native properties, including microscopic to macroscopic anatomy and mechanical properties. The BM has a random fibrillar network, a packing density of 48%, and a Young's modulus from 6 to 14 MPa [2]. Moreover, we found out that our scaffolds are biocompatible and we are carrying out additional investigation with ARPE-19 cells. However, to more closely imitate the BM, fiber diameters and scaffold thickness need to be further reduced. The successful outcome of this study will inform the treatment of an optimal substrate for RPE transplantation.

THE STRATEGY TO IMPROVE THE LACK OF VASCULAR FORMATION IN CHEMICAL CROSSLINKED HYDROGEL

Shih-Yen Wei[1], Ying-Chieh Chen[1]

To decrease the time needed to vascularize an engineered tissue, collagen hydrogel with biodegradability, biocompatibility and permeability provided suitable microenvironments to support cell-based functional vascular networks formation. However, cells into collagen hydrogel resulted in extensive contraction and rapid degradation rate which imitated their utilization as a permanent cell-laden graft. Many studies had synthesized chemical crosslinked collagen hydrogels to decrease its volume contraction, slow down its degradation rate, and increase its mechanical stability, which unfortunately impeded the formation of blood vessels in vivo[1-3]. Here, we conjugated tyramine hydrochloride (-Ph) on collagen molecules to synthesize the chemical crosslinking collagen-Ph hydrogel crosslinked by horseradish peroxidase (HRP) and hydrogen peroxide (H2O2) as a model to understand and overcome the difficulties on engineering vascular networks. Results showed poor permeability and long-lasting inflammatory response of collagen-Ph hydrogels limited the capability of human umbilical vein endothelial (HUVECs)/mesenchymal stem cell (MSCs)-mediated vasculature formation in vivo. Thus, we added the designed spacer to increase the diffusion efficiency of the hydrogel by 2.5 times, and consumed unreacted crosslinkers to lower the density of infiltrating neutrophils and macrophages to half on day 2 to 4 after implantation. These strategies significantly increased the density of engineered cell-mediated blood vessels in collagen-Ph hydrogel by 2 times. Taken together, our data suggested that increasing diffusion of oxygen and nutrition through hydrogel and completing crosslinking reactants play important roles in engineering cell-mediating functional vascular networks formation in chemically crosslinked hydrogels.

The generation of tissue-mimetic living structures of clinically-relevant size remains a major challenge in tissue engineering. 3D-bioprinting is a promising approach to shape cell-laden biomaterials into complex architectures, but current techniques like extrusion bioprinting (EB) and digital-light processing (DLP), operating in a layer-wise fashion, pose scalability challenges and struggle to resolve certain free-form geometrical features typical of biological tissues. Herein, the concept of volumetric bioprinting (VBP) by ultra-fast visible-light tomography-inspired fabrication is introduced, demonstrating the fabrication of complex, cell-laden, cm-scale biological structures within seconds.

A gelatin-based photosensitive bioresin was developed for VBP. Centimeter-scale auricle constructs were printed in 22.7s with high volume accuracy (5.71±2.31% mismatch vs. CAD design) exposing the bioresin to visible-light (λ=405nm) shaped as multiple tomographic filtered backprojections. Printing time remained constant for samples of 1.23 and 4.14cm3, in contrast to EB (~30-90min) and DLP (~20-30min) printing. VBP-printed cells maintained high viability (>80%). Complex, mesenchymal stromal cell-laden trabecular bone models with convoluted porous networks were accurately resolved with features down to 144.69±13.55µm. After endothelial cell seeding, constructs showed enhanced neo-vessel formation. Finally, printed meniscus constructs cultured for 28-days produced fibrocartilage-like matrix and exhibited increasing compressive properties over time, approaching values comparable to native meniscal fibrocartilage (~300kPa).[1]

This study established a novel approach for bioprinting complex, tissue-like architectures within seconds. Short printing times and design freedom make this technique appealing for biomedical applications like patient-specific grafts and in vitro models. The findings shown here open new avenues for designing the next generation of biomaterial-based bioprinted constructs of clinically-relevant sizes.

The aim of this study was to develop an effective decellularization method by ultrasound followed by wash steps. Different power value of sonication was tested for the efficacy of decellularization in human umbilical artery (sDHUA). The DNA content, histological staining, mechanical property and biocompatibility were evaluated. The sDHUA was further implanted into rat abdominal aorta. Magnetic resonance angiography (MRA) for the implanted grafts were achieved. The results demonstrated that sDHUA maintained mechanical property while preservation of collagen, elastin, fibronectin and laminin. Recellularization of HUVECs indicated that sDHUA provided niches for cells to reside in, presenting in vitro cytocompatibility . Further implantation test also indicated the fitness of sonication treated human umbilical artery as a scaffold for small-caliber tissue engieerd vascular graft.

VISCOUS FINGER AS SHORT TIME PATTERNING TECHNIQUE FOR ENGINEERING 3D THICK HYDROGELS

Min-Chun Tsai$_P$[1], Ying-Chieh Chen[1]

[1] *National Tsing Hua University Department of Materials Science and Engineering*

Corresponding author's email: j85111121@gmail.com

The size of tissues is much larger than the distance of diffusion limit, so rapidly providing blood vessels to embedded cells with sufficient nutrients and oxygen is regarded as a major strategy for the success of bioengineered tissue constructs. The engineered structure of the viscous fingers similar to natural vascular network were used as the patterning method for bioengineering vascularized tissues in our study. Viscous finger refers to a high-viscosity fluid driven by a low-viscosity fluid between parallel plates. Also, low-viscosity fluid is expected to precisely detour the microgel encapsulated in high-viscosity one and form the fingers. After crosslinking, a finger-like gel is formed between the base gel interfaces, which is a sandwich-like structure from the side view.

By controlling viscosity, flow rates of photo-crosslinkable cell-laden pre-polymer solutions, and the gap between two parallel plates, the length (0.6-1 cm), the width (100-400 μm) and the distribution density (104-9x104 # /ml) of fingers with controllable size of network structures (4-20 cm2) within less than 10 seconds could be precisely engineered. After photo-crosslinking at suitable conditions, the physical properties of base and finger gels could be manipulated individually, which successfully controlled and guided various cells spreading and growth direction to engineer vascular like structures in vitro in a short time. Besides, this technique could be applied to generate functional lumens with core-shell structure for dynamic microfluidics culture. Our 3D cell patterning technique extends the potential for modelling and fabricating thick vascularized tissues like constructs for both ex vivo and in vivo applications.

SYNERGISTIC CONTROL OF MECHANICS AND MICROARCHITECTURE OF 3D HYDROGEL FOR ENGINEERING HEPATIC TISSUE

Chaenyung Cha[P][1]

[1] *Ulsan National Institute of Science and Technology*

Corresponding author's email: ccha@unist.ac.kr

Culturing autologous cells with therapeutic potential derived from a patient within a bioactive scaffold to induce high functioning tissue formation is considered the ideal methodology towards realizing patient-specific regenerative medicine. Hydrogels are often employed as the scaffold material for this purpose mainly for their tunable mechanical and diffusional properties as well as presenting cell-responsive moieties. Herein, a two-fold strategy was employed to control the physicomechanical properties and microarchitecture of hydrogels to maximize the efficacy of engineered hepatic tissues. First, a hydrophilic polymeric crosslinker with a tunable degree of reactive functional groups was employed to control the mechanical properties in a wide range while minimizing the change in diffusional properties. Second, photolithography technique was utilized to introduce microchannels into hydrogels to overcome the critical diffusional limit of bulk hydrogels. Encapsulating hepatic progenitor cells derived via direct reprogramming of tissue-harvested fibroblasts, the applications of this strategy to control the mechanics, diffusion, and architecture of hydrogels in a combinatorial manner could maximize their hepatic functions. The regenerative capacity of this engineered hepatic tissue was further demonstrated using an in vivo acute liver injury model.

GRAFT ARCHITECTURE GUIDED SIMULTANEOUS CONTROL OF DEGRADATION AND MECHANICAL PROPERTIES OF IN SITU FORMING AND FAST DISSOLVING POLYASPARTAMIDE HYDROGELS

Chaenyung Cha[P][1]

[1] *Ulsan National Institute of Science and Technology*

Corresponding author's email: ccha@unist.ac.kr

Polyaspartamide, derived from polysuccinimide (PSI), has the advantage of conveniently presenting desired functional groups by ring-opening addition of amine-based nucleophiles to the succinimidyl ring moieties of PSI. Using diamines with varying lengths of poly(ethylene glycol) linker, polyaspartamide presenting amine groups with controllable grafting density and length, namely poly(2-hydroxyethyl aspartamide)-g-amino-poly(ethylene glycol) (PHEA-PEGAm) could be synthesized. This PHEA-PEGAm was then used to develop in situ forming hydrogels by Schiff base formation with aldehyde-containing alginate (Alg-ALD). By modulating the graft architecture (i.e. grafting length and density), the mechanical properties of resulting Alg-PHEA hydrogels could be controlled in a broad range. Remarkably, the hydrogels were shown to undergo facile degradation and complete dissolution in physiological conditions, regardless of hydrogel mechanics, by the expedited hydrolysis through the action of remaining amine groups, which was also heavily influenced by the graft architecture. Moreover, the rate of degradation could be further controlled by additional ionic crosslinking of alginate. The potential application as an injectable drug delivery system was demonstrated by measuring drug release kinetics and monitoring degradation ex vivo.

DEVELOPMENT OF FABRICATION METHODS FOR LARGE-SCALE MANUFACTURING OF CLINICAL GRADE ECM HYDROGELS.

George S. Hussey[P][1,2], Stephen F. Badylak[1,2]

[1] *University of Pittsburgh*

[2] *McGowan Institute for Regenerative Medicine*

Corresponding author's email: husseygs@upmc.edu

Extracellular matrix (ECM) hydrogels have been used in numerous preclinical and clinical applications to facilitate repair of a variety of tissues. However, a major limitation to widespread clinical translation of ECM hydrogels is the lack of large-scale manufacturing techniques. ECM hydrogel products used for preclinical and clinical studies are fabricated using laboratory-based processes that have focused on enzymatic digestion of the ECM; or the use of chaotropic extraction buffers which can affect protein structure and function. Without the development of scalable, production-ready manufacturing processes, these ECM hydrogel products will fail to meet their true potential in regenerative medicine-based clinical applications. Herein we report a method to prepare hydrogels from ECM bioscaffolds using ultrasonic cavitation. The solubilized ECM can be induced to self-assemble into a hydrogel by adjusting temperature; the material properties of the gel can be tailored by adjusting ECM concentration and sonication parameters; and the bio-inductive properties of the hydrogel appear identical to enzymatically produced hydrogels. Moreover, the ultrasonic approach lends itself to large-scale manufacturing over traditional enzymatic methods in several aspects. First, the concentration range can be expanded from 2-20mg/ml (the limit of enzymatic methods) to 25-100mg/ml using the ultrasonic cavitation method, allowing for fine-tuning of the viscoelastic properties. Second, processing time is dramatically reduced from days, to the order of minutes. ECM hydrogels prepared using ultrasonic fabrication method can conform to customizable 3D geometries and may also support the incorporation of cells or therapeutic drugs, thereby expanding their possibilities for tissue engineering and regenerative medicine-based clinical applications.

When the skin is wounded, multiple cell types need to be coordinated following precise stages to bring about healing. (Rodrigues et al) These stages are coagulation, inflammation, re-epithelialization, and remodeling that are an orderly sequence of overlapping, interacting processes. (Shedoeva et al) This project aims to design a biomaterial that can be used to treat compromised wounds using hydrogels based on chitosan. Biomolecules derived from coconut, avocado and nopal are incorporated into the gel in order to match the healing stage in which they are required. Hydrogels are performed by an injection system resulting in the formation of chitosan fibers, which receive a multilayer treatment using a thickening procedure by pH changes and the elaboration of a more resistant layer using a plasma reactor. (Al Dybiat et al). As we mentioned before, the layers will release different biomolecules at each stage: In the inner layer, the avocado oil is added because it can promote collagen synthesis (Oliveira et al); required at the re-epithelialization stage. In the middle layer, nopal extract is incorporated because it can modulate the inflammatory response. (Antunes et al). Finally, in the outer layer biomolecules from coconut oil composed mainly of monolaurin are incorporated. They show antimicrobial activity due to disintegration of the lipid membrane of bacteria such as Staphylococcus aureus (Preuss et al) and thus reinforcing the antibacterial property of chitosan. As a result, we present the curves of release of the different biomolecules contained in the extracts and the structural characterization of the hydrogel.

We evaluated implantation of dHUAs in rat abdominal aorta as xenogenic transplantation model for up to 3 months. Totally, 12 dHUAs in length about 1-cm were implanted in rat abdominal aortas. Explantation of dHUAs was done at day-1, day-14, 1-month and 3-month for histological examination (each n=3). Magnetic resonance angiography (MRA) was also performed to evaluate graft patency at 30 & 90 days (each n=2). In histology, some red blood cells (RBCs) flew into the walls of dHUA and some inflammatory cellular (CD 68) infiltration was noted at day-1. At day 14, few endothelialization was noted in H&E, CD31, vWF stainings. There were collagen fibers, elastin fibers and α-SMA expression in vessel walls. Inflammatory cells of CD68 and CD163 were both noted. Endothelialization, collagen/elastin regeneration, α-SMA expression and inflammatory cell infiltration persisted at day-30 and day-90. MRAs demonstrated patency of dHUAs at day-30 and day-90. But graft dilatation was noted grossly and in image study. Briefly, dHUAs could maintain patency in the xenogenic model. Endothelialization was observed since day-14. Regeneration of collagen/elastin and increase of cellularity were also noted thereafter. However, dilatation of dHUAs was observed, which indicates insufficiency in transforming dHUAs into normal vascular tissues after 90-day of xenogenic transplantation.

[1] *Paracelsus Medical University - Institute of Tendon and Bone Regeneration*
Corresponding author's email: andreas.traweger@pmu.ac.at

Tendon disorders and injuries are one of the most common musculoskeletal disorders and recent evidence has clearly implicated the presence of immune cells and inflammatory events during early tendinopathy. However, the origin and properties of these cells remain poorly defined and the presence of tissue-resident cells fulfilling macrophage- or monocyte-related functions in healthy tendons has not been thoroughly investigated. We now describe a novel tendon-resident cell population ("tenophages") expressing the fractalkine receptor chemokine (C-X3-C motif) receptor 1 (Cx3cr1) and its highly selective ligand Cx3cl1 as well as the peptide hormone epiregulin (Ereg) in healthy tendons. Interestingly, not only did we observe expression in perivascular cells, but also very distinctly in cells embedded in the dense, collagen-rich tendon matrix fulfilling macrophage-like functions. Generally, the CX3CR1/CXCL1 signaling axis mediates chemotaxis and adhesion of immune cells and is involved in the pathogenesis and progression of various inflammatory disorders. We therefore propose that this newly identified cell population fulfils a surveillance function and is activated upon tendon tissue injury or pathological stress. Further, given the role of CX3CR1/CXCL1 in cell proliferation, angiogenesis and fibrosis upon inflammation, all hallmarks of tendinopathy, targeting this signaling axis could potentially open up new vistas in treating tendinopathies.

The main challenge for in vitro tumor modeling is the development of biomaterials that fully reproduce the biological, chemical and mechanical complexity of the 3D tumor microenvironment [1]. Recent advances in materials sciences and biotechnology have permitted the development of advanced biomaterials that copycat the features of the native ECM. For example, the high expression of hyaluronic acid (HA) in the tumoral ECM can be recapitulated using 3D hydrogels to study its biochemical impact in cancer cells. In particular, the binding affinity of HA with CD44 receptor can be studied, as well as the alteration of the HA mechanical properties as a function of its MW and its impact in tumor progression [2]. Similarly, silk fibroin can be exploited for tumor modeling. It can be blended with other biomaterials to negotiate its mechanical properties, biodegradability and biocompatibility. We have shown that silk fibroin, alone or in combination with gellan gum, supported the growth of cancer cells [3,4]. The co-culture of cancer cells with fibroblasts, mesenchymal or adipose stem cells mimicked better the tumor microenvironment and the heterogeneous niche regulates drug response. Next, we used collagen I as an in vivo-like model of the tumoral microenvironment to investigate the invasion capability of cancer cells. We found that cell invasiveness could be assessed by using a novel morphodynamic biomarker with high predictive power. Finally, we developed a breast cancer model to study the interaction of cancer cells and macrophages using a microfluidic chip (Acknowledgements: H2020-WIDESPREAD-2014-668983, FoReCaST) and FCT (PTDC/BTM-ORG/28168/2017; CEECIND/00352/2017; PTDC/BTM-ORG/28070/2017).

Cell encapsulation strategies offer high control of cell behaviour and also protection against harsh conditions. Inspired by the biosilicification process in diatoms, tough silica shells can be engineered to protect the cells from extreme conditions. Using stem cells to reproduce such event could enhance their protection against harsh conditions, but this strategy is inadequate for long-term applications, as it restricts cell functionality and viability.1 On the other hand, partial coatings of individual mammalian cells would offer enough support while maintaining their functionality and ability for delivering molecules and other biochemical cues. Thus, we report innovative concept and strategy, where silica-based partial coatings (silica backpacks) are formed at the surface of individual stem cells. Based on electrostatic interactions and sol-gel process under mild conditions, only a part of cell surface displays a silica backpack. The results reveals that approximately 57% of cellular population present the silica backpacks and are able to survive for longer than 7 days than the cells without the backpacks in suspension conditions, forming larger aggregates, which suggests prolonged cell survival and functions in suspension. This work is an important contribution to the efficacy increase in cell-based therapies, especially in injectable cell systems. Furthermore, it also will provide a potential platform to promote cell differentiation.

The recent description of progenitor cells in degenerated IVDs raised the possibility of harnessing their regenerative capacity for endogenous repair. Here, we developed an polysaccharide microbead delivery system (PMBs) for the sequential release of chemokines (CCL5) and nucleopulpogenic factors (TGF-β1 and GDF5).

PMBs (mean diameter 100 µm), obtained by a water/oil emulsification process, exhibited sustained release of biological factors for 21 days. Bioactivity of CCL5 released from PMBs on human adipose-derived stem cells (hASCs), selected to mimic disc stem/progenitors, was demonstrated using a chemotaxis assay. PMBs loaded with either chemokine exhibited an increased migratory effect on hASCs over time. The regenerative effects were investigated in ex vivo spontaneously degenerated ovine IVDs. Fluorescent hASCs were seeded on the top cartilaginous endplates (CEPs); the degenerated NPs were injected with PMBs loaded with CCL5, TGF-β1, and GDF-5. Ovine IVDs were cultured for 3, 7, and 28 days to allow for cell migration and disc regeneration. Ex vivo migration of seeded hASCs from the CEP toward the NP was evidenced, with a significantly greater distance with loaded PMBs (5.8±1.3 mm vs. 3.5±1.8 mm with no PMBs). The overall NP cellularity, collagen II and aggrecan staining intensities, and the Tie2+ progenitor cell density in the NP were increased at day 28 compared to the control groups.

Using an ovine ex vivo model of spontaneously degenerated IVDs, we have shown that PMBs loaded with CCL5/TGF-β1/GDF-5 constitute an innovative sustained delivery system for recruitment of resident progenitors, followed by their differentiation, and the subsequent regeneration of IVDs.

INTRODUCTION: The use of microfluidic technologies to facilitate the creation of microporous annealed particle (MAP) hydrogels has garnered attention in recent years.[1] MAPs offer improved implant survival and tissue integration as compared to conventional nanoporous hydrogels.[2] However, the relatively slow production rates of microgels by current strategies has challenged translation of MAPs into clinical or industrial settings. Here, we report on the combined use of in-air microfluidics (IAMF) and Alginate-Tyramine (ATA) to enable ultra-high throughput production of dual crosslinkable microgels for the formation of MAPs.[3]

EXPERIMENTAL: ATA was produced by modifying alginate with tyramine using DMTMM-based coupling. Using IAMF, hepatic cell laden ATA microgels were prepared via ionic crosslinking under oil-free and surfactant-free conditions. ATA microgel slurries were photocrosslinked into MAPs and analyzed on viability, metabolic activity, hydraulic conductivity, micropore size distribution, pore interconnectivity, and mechanical properties.

RESULTS: UV-Vis confirmed successful ATA synthesis, which was confirmed crosslinkable via enzymatic and/or ionic crosslinking. Highly monodisperse (CV<5%) ATA microgels with diameters ranging from 50 µm to 350 µm were produced at rates as high as 3,5 mL/min. MAPs could be formed through visible light crosslinking. Confocal analysis confirmed an interconnected, porous network within MAPs. Both microgel and MAP formation associated with high viability and continued metabolic activity.

CONCLUSION: The combined use of IAMF and ATA allows for ultra-high throughput production of cell laden microgels that can be assembled into MAPs. We thus present a novel and highly scalable production platform for the creation of living microporous tissues.

EXPANSION OF THE EXTRAEMBRYONIC ENDODERM IN BLASTOIDS SUPPORTS POST-IMPLANTATION MORPHOGENESIS OF THE EPIBLAST

Erik J Vrij[1]

[1] *MERLN Institute for Technology-inspired Regenerative Medicine, Maastricht University, The Netherlands*

Corresponding author's email: e.vrij@maastrichtuniversity.nl

The early mammalian conceptus (blastocyst) contains two supporting extraembryonic tissues - the trophectoderm and the primitive endoderm (PrE) - that encase and guide the epiblast (Epi), which eventually forms the body. Due to the difficulty to manipulate blastocysts, the autonomous potential and the molecular interplays of PrE and Epi remain elusive. Here, we determine a combination of signaling pathways activators (Chir99021, Retinoic acid, Fgf4, and cAMP) that efficiently (80%) and rapidly (72 hours) induces naive embryonic stem cells to form a free-standing, three-dimensional PrE-/Epi-like niche in chemically-defined conditions (hydrogel-free, serum-free). Once established, this niche autonomously progresses, in minimal medium without signaling pathway modulators, into a post-implantation stage forming a pro-amniotic-like cavity surrounded by a polarized Epi covered with extraembryonic endoderm-like cells. Similarly, the expansion of the PrE-like cells within blastoids also allows for a subset of them to morphologically progress to E4.5 blastocyst-like structures containing a PrE epithelium fully enveloping the Epi compartment. Markedly, the expansion of the PrE in blastoids supports the survival, expansion and morphogenesis of a post-implantation-like Epi in vitro. Altogether, modelling early development in chemically-defined conditions delineates the sequence of pathways activities necessary to form a functional PrE/Epiblast niche, and highlights the co-development fueling post-implantation development.

Induced pluripotent stem cells (iPSCs) can differentiate into every cell type of the human body, but little is known about how specific surface patterns impact on pluripotency or guide lineage specific differentiation. There is accumulating evidence that the Yes-associated protein (YAP), a downstream effector of the Hippo pathway, might be of particular relevance for iPSCs and their response to surface topography. In continuation of our previous work, we employed multi-beam interference technology to generate sub-µm groove-ridge structures that guide orientation and organization of iPSC colonies. Structuring of polyimide (PI) films with a UV laser with 38 ns pulse duration to generate grooves and ridges with a periodicity of 650 nm and a depth of 200 nm, led to a 6-fold elongation of iPSC colonies compared to unstructured PI. To further investigate the relevance of YAP for mechanosensing of surface patterns, we used CRISPR/Cas9 technology to generate YAP-/- iPSC knockout lines. Thereupon, we analyzed the morphology of iPSC colonies with and without YAP deficiency. The aspect ratio was significantly lower for YAP-/- iPSCs on structured PI compared to wildtype iPSCs. We currently analyze how periodic sub-µm surface topography impacts on differentiation of iPSCs, particularly towards iPSC-derived mesenchymal stromal cells. During this differentiation process the elongation and orientation of iPSCs along the structured PI decreases. Our results indicate that YAP is a key driver for mechanosensing and growth response of iPSCs to sub-µm substrates.

3D bioprinting is a revolutionary biomanufacturing tool to fabricate on-demand replacement tissue and physiologically relevant 3D tissue and disease models to accelerate drug discovery. Despite promising research advancements, challenges remain for bioprinting tissues on-demand, including the need for reproducible commercially available ready-to-use bioinks. To further the advancement of the bioprinting field, we have developed a platform of bioink formulations, TissueFabTM, that are compatible with diverse cell types and bioprinting platforms and have high batch-to-batch consistency. TissueFabTM is a family of ready-to-use bioinks based on natural and synthetic materials including Gelatin, Alginate, Hyaluronic Acid and poloxamer etc. TissueFabTM bioink formulations are designed for optimal viscosity and mechanical properties for high resolution bioprinting and to maintain high cell viability (>80%). Photoinitiator selection and concentration was optimized for post-printing curing using a range of cyto-compatible wavelengths. The printability was assessed by printing with different commercially available microextrusion based desktop bioprinters thus demonstrating the printer agnostic characteristic of the bioinks. Bioink formulations were validated for high cell viability, proliferation and metabolic activity using C2C12 mouse myoblast cells and human mesenchymal stem cells(hMSCs). Bioprinted hMSCs encapsulated in TissueFab™ - GelMA-Bone bioinks show an increase in osteogenic differentiation. Additionally, TissueFab™-GelMA-Conductive bioinks exhibit enhanced conductivity making them attractive for bioprinting electroactive tissues. TissueFabTM bioinks provide a robust platform for microextrusion-based bioprinting various cell types with both high printability and cell viability. TissueFabTM bioinks enable on-demand tissue printing which is a tangible step forward for addressing drug testing and tissue engineering challenges.

Meninges are a membrane system composed of three distinct layers, that surround the central nervous systems (CNS). During adulthood, meninges contribute to the homeostasis of the CNS, with a presence of Nestin+ cells, forming a stem cell niche. Our goal is to study in-depth the human meningeal fibroblasts (MFs) to characterize cells, and to confirm the presence of neural stem cells (NSCs), a possible source of new cortical neurons that can partially overcome the senescence and the neurodegeneration.

We isolated MFs from 6 brain donors and skin fibroblasts (SFs) as control. We evaluated the timing of cell appearance, the cell orientation, and the growing rate. We evaluated protein markers by immunofluorescence. We also performed a deep sequencing to analyze differentially expressed genes.

Fibroblast cultures from meninges and skin show a clear difference in terms of cell mobility, quicker in the MFs while SFs show a good cellular orientation respect to the MFs. Both cell lines show equal level of protein markers Fibronectin, Serpinh1, and Beta-III-tubulin, but a different Nestin expression, more evident in MFs. We found 1145 deregulated RNAs and the deregulated pathways show the involvement of focal adhesion and ECM organization, confirming the differences founded at the morphological level.

We can conclude that MFs and SFs, despite to be both fibroblasts, they are very different cells. The morphological signature, the grow rate, the transcriptional profile, and in particular the different expression of Nestin open the possibility to a new use of MFs in aging or in tissue regeneration.

The engineering of minimalistic materials with specific geometry and size have been highlighted as a promising pathway for the development of new regenerative medicine solutions. Silica, an inorganic compound commonly found in nature, arise as a cheap inorganic source and chemically flexible for this purpose. In this work, we engineered thin silica microsheets with a defined size and high-fidelity shape using superhydrophobic-superhydrophilic microarrays [1, 2] as a new enabling tool to be used as an instructive biomaterial in biomedical applications. Sol-gel technique was performed in the production of the thin silica microsheets using biomimetic superhydrophobic platforms decorated with wettable spots. The results confirmed the manufacture porous silica platforms [3] with defined design (squares and circles) and thickness around 7 µm. Biomineralization studies have been also carried out where hydroxyapatite crystals in a flower-shape form were successfully observed. Based on the promising achievements, silica platforms will be doped with bioinstructive cues to evaluate the potential of these microplatforms for guiding stem cells during differentiation process in tissue regeneration applications.

OPTICAL COHERENCE TOMOGRAPHY FOR THE IMAGING OF 3D CELL CULTURES – CHANCES AND OPPORTUNITIES

Enno Hachgenei[1], Robert H. Schmitt[1]

[1] *Fraunhofer Institute for Production Technology IPT*

Corresponding author's email: enno.hachgenei@ipt.fraunhofer.de

3D cell cultures are becoming more and more important in a variety of different fields of research. They are already an essential part in the testing of pharmaceuticals and in the research of disease-mechanisms, as they can mimic the real processes much better in comparison to classic 2D cell cultures.

A major limitation when working with 3D cell cultures is the limited amount of structural information that can be extracted from the 3D cell culture without destroying it. Imaging modalities like microscopy, fluorescence microscopy or light sheet microscopy all share the same limitation in penetration depth. For imaging the inner structure of the cultures it is necessary to either slice them or clear them. As 3D cultures – especially organoids – are becoming more complex and bigger structures called assembloids are being developed, it becomes yet more important to non-invasively image the cell cultures during the cultivation process.

Optical coherence tomography (OCT) is an imaging modality which generates high resolved (2-10 µm) tomographic cross sectional images while being fully non-invasive and contactless. Therefore it is possible to monitor the development of a 3D cell culture regularly and by that gain information which would otherwise be lost.

The Fraunhofer IPT is developing methods to further advance OCT for the use on 3D cell cultures, those methods include the maximization of the imaging range (normally limited to about 500 µm) and the implementation of functional extensions to the OCT-systems which allow a direct characterization of the cell behavior within the 3D cultures.

The osteochondral junction is a highly organized tissue where the articular cartilage and the subchondral bone are intimately connected, representing a challenge to be reproduced in vitro [1]. In this study, we developed an in vitro vascularized osteochondral construct using a patent-pending dual-chamber bioreactor, that creates two connected but individually controlled microenvironments for cartilaginous and vasculo-osseous maturation [2]. Bone scaffolds were fabricated by 3D bioprinting gelatin, nanohydroxyapatite and genipin, and seeded with human mesenchymal stem cells (hMSCs) [3]. Cartilage scaffolds were fabricated by casting and UV crosslinking a 3:1 ratio of methacrylated gelatin (gelMA) and methacrylated hyaluronic acid (10% and 3.5% w/v, respectively, in PBS with 0.15% w/v LAP), with embedded hMSCs. Bone and cartilage scaffolds were cultured for 14 days individually in osteogenic medium (OM) and chondrogenic medium (CM), respectively [4]. Then, they were combined inside the bioreactor to form the osteochondral complex. The interconnected pore network of the bone phase was filled with human endothelial cells suspended in a hydrogel of 1:1 gelMA and fibrin [3]. A syringe pump delivered continuous media flow (2 ml/day) [2]. After 2 weeks, the constructs were removed from the bioreactor and resulted stable during handling, showing a good cohesion between phases. Live/dead assay confirmed ongoing cell vitality. Histology, immunohistochemistry and gene expression (real-time PCR) are used to validate the vascularized osteochondral model. This vasculo-osseous-chondral model represents an innovative platform to study the crosstalk between cartilage, bone, and vasculature as well as to model joint diseases and to test new drugs.

Adipose stem cells (ASCs) have multipotent differentiation capabilities, including myocytes. While no myogenesis-specific growth factors have been identified, yet, ASCs are reliably differentiated using muscle-tissue-conditioned-medium, without addition of further additives. Identification of a serum-free or human-compatible-serum is always focus for an in vivo application. We aimed to identify an optimal differentiation medium and ASCs were differentiated on a 3D-Silk-Fibroin-Scaffold with directed tubular microstructure to imitate the natural muscle environment.

Differentiation into the myogenic lineage was performed for 6 weeks using muscle-tissue-conditioned-medium. High-Glucose-Medium with 5%P/S was exposed to human muscle tissue blocks of 1cm3 for 72h. Other media with addition of Ultrosa or fetal-bovine-serum were conditioned with activated satellite-cells. We examined cellular vitality using PrestoBlue-conversion after cell seeding. Myogenic differentiation was evaluated by qRT-PCR and immunohistochemical-staining.

Successful differentiation of ASCs was achieved by conditioned medium in 2D and 3D culture. Addition of further substances, in particular of animal-origin, was prevented. Structural alignment along tailored tubes of the scaffold was evident. Muscle-tissue-conditioned-medium rendered superior effective differentiation of the ASCs into myogenic lineage than other media.

Muscle-tissue-conditioned-medium is a promising approach to myogenic ASC differentiation. Here we could show that without xenogeic supplements and without a co-culture with satellite-cells an easy and successful way to myogenic differentiation could be achieved. Identification of specific factors promoting myogenic effects observed is subject of further research. Directed growth on a 3D-Silk-Fibroin-Scaffold with directed tubular microstructure, mimicking muscle tissue, was shown. These data represent an important step towards in vivo use of animal-serum-free and biocompatible-cultured muscle tissue.

Pectin, a structural polysaccharide of plant cell walls, is finding increasing application in Tissue Engineering thanks to its biocompatibility, biodegradability and gelling capability [1]. However, the inadequate rheological properties limit its use in 3D bioprinting. In our previous work, we addressed this challenge by introducing (3-Glycidyloxypropyl)trimethoxysilane (GPTMS) as pectin crosslinker. The pectin-GPTMS reaction enables the bioprinting of customized three-dimensional scaffolds [2].

Here, these structures were used in combination to fibrin hydrogel to obtain composite scaffolds. We hypothesize that the stiffness of the scaffold-hydrogel system can be tuned by modifying the composition of the pectin scaffold. Therefore, three types of 3D bioprinted pectin-based scaffolds were obtained by tuning the GPTMS content and by incorporating nano-hydroxyapatite (nHA). Briefly, two water-based slurries of low-methoxyl pectin (4% w/v) and GPTMS (0.92 ml and 1.50 ml per pectin gram, respectively) were prepared [2]. An additional slurry was obtained by adding pectin (4% w/v) to a dispersion of nHA (50 % w relative to pectin) in a phosphate buffer solution (1X), and thereafter adding GPTMS (0.92 ml per pectin gram). Woodpile-shaped scaffolds were 3D bioprinted, frozen and freeze-dried.

After sterilization, the scaffolds were immersed for few seconds in a pre-gel solution of fibrin (fibrinogen 2.5 mg/ml and 0.5 U/ml thrombin) and the constructs were left to polymerize in a humidified chamber. A pool of human mesenchymal stem cells (hMSCs), isolated from four different patients, were used to assess the influence of the scaffold stiffness and composition on cell viability, proliferation and their osteogenic and chondrogenic differentiation.

Endocrine disruptors (EDs) are an exogenous group of compounds associated with thyroid malfunctioning in the human body 1, 2. Nonetheless, there are currently no adequate in vivo or in vitro models for the preclinical testing of these compounds since both animal models and 2D cell-based are not able to closely mimic physiologic conditions 3. During the last years, 3D-bioprinting technology emerged as an innovative tool in the field of regenerative medicine and drug screening that allows the creation of 3D well-organized structures that can mirror physiologically relevant architectures 4. Nonetheless, there are still numerous challenges linked to the optimization of the bioprinting process 5.
In this work, we evaluated a new bioprinting technique based on a microfluidic system with the future objective to produce a 3D-model of the thyroid gland. Microfluidic bioprinting has different interesting features including the possibility of fine control of solutions that flow through the nozzle together with a reduced shear-stress to the cells 6. We evaluated the effect of the fundamental parameters for obtaining a fine control over the bioprinted fibers for different biomaterials. We also assessed thyroid cells behavior inside hydrogels with different compositions by observing: viability, metabolic activity and the expression of specific functional markers during the first week of culture. Finally, we are exploring different techniques in order to produce a vascularized network for the construct. Our future objective is to be able to produce more complex and physiological relevant bioprinted construct that could be relevant for next-generation in vitro cell-based assays.

In recent years, several in vitro studies have investigated the interactions between the microorganisms that resides in the human gut microbiota and the host 1.

In this work we will study the microorganism's adhesion and the composition of a human gut microbiota taken from faecal samples cultured on an electrospun gelatine structure under dynamic conditions. Electrospun gelatine structures promote the formation of a stable biofilm compared to a positive control on a glass slide as demonstrated in previous works.

Initially we will evaluate the effects of fluid shear stress inside a culture chamber on a previously formed bacterial biofilm on the electrospun gelatine structures. To achieve this goal, we will analyse the biofilm formation using a crystal violet assay after 16 hour of flow respect to a static control. Initially E. coli and E. faecalis will be used as target bacteria for the study and then we will study the adhesion of the microorganisms from a human gut microbiota.

Finally, we will culture the human gut microbiota in dynamic condition at different times (i.e. up to 7 days). To analyse the bacterial cultures at different times, biofilm formation assays, bacterial viability assays (live/death imaging) and real time PCR and metagenomic analysis will be performed.

The realization of a dynamic in vitro model of the human gut microbiota that simulates the physiological microbial composition or an altered composition, can be used to connect this model to other cell compartments highlighting the role of the human gut microbiota on health and disease.

Each year in France many patients suffer from restenosis following the implantation of a stent. These complications are due to endothelial lesions, protein adsorptions or coagulation leading to the vessel occlusion. In this context, nitric oxide (NO), an endogenous radical gasotransmitter, plays a key role1. Our aim is to design NO eluting stent coatings composed of functionalized gold nanoparticles (AuNP). Layer-by-layer polyelectrolyte films were found suitable for the creation of a surface coating. Polyallylamine and polyacrylic acid embedding AuNP were defined as the optimal construction2. Here, the key point was the blood-compatibility of these films. The formation of the initial protein layer (approximative mass of 200 to 1000 ng/cm2) on the surface is known to lead to noxious process such as hemolysis, inflammation and coagulation, thus providing antifouling to the surface is essential. Protein antifouling using graft or block PAA-b/g-Polyethylene glycol (PEG) copolymers of various length as the last layer was investigated. A graft copolymer with a high ratio of short (2k) PEG grafting provided the best protein antifouling against plasma samples with a mass of adsorbed protein of 2 ± 40 ng/cm2 (direct measurement with Quartz Cristal Microbalance). This promising result tend to demonstrate a protein resistance suitable for blood compatible surfaces. Viability of endothelial cells, proliferation assay and angiogenesis as a function of the PEG copolymer used and induced by nitric oxide release are being studied. Finally, this study aims to define the optimal design of a nitric oxide releasing blood-compatible surface coating appropriate for a cardiovascular purpose.

Due to the unique combination of properties such as mechanical strength and toughness, biocompatibility, biodegradability, thermal stability, and easy processability [1,2] regenerated silk fibroin has been used as a functional biomaterial, adopted when a positive interaction with living tissue is required. While a plethora of micro and nanoscale architectures of silk fibroin have been explored in literature (films, fibers, microparticles, and gels), realizing large, macroscale objects of fibroin has been so far challenging. In this work we propose a low temperature sintering procedure based on a thermal-reflow to fast fabricate monoliths of solid-fibroin starting from lyophilized fibroin. Thermal-reflow is a well-known mechanism taking place when the glass transition temperature of the material is lower than the temperature used to process it. We were able to conduct a thermal reflow on lyophilized silk fibroin at 40 °C, associating water moisture absorption to a high-pressure compression in a stainless steal mold.

To optimize the amount of material undergone to the solid transition a full factorial design of experiment was used. We studied the material transformation by DSC, FTIR and SEM, proving both that the thermal-reflow occurs even a low temperature, if driven at high-pressure, and that an effective compaction can be performed only using low crystallinity fibroin. Finally preliminary in-vitro tests were conducted: human adipose-derived mesenchymal stem cells were seeded on LTS fibroin samples to evaluate cell adhesion by means of confocal microscopy. The preliminary biological results indicate the potentiality of LTS fibroin material for possible biomedical applications.

Cartilage lacks the ability to self-repair when damaged and despite recent intensive research, there is still no current regenerative treatment that provides an alternative to the existing permanent joint replacement implants. Mesenchymal stem cells (MSCs) are a promising source of cells for osteochondral regeneration, however, selectively promoting MSCs differentiation into appropriate cell lineages in situ is still challenging. It has been shown that matrix stiffness is a key determinant of MSCs differentiation, suggesting that the modulation of mechanical properties of the scaffold would be important in guiding stem cell differentiation into a specific cell lineage. In this study, we developed hybrid collagen and alginate hydrogels with tunable stiffness by varying the concentration of the cross-linker. Viability and proliferation of ovine MSCs encapsulated into hydrogels of different stiffness was evaluated by calcein-AM/ethidium homodimer and carboxyfluorescein succinimidyl ester (CFSE) Celltracker staining respectively. Moreover, nutrient uptake was measured using a fluorescent glucose probe within the 3D culture. After 7 days of culture cellular morphology of oMSCs within the hydrogels was assessed using both wheat germ agglutinin (WGA) and phalloidin staining. By modifying, formulation parameters five scaffolds ranging from 3.9 kPa to 40 kPa were successfully obtained. All hydrogels assure good nutrient transport as demonstrated by glucose uptake. Further, cells were viable and proliferating within all formulations. Interestingly oMSCs retained a rounded chondrocyte morphology within all hydrogels suggesting that the hydrogel itself, without any exogenous stimuli, might have an effect on oMSCs commitment.

PHOTODEGRADATION AND PHOTOCROSSLINKING DUEL CONTROLLED HYDROGEL

Lo-Yuan Liu$_P$[1]

[1] *The same*

Corresponding author's email: a30307a2000@gmail.com

Implantable fillers have been widely used in clinical and biomedical applications, such as skeletal muscle repair, tissue regeneration, drug release, etc. There always come out some unexpected problems following implantation, including wrong position, unexpected geometry, unsuitable stiffness and unsatisfied outcome, which need another surgery to remove implants. In the recent years, many types of hydrogel have been developed to overcome these problems, but most of them possess only one-direction to adjust their mechanical property, which is irreversible increase or decrease their stiffness. Here, we conjugated gelatin with photodegradable molecules (DBCO, NB-azide) and photocrosslinkable molecules (methacrylamide, MA) to synthesize photocrosslinking and photodegradation duel controlled gelatin-based hydrogels. We can reversibly control the mechanical properties by transdermal exposing gels to different wavelength of light. Physical properties affecting cell behavior inside hydrogels were also be investigated. Result demonstrated that this gelatin-based hydrogel is biocompatible and biodegradable. Besides, our findings also showed that dynamic controlling stiffness in situ influenced proliferation and differentiation potential of embedded human bone marrow derived mesenchymal stem cells (MSCs) in 3D culture. Moreover, we also co-cultured MSCs and human umbilical vein endothelial cell (HUVECs) into hydrogels to evaluate the effect of dynamical change in hydrogel stiffness on cell-mediated blood vessel network formation. Results demonstrated that the hydrogels could help embedded MSCs and HUVECs to grow and self-assembly form functional blood vessels in vivo . These results represented that our gels have great potential used in regenerative medicine and tissue engineering.

Infection is among the main complications related to implantation of biomedical devices, hence its prevention is important to avoid severe complications and implants failure. To this aim, silver coating are intensively studied and largely applied to coat a variety of materials.

However, although efficacy of the films against planktonic cells is widely demonstrated, the evaluation of their effects on biofilm is largely neglected. In addition, deposition of the coatings onto porous and/or heat sensitive substrates can be challenging and frequently results into significant substrate damage, limited reproducibility, detachments, low control over film thickness and silver release, all possibly leading to cytoxocity and inflammation.

Here, antibacterial nanostructured silver-based thin films are proposed, obtained by a novel plasma-assisted technique, Ionized Jet Deposition, that permits to obtain adhesive films with a fine control over thickness. Coatings are characterized in terms of morphology and composition and their antibacterial and antibiofilm efficacy are shown against E. coli and S. aureus. Then, application to polymeric electrospun patches (Poly(L-lactic acid), Nylon, polyester polyurethane) is proposed, for manufacturing of antibacterial textiles.

Results indicate that the coatings are composed of nanosized aggregates of metallic silver, showing anti-bacterial effect against both planktonic and biofilm cells. Their application onto specific devices for testing bacterial adhesion was demonstrated to significantly reduce biofilm formation by all the bacterial strains under analysis. When deposited onto electrospun polymers, the films grew around the fibers guaranteeing anti-bacterial efficacy, without altering their shape and the porosity of the patch or causing significant damage to the substrate.

Manual suturing is the current gold standard for intestinal anastomosis, being a difficult and time-consuming procedure [1-2]. Here, we designed and fabricated 4D printed tubes made of biobased and biocompatible regenerated silk (RS) and poly(3-hydroxybutyrate-co-3-hydroxyvalerate) (PHBV) to be used as sutereless clips in intestinal anastomosis. The rationale of our innovative 4D structures is the negative expansion coefficient of RS when exposed to high relative humidity (HRH), as in human body. B. mori cocoons were degummed in NaHCO3; then two solutions were prepared: i)RS/CaCl2: silk fibers dissolved in CaCl2/formic acid; ii)RS/CaCl2/KNO3: RS/CaCl2 solution with the addition of KNO3. PHBV was dissolved in chloroform [2]. Bilayer tubes were 4D printed using an extrusion-based 3D printer, with a 5mm rotating spindle. The inner layer was made of PHBV, thus creating a waterproof layer. The external layer was made of RS/CaCl2 or RS/CaCl2/KNO3. Tubes were characterized by weight variation in HRH, FTIR spectroscopy and compression test. KNO3 promotes the formation of the β-sheet intramolecular crystalline structures, stabilizing the tubes and enhancing its resistance to collapse. Finite element models were performed to analyze the contraction of the 4D printed tube under thermal stimulus. They showed that at 37°C the tubes contracts radially, compressing the intestine wall, with a bigger compression when RS/CaCl2/KNO3 is used. This result agrees with experimental evaluation of bursting pressure. In conclusion, RS/CaCl2/KNO3 -PHBV tubes are promising devices for biobased sutureless anastomosis clips. In the next future, our 4D printed device will be used in mices to verify anastomosis capabilities in vivo.

Abdominal adhesions are common complications after medical surgery. Adept®, Interceed® and Seprafilm served as adhesion barriers are currently used in surgeries, but its drawbacks are uncontrollable biodegradability and insufficient coverage on wound with complex geometry shape, so scientists have paid more attention to develop materials acting as physical barriers to prevent postoperative adhesion. Serum albumin is abundant protein in blood, and its non-immunogenicity, low surface interaction energy, capability to transport drugs and long circulatory half-life make it suitable for being a candidate material to prepare bovine serum albumin (BSA) hydrogels. Here, tyramine (-tyr) and 2-Aminoethyl methacrylate hydrochloride (-AEMA) were single or double introduced to BSA to form BSA-tyr, BSA-AEMA and BSA-tyr-AEMA conjugates. Through chemical-crosslinking, photo-crosslinking or sequential chemical- and then photo-crosslinking, gelation time, microstructure and mechanical properties of BSA hydrogel can be modulated in situ by using different concentrations of H2O2 or UV exposure time, which depending on the severity and location of injury. Our findings demonstrated that dynamically tailoring physical properties of salicylic acid-loaded BSA hydrogels successfully controls releasing profiles of salicylic acid ex vivo. Additionally, a mouse model of serious sidewall defect-bowel abrasion was employed, and a significant reduction of post-operative peritoneal adhesion has been observed on drug-loaded hydrogel. This hydrogel-based drug delivery system is potentially promising for adhesion prevention in clinical therapy.

Compartmentalized systems allow the confinement of important biomolecules and cells, creating an appropriate and controlled atmosphere for bioassays, cell mimicry of regulatory mechanisms, and (micro)niches studies1. Liquid-core capsules have been suggested as semi-permeable moieties with spatial homogeneity, however, most fabrication methodologies either rely on the use of organic solvents or are time-consuming. Thus, aqueous two-phase systems emerged as a biocompatible and adaptable platform for the production of capsules for autonomous production of micro-tissues, which may be used individually or combined as a tissue engineering bottom-up strategy. Moreover, the lack of cell-adhesive sites in liquid-core structures often hampers their use as platforms for stem cell-based technologies that depend on long-term survival and multilineage differentiation. Hence, these constructs are often used to take advantage of biomaterial-free cell-directed self-organization, particularly explored for short-term cellular aggregation and consequent organoid formation.
Here, we describe the cell culture of mesenchymal stem/stromal cells and microcarriers in one-step rapidly formed robust polymeric capsules formed by interfacial complexation of oppositely charged polyelectrolytes in an all-aqueous environment. MSCs isolated from the umbilical cord were encapsulated with and without microcarriers to serve as adhesion sites. Cells were characterized for their proliferation for more than 21 days in capsules prepared either manually, by drop-wise addition (millimetric size range), or by scalable electrohydrodynamic atomization (micrometric size range). The system was cultured under static or stirred environment, showcasing its robustness, stability, and versatility. Changes in cell stemness or lineage induction, overtime, are currently being investigated, as well as the resulting product of secreted factors.

Induced pluripotent stem cells (iPSC) open up the unique perspective of manufacturing cell products for drug development and regenerative medicine in tissue, disease and patient-specific forms. iPSC can be multiplied almost without restriction and differentiated into cell types of all organs. The basic requirement for clinical use of iPSC is a high number of cells, which must be produced cost-effective while maintaining reproducibility and high quality. Compared to manual cell production, its automa-tion offers a unique chance of reliable reproducibility of cells in addition to cost reduction and in-creased throughput. StemCellFactory is a prototype for a fully automated production of iPSC. How-ever, in addition to the already tested functionality of the system, it must be shown that this automa-tion brings necessary economic advantages.

This presentation shows that fully automated stem cell production offers economic advantages in addition to increased throughput. First, biological and technological basics for a fully automated pro-duction of iPSC are presented. Second, the basics for profitability calculation are presented. Third, profitability of both manual and automated production are calculated. Finally, different scenarios effecting the profitability of manual and automated production are compared

INTRODUCTION: Tendon repair is challenging due to its hypocellularity, hypovascularity and inadequate regenerative capacity [1], underscoring the importance of developing new approaches that augment tendon repair. Building on our previous development of a urea-extracted tendon ECM fraction (tECM) that promotes tenogenesis of human adipose-derived stem cells (hASCs) [2], this study aims to evaluate the tenogenic potential of an hASC/tECM-incorporated, tough hydrogel as a novel approach to enhance tendon repair.

METHODS: hASCs were isolated from the infrapatellar fat pad tissue of total knee arthroplasty patients, and bovine tECM was prepared as previously described [2]. hASCs and tECM were incorporated into an interpenetrating polymer network hydrogel consisting of poly(ethylene glycol) diacrylate (PEGDA) and sodium alginate, with or without uniaxial cyclic tensile conditioning [3]. Ensuing analyses included mechanical tests, ex vivo degradation, biocompatibility, and pro-tenogenic effects of the tECM-enriched hydrogel on hASCs.

RESULTS: hASCs encapsulated in tECM-supplemented PEGDA-alginate hydrogel (125±14.2kPa) exhibited sustained viability (Live/Dead staining), proliferation (dsDNA assay), and enhanced tenogenic differentiation (tenogenesis-associated markers via immunofluorescence and qRT-PCR) compared to hydrogel alone group. Cyclic tensile loading further facilitated hASC tenogenesis and cell alignment along the loading direction compared to unloaded tECM-hydrogel group.

DISCUSSIONS: Main findings include (1) PEGDA-alginate hydrogel is mechanically robust and biocompatible, and (2) hASCs seeded in tECM-supplemented PEGDA-alginate hydrogel exhibit increased tenogenic differentiation, further enhanced by uniaxial cyclic loading, and provide a rational basis for application of tECM-tough hydrogels in tendon repair.

The 5D printing (1) aims the tumour regression, supporting surgery training (2) with bionic and personalised medicine (3) via synthetic biology. The fabrication of these devices requires the implementation of new type of biofactory, the industry 5.0 (4). In the society 5.0 (5) this type of production paradigm (6) uses artificial intelligence for the optimal management of process data. The study describes how it is possible to structure the human-cyber-physical space (5) through the global standard method for society 5.0, developing the digital bio-libraries (7) linked to a specific pathology, processing data for disease regression and rehabilitation therapy. We analysed the bone loss of 12 glenoid in-vivo utilising three different methods: Pico, De Filippo (8) and FMD. The first is commonly used to define the type of therapy, evaluating the circles inscribed in the right and left bidimensional surface glenoid of the same patient; the second improves the quality of results studying the complete glenoid interaction surface; the third describes the functional glenoid trajectory supporting its digitalisation. The continuous improvement is assured realising and customising internet-of-thinks mechatronic devices, exploring the four phases of the cyberspace: big-data analysis, advanced diagnostic, new generation of intelligent manufacturing and zero-failure activity. This document aims to support bioengineers, biologists and innovation managers in the development of future industry 5.0 and digital libraries related to bionic and biosynthetic design, through the use of artificial intelligences.

By the rapid advance toward the industrialization of regenerative medicine industry, there are explosive demand for more effective and more stable cell manufacturing technologies. However, even at present, the industrial-scale cell product manufacturing with good quality control is still technologically difficult. The biggest reason of such instability and inefficiency of the present cell manufacturing is that most of culture operations are relying on human skills and experiences. Therefore, although few product manufacturing can succeed, scale-up which overwhelms the key-person's capacity is hopeless.For efficient scale up, "mechanization" to automate manual operation is essential. However, the operation mechanization is also practically difficult. Because, there are no know-hows or literature who teach the manufacture "what parameters would be critical in mechanized process". Therefore, manufacturer has to struggle for long period with costly and time-consuming trial and errors for clarifying critical parameters. However, such trial and errors are rather based on expert's feeling than logical data, therefore the investigation commonly become inefficient and costly.Our group had been working with "morphology-based analysis of cells" by combining the most recent image-processing and machine learning technologies [1]. In this study, we focused to non-invasively but quantitatively analyze the effect of mechanical stress on human induced pluripotent stem cells (iPSCs). In this work, we will show various kinds of "mechanical stresses" that can affect the culturing cells during their mechanized cell culture process, and indicate our morphological profiling can quantitate such "critical process parameter" with extremely low cost only from the early images.

Human Adipose-derived Stem Cells (hADSCs), which can be collected by subcutaneous liposuction, offers a great feasibility of obtaining stem cells for therapeutic use. Furthermore, high healing ability has been reported for liver diseases and damaged skin regeneration, and its application as medicinal products have been promoted. However, a quality evaluation method in cell manufacturing has not yet been established; therefore, a highly efficient, non-invasive, and quantitative evaluation system is required.

To achieve such performances, image-based morphological information is one of the most promising and expected in-process measurement index that can be introduced in facilities easily. Our group has been reported early and robust morphology-based label-free cell evaluation methods applied to bone-marrow derived mesenchymal stem cells and induced pluripotent stem cells, and has reported the effectiveness of morphological analysis to sensitively detect "irregulars" in the culture [1].

In this work, we collected over 14000 images of hADSCs' images together with its quality decay values by the continual passages. From the images, we extracted "morphological heterogeneity information" as a fingerprint feature for quality prediction.

Our data indicated that our morphological modeling and visualization of their heterogeneity efficiently contributed to sensitively detect the irregular quality decay in hADSCs only from their early images. Our results show that the qualities of hADSCs in the manufacturing process can be modeled with good accuracy by comprehensive imaging and information analysis, therefore can be applied to the daily quality monitoring for sensitive label-free detector for cellular product manufacturing.

CHEMO-MECHANICAL MODELING OF ALGINATE HYDROGEL IN 3D BIO-PRINTING AND DRUG DELIVERY

Aidin Hajikhani[P][1], Michele Marino[2], Jorge-Humberto Urrea-Quintero[1], Peter Wriggers[1]

Alginate hydrogel is a natural polymer which has been widely used as bio-ink for the production of biological scaffolds for cell growth, and drug delivery. For stabilizing the polymeric structure of the bio-ink, alginate encounter slight crosslinking by adding an ionic stimulus (cross-linker), such as Calcium(1,2). The crosslinking process (Sol-Gel) is promoted by the diffusion of the solvent and the onset of chemical reactions in the hydrogel(3,4). Hence, the structural resolution, shape fidelity and cell survival depend on properties and characteristics of the bio-ink during the process. This work aims to develop a constitutive theory and a computational model of the crosslinking-dependent swelling and shrinking mechanisms in alginate hydrogels. The crosslinking process consisting syneresis and swelling affect the pore pressure, in turn responsible for residual stresses. Constitutive laws are defined from thermodynamical principles. The coupled system includes balance of linear and angular momentum as well as mass balance for multiple species. Consequently, the developed computational framework allows to predict stress distribution inside the hydrogel as a function of internal chemical reaction and the fluid diffusion(5). Numerical approaches for multiphysics mechanisms have been developed and implemented in a finite element framework, considering the monolithic coupling of chemical transport and mechanics(6). The importance of accounting for the coupling chemo-mechanical effect between the crosslinking shrinking and the fluid-driven swelling phenomenon is highlighted, showing the effectiveness of the proposed model.

Tendon injuries combined with limited healing capacity of tendon tissue have resulted in a clinical challenge and an increasing need for tendon regeneration therapies. Recapitulating the tendon extracellular matrix (ECM), predominantly consisting of aligned collagen type-I fibers, presents a bottleneck for developing such therapies [1]. Biofabrication technologies were proposed for creating collagen microstructures with controlled fiber alignment [2]. Microfluidic systems have been explored to a lesser extent [3]. Here, we present a microfluidic platform with integrated micropillar arrays to create aligned collagen fibers for studying tendon regeneration. The corresponding device was fabricated using soft lithography. Micropatterns of aligned collagen were created by flowing a collagen solution through the pillar arrays followed by crosslinking. We hypothesized that the combination of the geometry of arrayed pillars and laminar flow aligns collagen fiber to the flow direction. The results confirmed this hypothesis, showing higher fiber alignment between the pillars compared to non-pillar regions. Primary rat tenocytes were cultured on the micropatterns, and analyzed for morphology and expression of tenogenic markers including the transcription factor scleraxis (SCX). Preferred adhesion and growth of tenocytes was observed on the collagen micropatterns. Cells cultured on aligned and randomly oriented fibers showed distinct elongated and spread morphologies, respectively. SCX levels of tenocytes were significantly higher on aligned fibers compared to randomly oriented ones and regions without collagen. In conclusion, we established a microfluidic-based method to create collagen micropatterns with aligned fibers that promote tenocyte adhesion and elongation, maintain phenotype, and can provide a microenvironment for tendon regeneration studies.

Despite the occurrence of up to 200 cases of traumatic spinal cord injury (SCI) per million people per year in Europe, no effective treatment to restore cord function currently exists [1]. The inhibitory nature of the injury site and poor intrinsic healing capacity of injured neurons create a challenging environment for repair. Building on our group's work on peripheral nerve repair [2], we hypothesized that a scaffold with a controlled pore architecture could be functionalized with neurotrophic matrix proteins to bioactively promote axonal growth. A neurite outgrowth assay was conducted using human and mouse neuronal cells to screen neurotrophic matrix components and a synergistic combination of collagen type-IV and fibronectin exhibited potent neurotrophic effects similar to BDNF-supplementation (Brain-derived neurotrophic factor).

Both matrix proteins were combined with a hyaluronic acid (HyA) hydrogel and freeze-dried, forming a microporous scaffold containing a linear pore structure. The stiffness of the scaffolds was tuned to match the soft (<1 kPa) properties of healthy cord. Seeded neurons were examined after 3 weeks of culture using metabolic assays as well as confocal and light-sheet microscopy. The neurons exhibited excellent cellular infiltration, significantly higher ($p>0.001$) metabolic activity, increased ßIII-tubulin expression ($p>0.01$) and enhanced neurite outgrowth compared to stiffer scaffolds ($E=3.65\pm0.97$ kPa) or HyA-only controls. These data indicate that matrix components can act as potent neurotrophic signalling molecules and that scaffold stiffness plays a key role in modulating this interaction with important implications for design of bioactive scaffolds for SCI-repair. Funded by the IRFU Charitable trust and SFI-AMBER Centre.

IN VITRO-IN SILICO MODELS OF TUBULAR TOXIN TRANSPORT

Jasia King[P][1], Roman Truckenmüller[1], Stefan Giselbrecht[1], Aurélie Carlier[1]

[1] Maastricht University

Corresponding author's email: j.king@maastrichtuniversity.nl

2 million patients are currently suffering from end-stage renal disease worldwide, with current therapies limited to transplantation or dialysis. Dialysis is a passive system in which small unbound-toxins are removed from circulation, leading to an accumulation of protein-bound uremic toxins (PBUT). This study focuses on developing an in silico model of the PBUT transport in the proximal tubule (PT) verified by in vitro experiments. It is our intention to use the in silico model to make informed decisions on the in vitro design of a bioartificial kidney subunit.

ciPTEC-OAT1 (PT-cells expressing transporters) were seeded on collagen IV-coated porous polycarbonate membranes using 1E5cells/cm2. Uptake and kinetic transepithelial assays were performed on the monolayers with 10 µM of fluorescein as a model toxin.

A non-spatial kinetic binding model was developed using literature values for indoxyl sulphate, albumin and transporter interactions, and simulated in VCell (https://vcell.org/). The system was modelled in 2-compartments representing the basolateral and apical compartments of the in vitro PT transport. Initial conditions were set using respective values from in vitro experiments. The in vitro data was used to estimate parameters of toxin binding to the transporter and transporter density using VCell.

The fluorescein versus time curves obtained from the transport assays were fitted in the VCell model resulting in forward rates that compare well to the trends in literature. The calibrated model will be used in future work to explore the effects of altering physical and chemical parameters of the system in order to predict the optimal device design.

Introduction: Organoids mimicking the development, physiology and disease of the gastrointestinal system have constituted a topic of broad interest. Here, we describe a method to culture intestinal organoids inside microwell arrays[1]. By adapting previous protocols[2,3], we were able to grow organoids for up to 13 days without embedding them in solid Matrigel but instead supplementing the medium with highly diluted Matrigel.

Methods: Microwell arrays were fabricated from thin polycarbonate films by microthermoforming[1]. Mouse intestinal organoids were preserved as previously described[2]. Following passaging, organoid fragments were resuspended in medium supplemented with 5% Matrigel, and seeded into microwell arrays.

Results: Microwells were dimensionally characterized by 3D laser scanning microscopy. The inner diameter and depth of the microwells were 500µm and 300µm, respectively. Structural analysis of organoids showed similar morphology (crypt-villus architecture surrounding a central lumen) and size as organoids grown embedded in Matrigel. The polarity in the intestine is marked by F-actin–rich brush border on the apical side and E-cadherin on the basolateral side. Immunofluorescent stainings showed disrupted polarity in organoids cultured in Matrigel already after 10 days. In contrast, organoids in microwells seem to preserve distinct apico-basolateral borders for the whole culture period. On the other hand, qPCR and stainings for proliferation and differentiation revealed similar expression patterns for organoids in both culture systems. These data confirm the applicability of our microwell platform to intestinal organoid culture and pave the way towards simplified micromanipulation, automated and high-resolution imaging, dynamic culture of organoids and defined exposure of organoids to soluble compounds.

Critical bone defects with sluggish rate of auto-osteoconduction and imperfect reconstruction urge to develop an alternative approach for regeneration of bone. Tissue engineering for bone regeneration signifies an innovative way to overcome this problem and creates an alternate for bone tissue substitute. Polymer based nanohybrid materials have been widely used for bone tissue regeneration because of their tuneable physicochemical properties and excellent osteoconductive bioactivity. Amongst different fabrication techniques, 3D printing technique is obviously most efficient and advanced way to fabricate the osteoconductive scaffold with control porous structure.1 In the current article, the synthesized polyurethane-urea (P12) based nanohybrid scaffold is fabricated by 3D printing technique by incorporating osteoconductive nanomaterial, titanium phosphate adorned nanohydroxyapatite (TP/nHA).2 The scaffold has been printed at ambient temperature using high viscous polymer slurry in THF. After fabrication, the surface of the scaffold has been modified with the immobilized biomolecule polydopamine (PDA).3 The surface modification of the scaffold has been assessed through AFM, FESEM and XPS study. The incorporated TP improved the physico-mechanical properties of the scaffold drastically through the dative bone formation between the vacant d orbital of the titanium atom and the lone pair electron of amide linkage of the polyurethane-urea. The introduced hybrid nanomaterial within the scaffold also promoted the polydopamine coating by the electrostatic attraction between the positive charged titanium ion and the negative charged hydroxyl group of dopamine. In vitro and in vivo assessment indicates the superior osteogenic bioactivity of the PDA immobilized polyurethane-urea based 3D printed scaffolds without exhibiting any toxic effects.

DECELLULARIZED MATRICES OF MESENCHYMAL STROMAL CELLS CULTURED UNDER 20 AND 5% O2 DIFFERENTIALLY REGULATE CELL FUNCTIONS AFTER RECELLULARIZATION

Diana Matveeva[P][1], Sergei Buravkov[2], Elena Andreeva[1]

The decellularized extracellular matrix (dcECM) is attractive as a source of biological scaffolds for tissue reconstruction. Mesenchymal stromal cells (MSCs) are key components of connective tissue and produce specific ECMs depending on specific tissue milieu. The O2 levels are crucial for microenvironmental regulation of MSC functions. Here we prepared and characterized dcECMs from MSCs permanently cultured under 20% or 5% O2.

Dense monolayers human adipose-derived MSCs were decellularized with 0.5% Triton-X100/20 mM NH4OH/PBS. Scanning electron (SEM) and confocal microscopy were used to examine dcECM morphology. To test functional activity (adhesion and osteo-differentiation), dcECM from 20% O2 (20-dcECM) or 5% O2 (5-dcECM) were recellularized with MSCs at 20% O2. Collagen I coating was used for comparison.

According to SEM, under 5% O2 dcECMs were formed by dense network of thin intersecting fibers, while membrane-like structures without separation into individual fibrils were noted at 20% O2. The efficiency of MSC adhesion was higher on 5-dcECMs after recellularization. At early steps of adhesion, dish-shaped MSCs were prevailed on collagen, most of MSCs on dcECMs had numerous pseudopodia. Both types of dcECMs effectively supported the MSC expansion. Osteo-differentiation of MSCs was more pronounced on dcECMs than on collagen. The spontaneous activity of alkaline phosphatase was 2 times lower on 5-dcECMs, this effect was canceled upon osteoinduction.

The data demonstrate the role of local milieu in regulation of capacities of MSC-derived dcECM when dcECMs are applied as biocompatible coatings for scaffolds.

Many laboratories have developed tissue-engineered approaches based on the ability of mesenchymal cells to assemble in vitro their endogenously-secreted extracellular matrix. However, patient-to-patient variability of this cell-assembled extracellular matrix (CAM) production can be a hurdle for clinical applications. This study aimed to evaluate this variability as well as parameters that drive CAM production. To this end, human CAM sheets were produced using different primary dermal fibroblast populations obtained from 21 donors/patients requiring arteriovenous shunt.

Results demonstrated that the strength, the thickness, and the hydroxyproline content of the CAM sheets varied between donors by 33% (coefficient of variation), 19%, and 24%, respectively. Another objective was to characterize the CAM matrisome to better understand its relation with the CAM properties. The CAM sheet strength showed moderate and strong positive correlations with the CAM thickness and hydroxyproline quantity, respectively. A detailed CAM matrisome characterization was performed by mass spectrometry and confirmed the inter-donor variability in term of CAM protein composition. Data also revealed that the CAM strength correlates with collagen alpha-1(I) chain abundance. The CAM thickness showed strong correlations with fibrillin-1, dermatopontin, and peroxidasin, which are involved in collagen fibril formation and stabilization. In addition, the CAM hydroxyproline quantity intensely correlated with proteoglycans (e.g. decorin) and ECM regulators (e.g. serpin H1) involved in collagen fibril biosynthesis.

Finally, this study formally evaluates the CAM inter-donor variability in a clinical manufacturing context. Furthermore, the detailed CAM composition characterization identified molecular predictor of the CAM properties and possible targets for improving CAM strength.

Recent advances in peripheral nerve injury treatments have focused on tissue engineering approaches which combine therapeutic cells and biomaterials. However, the design of bioengineered nerve repair constructs (NRCs) has so far been informed predominantly by experiments, which can be time-consuming and result in substandard designs. Mathematical modelling offers a cost- and time- effective way of studying the behaviour of therapeutic cells in NRCs and allows us to make better-informed predictions about their overall efficacy.

Values of unknown parameters that describe the behaviour of differentiated human neural stem cells under a range of physiologically-relevant conditions were initially calculated based on experimental observations obtained from a well set-up. These were subsequently used in a multiphysics mathematical model of an NRC design2. We then simulated a variety of cell seeding strategies and temporal changes on cell survival and vascular endothelial growth factor (VEGF) release. Finally, based on the simulation results, we examined different fabrication techniques that would enable successful patterning of cells within engineered NRCs.

Simulation results indicate that the use of lower seeding cell densities could lead to higher viability of cells within the first few days post-implantation. Moreover, non-uniform seeded cell distributions could enhance overall cell survival and promote the creation of VEGF gradients to encourage neo-vascularisation. Based on the model predictions, 3D neural tissue replacements with optimised cellular distributions were manufactured using microfabrication techniques.

The results of this work highlight how interdisciplinary approaches can accelerate the design of nerve repair constructs for future translation into the clinic.

Induced Pluripotent Stem Cells (iPSCs) have become an integral part of biomedical research in the last fourteen years. iPSCs overcome some ethical challenges inherent to embryonic stem cells; however, it has ethical challenges of its own. Ethical challenges in the research phase that have been described in the literature concern the collection, storage and use of donor material, and questions about ownership. Moving towards clinical translation, ethical challenges such as undesirable side-effects, teratoma formation, stem cell tourism and costs of therapy could arise (2,3).

Yet, little is known about the perspectives and experiences of stakeholders such as iPSC-researchers, regulators and (former) patients concerning how to deal with these challenges. Therefore, in order to get these insights, we have conducted focus groups with stem cell researchers, regulators and (former) patients with chronic lower back pain. The results of these focus groups have been analysed. In this paper the results of these focus groups will be discussed. The results shed light on amongst others what the role of policy should be in dealing with ethical challenges and what researchers need to be able to deal with the ethical challenges of iPSC-research.

CHARACTERISING THE PROTEOME OF THE FOETAL NOTOCHORDAL CELL: IMPLICATIONS FOR INTERVERTEBRAL DISC DEGENERATION AND REGENERATION

Stephen M Richardson[P][1], Lizzy Ward[1], Richard D Unwin[1], Anna L Tierney[1], Andrew W Doswey[2], Judith A Hoyland[1]

Corresponding author's email: s.richardson@manchester.ac.uk

Loss of large, vacuolated notochordal cells (NCs) from the human intervertebral disc (IVD) is thought to initiate degeneration and associated back pain. It is therefore hypothesised that implantation of NCs may halt or reverse degeneration and thus relieve back pain. However, NCs are lost in early childhood, therefore iPSCs differentiation to NCs offers a clinically-viable cell source. Here we aimed to characterise the proteomic profile of the human foetal NCs, versus surrounding annulus fibrosus (AF) cells. FACS sorting for CD24, a known NC marker, was used to isolate NC (CD24+) and AF (CD24-) cells from microdissected human IVDs (14-15 weeks post-conception, n=3). Following iTRAQ isobaric tagging, TripleTOF mass spectrometry and subsequent bioinformatics, differential protein expression was validated by immunofluorescence. Our study revealed 100 up-regulated and 8 down-regulated proteins in the CD24+ population ($-1.5 \geq FC \geq 1.5$, $P \leq 0.1$), including known (e.g. keratins 8 and 19) and novel phenotypic markers. Ingenuity Pathway Analysis (IPA) revealed pathways known to play an important role in NCs and IVD homeostasis, such as NRF2-mediated oxidative stress response and caveolar-mediated endocytosis, and putative upstream regulators known to be active in NCs e.g. TGFβ1 and SMAD3. The same analysis predicted many previously unknown proteins, pathways and regulators to be active or repressed in NCs. Together, these results validate our method as a powerful tool for isolation and proteomic analysis of foetal NC cells and reveal novel proteins and pathways of potential use in the development of future strategies for the study and treatment of IVD degeneration.

The high prevalence of antibiotic resistance is now considered a major global challenge. Conventional therapies for treating skin wound infection with extensively drug-resistant (XDR) bacteria are likely to be inadequate due to the lack of efficient antibiotics. In this study, we have evaluated the optimized concentration of Colistin and Meropenem as a combined drug. Antibiotic-loaded thermo-responsive chitosan (TCTS) hydrogel was evaluated as a potential formulation to protect full-thickness wounds infected with XDR bacteria isolated from burn patients, both in vitro and in vivo in a rat model. Antibacterial activity of the TCTS hydrogel against standard strain and clinical isolates of Acinetobacter baumannii and Pseudomonas aeruginosa, cytobiocompatibility for Hu02 fibroblast cells, chemical structures, morphologies, degradation rate, swelling ratio, and release behavior were determined in vitro. The results of disk diffusion assay showed that the antibacterial activity of TCTS hydrogel is optimal at concentration of 8 µ/ml and 4 µ/ml for Colistin and Meropenem, respectively. The TCTS hydrogel itself didn't exhibit antibacterial effect. Furthermore, MTT showed no cytotoxicity of TCTS hydrogel against fibroblasts. In vivo study showed significant acceleration of wound healing, re-epithelialization, wound closure, collagen disposition, up-regulated CD31, and decreased colony count in the TCTS hydrogel-loaded optimized concentration of antibiotics group compared with TCTS hydrogel and gauze as control groups. The results of this study showed great promise for drug-loaded TCTS hydrogel as a wound dressing for managing wounds infected with XDR bacteria.

Within the EVPro project the design for manufacture optimisation of a microfluidic lab on a disc (LoaD) platform for size sorting, antibody based classification and retrieval of extra cellular vesicles (EVs) derived from mesenchymal stem / stromal cell (MSCs) has been investigated. EVs generated from MSCs grown under static cell culture conditions (multilayer culture flasks) and using a hollow fibre bioreactor (HFBR) have been examined.

The innovative LoaD device has been developed for capture and differentiation of the EVs based on size categorization (in the region <200nm, with separations in the sub-regions of 100nm – 70nm, 70nm – 50nm and <50nm). Once captured and categorized by size, the EVs will be examined for their expression levels of the relevant therapeutic biomarkers (CD9, CD63 and CD81). Filter membrane configurations to perform the size based classifications of the generated EVs have been reviewed and finalized. LoaD designs using rapid prototyping, xurography and milling have been generated and upon completion of fluidic validation will be transferred for generation of an injection moulding tool for pilot scale LoaD manufacture.

The finalized device will serve as an at line quality check tool for EV production derived from MSC culture methods. The device will also assist the EVPro project partners with GMP compliance and up scaling to a GMP facility for EV production.

This project has received funding from the European Union's Horizon 2020 research and innovation action under grant agreement No. 814495-EVPRO (www.evpro-implant.eu)

Background. Adipose tissue is an accessible source of endothelial cells (AMVECs) for vascular tissue engineering. However, their cultures are frequently overgrown by residual stromal cells (ASCs) from the sorting procedure. The challenge in expanding AMVECs was investigated to facilitate their procurement in large quantities with high purity.

Methods. CD45–CD31+ AMVECs were isolated using immunomagnetic microparticles (IMPs). Efficacy was evaluated by flow cytometry (FCM). IMP localization was assessed by confocal microscopy. Prevalence of ASCs with bound/internalized IMPs was determined using FCM. Proteomics was used to identify an AMVEC-specific immunophenotype. Anti-CD31 and anti-CD93 IMPs were characterized by Coulter counter, and their binding/internalization by ASCs was compared by FCM.

Results. AMVECs were 98.3±1.0% CD45–CD31+, a 34-fold enrichment (2.9±0.6%; $p<0.05$). However, 85% of cultures were overgrown by CD45–CD31– ASCs, despite sequential enrichments. ASCs exhibited membrane-bound and internalized anti-CD31 IMPs. Percentage ASCs with membrane-bound IMPs decreased over time (0.33hrs: 12.1±3.2% vs. 7dys: 4.4±2.1%; $p<0.05$), while IMP internalization increased over time (0.33hrs: 5.0±2.8% vs. 7dys: 26.3±7.5%; $p<0.05$). Proteomics found ASCs and AMVECs shared conventional immunophenotypic markers, including CD31, and identified CD93 as being AMVEC-specific. Anti-CD31 and anti-CD93 IMPs exhibited similar sizes (5.0±0.6 vs. 5.0±0.5 µm, respectively), and their binding (3.8±0.5% vs. 3.9±0.9%, respectively) and internalization (8.6±5.8% vs. 7.6±5.2%, respectively) by ASCs was comparable after 48hrs in culture.

Conclusion. Non-specific internalization of IMPs by residual ASCs from the sorting procedure precludes the sequential enrichment of contaminated AMVEC cultures. Exclusion of IMPs from cultures will reduce the prevalence of their internalization by ASCs and, thereby, enable sequential enrichments.

Cartilage is a very complex tissue with poor regenerative capacity due to its avascularity and absence of nerve and lymphatic innervation. Among the different strategies to regenerate cartilage defects, the use of decellularized scaffolds from native cartilage has become of great interest, but the remaining dense matrices are difficult to recellularize. Two strategies have been developed recently by our group to perforate the dense matrix: laser-engraving of articular cartilage and enzymatic treatment of auricular cartilage. Within this study, we want to combine both strategies, comparing the efficiency of laser-engraving auricular cartilage with a CO2 or a femtosecond laser, and further test the performance of chondrocytes of different age. Scaffolds were prepared from cartilage discs from auricular cartilage from bovine ears. They were, subsequently, laser engraved and chemically treated with different formulations containing elastin, pepsin, and HCl. For recellularization, human chondrocytes from different donors were labeled with vital dyes, pooled, and cultured under dynamic conditions. The scaffolds lasered with femtosecond laser showed better integrity than those with CO2. Furthermore, repopulation of the laser incised auricular scaffolds was achieved within a few days and was less influenced by the laser pattern than the chemical treatment. Besides, donor age influenced the speed of cell distribution within the scaffold. Overall, this study proved that laser-engraving is a feasible efficient method to improve cell infiltration in auricular cartilage scaffolds making them an ideal chondrogenic environment for the treatment of cartilage defects.

OPTICAL FIBER-BASED APPROACH TO CREATE MICROFLUIDICS PLATFORMS: A STRAIGHTFORWARD SOLUTION FOR THE PRODUCTION OF MICROGEL BIOINKS

Alessandro Cianciosi[1], Jürgen Groll[1], Tomasz Jüngst[1]
[1] *Department of Functional Materials in Medicine and Dentistry and Bavarian Polymer Institute, University of Würzburg*
Corresponding author's email: alessandro.cianciosi@fmz.uni-wuerzburg.de

Biofabrication techniques bear the potential to generate biologically functional products [1]. Recently, great attention has been put on the development of new bioinks [2]. A promising alternative to conventional inks are cell-laden jammed microgel inks [3]. The microgels, which are the crucial building blocks for this bioink type, can be obtained using droplet-generating microfluidic devices. Despite the great advances in the fabrication of microfluidics chips, most of the approaches are still time consuming and expensive [4]. This study proposes a novel, cost effective, fast and versatile process for the fabrication of microchannels based on an optical fiber (OF)-coupled LED light. The OF is integrated with a commercially available FDM printer, which controls its movement complying with a predetermined microfluidic design. This method relies on selective photo-patterning of a thin layer of light-sensitive resin deposited onto a cover slip using the OF as light-source. An elastomer (PDMS) is used for molding and the microfluidic chip is obtained after plasma bonding of the PDMS to a cover slip. A key aspect of the study is analysing the resolution of the microchannels, which is demonstrated to be influenced by OF speed, light intensity and resin layer thickness. The microfluidic chips are used to generate homogeneous cell-laden microgels from hydrogel precursors which can be jammed into microgel bioinks for extrusion-based bioprinting. In conclusion, this study shows an easy and straightforward approach for the fabrication of microfluidics platforms, which enables the production of microgel-based bioinks for extrusion-based bioprinting.

Background

Accumulating evidence suggest that cellular senescence influences kidney fibrosis. Senescent cells secrete senescence-associated secretory phenotype (SASP) markers that can be involved in diverse signaling pathways, influencing kidney fibrosis. Recent studies have focused on clearing senescent cells as treatment option for kidney fibrosis. Our previous study suggested that ciPTEC-OAT1 is a suitable model for studying kidney diseases. Here we investigated whether ciPTEC-OAT1 can also be a potential senescence model.

Methods

CiPTEC-OAT1 cells were seeded into 6-well format plates and were grown at 33℃, then transferred to 37℃ for maturation and cultured for 12 days. The culture medium and cell lysate were collected on day 3, 6, 9 and 12, and used for detecting senescence phenotypes, including apoptosis markers, DNA damage markers, and common SASP factors on the gene and protein level.

Results

Long-time (>6 days) maturation at 37℃ affects the senescence phenotypes. Compared to non-heat transferred cells, heat transferred cells showed an upregulation of p21 ($p<0.001$), PAI-1 and IL-6 ($p<0.05$), and a downregulation of Lamin B1 ($p<0.01$) on the mRNA level. On the protein level heat transferred cells showed an upregulation of Bcl-2 ($p<0.01$) and Bax ($p<0.05$), and a downregulation of Mcl-1($p<0.05$), Puma ($p<0.05$), BID ($p<0.05$) and Bim ($p<0.05$), suggesting anti-apoptosis pathway is activated. Further, common SASP factors like IL-6, TNF-α and TGF-β ($p<0.05$) were also upregulated on the protein level during maturation.

Conclusion

The results suggest that ciPTEC-OAT1 obtain senescence phenotype over time under maturation at 37℃. Future studies will be directed to evaluate senolytics-response in this senescence model.

For bone regeneration, there is great precedence to develop instructive acellular technologies that circumvent limitations with the translation of cell-based therapies. Extracellular vesicles (EVs) derived from osteoblasts enhanced stem cell mineralisation compared to BMP-2 (1, 2). Regulating the cell's epigenetics through histone deacetylase (HDAC) inhibition enhances their differentiation potential. Therefore, this study investigated altering osteoblasts epigenetic functionality via the HDAC inhibitor Trichostatin A (TSA) on promoting osteoblast-derived EVs potency.

TSA effect on osteoblast epigenetic functionality and mineralisation was determined by quantifying HDAC activity and calcium deposition. EVs were isolated from untreated/TSA treated osteoblasts for 2 weeks. EV size and concentration were defined using nanoparticle tracking analysis. EVs microRNA expression was evaluated using microarray analysis. Osteogenic differentiation of human bone marrow stromal cells (hBMSCs) cultured with untreated (MO-EVs)/TSA treated osteoblast-derived EVs (TSA-EVs) was evaluated by qPCR, biochemistry and histological analysis.

TSA significantly reduced osteoblast HDAC activity and enhanced calcium deposition when compared to untreated cells. The quantity of EVs generated, in addition to their protein content and size correlated with the degree of osteoblast differentiation. TSA-EVs accelerated hBMSCs proliferation and migration compared to MO-EVs. Importantly, TSA-EV treatment significantly upregulated hBMSCs osteoblast-related gene/protein expression (ALP, Col1a, BSP1, OCN) and promoted extracellular matrix mineralisation when compared to MO-EV treatment during osteogenic culture. Microarray analysis revealed TSA-EVs were enriched with several pro-osteogenic microRNAs involved in regulating mechanisms such as "endocytosis" and "Wnt signalling pathway".

Together, epigenetic reprogramming provides a novel engineering approach to enhance the therapeutic efficacy of osteoblast-derived EVs for bone augmentation strategies.

Although during physio-pathological processes there is an extensive crosstalk among musculoskeletal tissues, traditionally the single components have been studied separately1. To better investigate the pathogenesis of specific musculoskeletal diseases, it is necessary to develop advanced in-vitro models able to replicate the architecture and interface of musculoskeletal tissues through the integration of multiple biological components in the same device2.
Here, a mesoscale human muscle-tendon-bone interface was created using a perfusable multi-chamber device. Computational simulations were performed to optimize the geometry of the device and minimize (<10%) the level of mixing of the different media used to culture the different tissues, while allowing an adequate fluid dynamic stimulation of the biological construct (mean fluid velocity 7mm/s, mean wall shear stress 25mPa). 12 different configurations were tested using a syringe pump to perfuse the device. A digital light processing-based bioprinter was applied to produce the biological construct orienting muscle and tendon fibers towards the main direction of the flow and replicating the bone macroscopic porosity3. A single process was used to realize the continuous biological construct, embedding in gelatin/methacryloyl-based hydrogel myoblasts, tendon fibroblasts, and osteogenically differentiated mesenchymal stem cells4.
Multi-cellular constructs structurally and functionally connected were developed stimulating each tissue with the proper conditions to optimize their maturation. Subsequently, a model of tendinous inflammation, observable in every tendinopathy, was developed assessing its propagation towards muscle and bone. The proposed model represents an innovative and versatile tool to investigate all those physio-pathological mechanisms in which the crosstalk between different tissues plays a dominant role.

SECRETORY AND TRANSCRIPTIONAL ACTIVITY OF RAT BONE MARROW OSTEOPROGENITORS AFTER 14-DAY HINDLIMB SUSPENSION

Elena Markina[P][1], Milena Daniel[1], Ludmila Buravkova[1]

[1] SSC RF – IBMP RAS, Moscow

Corresponding author's email: goncharova-tim@list.ru

It is known that during space flight and under simulation of microgravity effects, negative changes in bone tissue are observed. The RANK/RANKL/OPG system and proinflammatory mediators (IL-1,-6,-11, TNF-a) play a significant role in bone remodeling processes. Studies of changes in the potential of bone marrow osteoprogenitors in microgravity are relevant of understanding of bone regenerative processes.

The goal of our work was to study the effect of 14-day suspension and subsequent 14-day recovery on the secretory and osteoprogenitors transcriptomic activity. For this purpose, the rat bone marrow cultured stromal cells secretom was investigated. Gene transcription in MSCs was determined by quantitative PCR.

After hindlimb suspension, the SPP and Cxcl12 genes expression in MSCs was down-regulated and osteoprotegerin (OPG) and sclerostin (SOST) concentration in cultured medium was decreased. At the same time the level of IL-6 and TNF-a was increased. After readaptation, the expression SPP, Cxcl12 genes was the same the same as in the control group. The OPG concentration was high and the SOST secretion remained low. At the same time, the IL-6 and TNF-a concentration in the culture medium was decreased up to control level.

Thus, the support unloading during 14 days leads to an inhibition of the bone marrow osteoprogenitor activity, which determined the processes of bone remodeling. This was accompanied by decreasing of their osteoplastic function. After 14-day readaptation, osteogenic bone marrow progenitor activity recovered.

This work was supported by the basic research program of the SSC IMBP RAS 65.3 and the RFBR grant 19-015-00206

Objective: In many clinical situations, the need for skin grafting is raised. One method of providing connective tissue is xenograft or allograft acellular Dermis. If the specifications of the xenograft meet the requirements for the transplant operation, it is superior to the allograft; one of these capabilities is the mechanical properties of alternative skin tissue. This study aimed to investigate the mechanical properties of Lapine cellular Dermis tissue versus the mechanical properties of human cellular skin for extensive production and tissue replacement applications.

Methods: Human and rabbit skin samples were divided into two groups of control and intervention after transfer to the laboratory. In the intervention groups used the same acellularization protocol for Lapine tissue and for human tissue. The control groups did not receive any treatment. After removing the cells from the tissues, the necessary incisions and molding were performed on the samples, and all groups were subjected to a tensile test with the Instron 5566, USA, and the amount of tissue tension compared. The rate 5mm/min.

Results: The results showed that in human samples, the difference in tensile properties between the intervention group and the control group was significant ($p<0.001$). This difference was also significant in the rabbit samples ($p<0.001$). In addition, there was a significant difference between the human intervention group and Lapine ($p<0.001$).

Conclusion: Despite the significant differences between the control and intervention groups and also between the intervention groups, the values obtained are still acceptable as a skin alternative according to previous studies.

MICRO ENGINEERED PLATFORMS TO STUDY AND CONTROL EMBRYONIC MORPHOGENESIS USING IN VITRO STEM CELL-BASED MODELS

Pinak Samal[1], Clemens van Blitterswijk[1], Roman Truckenmüller[1], Stefan Giselbrecht[1]

[1] *MERLN Institute for Technology-Inspired Regenerative Medicine, Maastricht University, Universiteitssingel 40, 6229 ER Maastricht, The Netherlands*

Corresponding author's email: p.samal@maastrichtuniversity.nl

Stem-cell-based in vitro models of morphogenesis can help shed light on the mechanisms involved in embryonic patterning. These models have been previously showcased by others using traditional cell culture platforms which have limited single-cell imaging capabilities and control over the biological system. Using micro engineered tools can help in precise control over the culture microenvironment and real-time data acquisition. This can in turn aid in further understanding the underlying mechanisms involved in tissue formation. Here, we describe thin polymer based microdevices, which were fabricated using microthermoforming, and show their application to study in vitro morphogenesis(1). A pipeline consisting of open-source software to quantify 3D cell movement within stem cell aggregates using automated image acquisition was developed. Finally, the platform was applied to study and control morphogenesis in 3D cultures of the P19C5 mouse cell line and mouse embryonic stem cells (mESCs), which both show symmetry breaking and axial elongation events similar to early embryonic development. The results obtained in this study indicate that polarization and elongation of the mESC aggregates are dependent on directed cell migration. The platform was applied for testing the effect of the drug Latrunculin A on aggregate morphogenesis and exposure to the drug was found to impair cell migration within the aggregate. Overall, this method paves way for high-throughput studies and drug testing applications using in vitro models, which mimic embryonic development.

Introduction: The formation of the terminal complement complex (TCC), a complement system activation product that triggers inflammation and cell lysis, was previously identified in degenerated discs, being correlated with their degeneration degree [1]. However, it is unclear which molecular factors play a role in complement activation during disc degeneration (DD). Therefore, we investigated possible triggers of TCC formation in DD.

Methods: Disc biopsies were collected from adolescent idiopathic scoliosis (AIS, n=8, age 16±3) and DD (n=11, age 56±15) patients with ethical approval and informed consent. Standardized tissue punches from nucleus pulposus (NP), annulus fibrosus (AF) and endplate (EP) were separately cultured. Tissues were stimulated with medium containing 5% human serum alone or supplemented with interleukin-1β (IL-1β, 10ng/mL) or cathepsin-D (0.5ug/mL). Serum-free medium served as control. TCC formation and CD59 (TCC inhibitor) expression were analyzed by immunohistochemistry. Statistics: one-way ANOVA.

Results: No differences were found between scoliosis and DD patients. IL-1β stimulation led to lower percentage of TCC+ cells in AF and EP ($p<0.05$), whereas cathepsin-D significantly increased TCC deposition in NP ($p<0.01$). The percentage of CD59+ cells significantly increased in AF and NP after cathepsin-D stimulation ($p<0.05$).

Conclusion: Interestingly, IL-1β led to less TCC deposition in AF and EP, indicating that it may influence DD it via a negative feedback mechanism. In contrast, cathepsin-D, an important player in osteoarthritis, but poorly described in DD, triggered TCC deposition in NP. Mechanistic studies are ongoing, but these results suggest a functional relevance of IL-1β and cathepsin-D in modulating TCC formation in DD.

ULTRA-HIGH THROUGHPUT PRODUCTION OF HOLLOW MICROMATERIALS BY IN-AIR MICROFLUIDICS FOR TISSUE ENGINEERING APPLICATIONS

Bas van Loo[1], Nuno Araújo-Gomes[1], Vincent de Jong[1], Tom Kamperman[1], Jeroen Leijten[1]
[1] *Department of Developmental BioEngineering, TechMed Centre, University of Twente, the Netherlands*

Introduction:
Hollow micromaterials such as hydrogel microcapsules are gaining attention for the production of cellular aggregates and drug delivery purposes.[1] Although microfluidic production of microcapsules offers several advantages over conventional micro-aggregate forming techniques, current approaches suffer from low production throughputs and required use of oils and surfactants, which hinders clinical and industrial applications. To address this challenge, we report on the use of a recently developed platform, named In-Air microfluidics[2], enabling ultra-high throughput production of multiple types of hollow micromaterials in an oil-free and surfactant-free manner.

Methods:
Multiple In-Air microfluidic designs were assessed on their ability to produce hydrogel microcapsules composed of a 10% dextran core and a 0.2% alginate shell. Monodisperse microcapsules with diameters between 80 and 300 µm were produced with production rates as high as 6 ml/min.

Results/discussion:
A two nozzle design effectively produced bulk gels composed of monodisperse hollow compartments. Collecting the flow-through in a stirred collection bath with optimized rotational speed allowed for production of continuous microfibers with regularly spaced hollow compartments. These compartmentalized fibers can form large amounts of consistent and functional 3D microtissues which benefits straightforward retrievability for in vivo applications. Using a three nozzle approach, individual monodisperse single-, double-, and triple-core hollow microgels could be produced in an ultra-high throughput and single-step manner. Microcapsules demonstrated high cell viability and allowed for 3D cellular microtissue formation.

Conclusion:
In-Air microfluidics can be used to fabricate distinct hollow-core micromaterials in a clean and ultra-high throughput manner to facilitate clinical and industrial applications of hollow micromaterials.

Background. Endothelialized vascular prostheses exhibit comparable patency to gold-standard vein grafts[1]. However, patients with acute ischemia cannot tolerate the prolonged endothelialization procedure, which is largely due to the expansion of endothelial cells (ECs) from explanted veins[1]. Adipose-derived ECs (AMVECs) can be readily harvested intra-operatively, but have failed to improve patency[2]. It was hypothesized that residual stromal cells (ASCs) from the sorting procedure undermine the temporal stability of the AMVEC-derived endothelium.

Methods. In vitro models were generated from human adipose tissue. Population doubling times (PDT) of AMVECs and ASCs were characterized. Cells were seeded in pre-defined proportions to re-capitulate different efficacies of AMVEC enrichment. Effect on proliferation was assessed by flow cytometry, and localization by confocal microscopy.

Results. PDT of AMVECs > ASCs (51.3±9.1 vs. 23.6±3.3hrs, respectively; $p<0.05$). AMVEC proliferation was correlated with seeding purity, exhibiting growth inhibitions of 59.5±12.8% and 83.7±7.5% when ASCs comprised 20% and 80% of the seeding density, respectively ($p<0.05$). These disparate growth-kinetics culminated in AMVECs comprising 23.0±17.1% and 1.0±0.8% of the co-cultures after only 4dys ($p<0.05$ vs. 80% and 20% seeding purity, respectively). While pure AMVECs (98.8±0.8% CD31+) integrated into a stable monolayer for >21dys, mixtures of AMVECs and ASCs (1:1) reorganized into microvascular networks in <7dys.

Conclusion. AMVEC-seeded vascular prostheses tend to stenose from diffuse neo-intimal hyperplasia[2]. This may be attributed to poor seeding purities and the disparate growth kinetics of AMVECs and ASCs, which also destabilizes the endothelium. Strategies to obtain pure AMVECs to improve the temporal stability of the endothelium are under investigation.

The growth of cultured cells is governed by factors within the microenvironment[1]. The dynamic motion of blood through tissue is absent in conventional cell culture and while several systems have attempted to introduce dynamic fluid flow to support cell models in vitro these often have a large footprint, require complex apparatus, are expensive, and have limited scalability.

To overcome these limitations, we have developed a compact benchtop perfusion bioreactor system which allows three-dimensional, centimetre-scale cell constructs to be formed with fluid flow through multiple cell layers maintaining high, homogenously distributed nutrient availability. Using computational fluid dynamics, the levels of mass transfer and shear stress in the system have been calculated and tuned to guide bioreactor design and operation in consideration of the tissues grown. The liver was chosen for preliminary testing of our novel device as it is a complex and highly perfused organ that should benefit from media perfusion and increased mass exchange[2].

Culture of HepG2-based liver models utilising Alvetex® Scaffold as a supporting membrane for the cells in this bioreactor system led to a more physiologically relevant morphology with greater expression of key drug transporters and formation of hepatocyte-specific structures such as bile canaliculi compared to static cultures. Further work with this system has incorporated additional oxygen control allowing the culture of ex vivo precision-cut liver slices which demonstrated sustained viability during multi-week culture. These results demonstrate the potential for this bioreactor technology to produce physiologically relevant cultures in a well characterised microenvironment whilst keeping technical complexity low.

Mesenchymal stromal cells (MSC) derived from human umbilical cord Wharton's jelly (WJ) have a wide therapeutic potential in cell therapy and tissue engineering because of their multipotential capacity, which can be reinforced through gene therapy in order to modulate specific responses. However, reported methodologies to transfect WJ-MSC using cationic polymers are scarce. Here, WJ-MSC were transfected using 25kDa branched-PEI and a DNA plasmid encoding GFP. PEI/plasmid complexes were characterized to establish the best transfection efficiencies with lowest toxicity. Expression of MSC-related cell surface markers was evaluated. Likewise, immunomodulatory activity and multipotential capacity of transfected WJ-MSC were assessed by CD2/CD3/CD28-activated PBMNC cocultures and osteogenic and adipogenic differentiation assays, respectively. An association between cell number, PEI and DNA content, and transfection efficiency was observed. The highest transfection efficiency (11.9±2.9%) at the lowest toxicity was achieved using 2 ng/uL DNA and 3.6 ng/uL PEI with 45,000 WJ-MSC in a 24 well-plate format (200 uL). Under these conditions, there was no significant difference between the expression of MSC-identity markers, inhibitory effect on CD3+ T lymphocytes proliferation and osteogenic/adipogenic differentiation ability of transfected WJ-MSC, as compared with non-transfected cells. These results suggest that functional properties of WJ-MSC were not altered after optimized transfection with PEI.

Reconstruction plates, used to bridge segmental defects of the mandible, are subjected to repeated stresses of mastication. High stress concentrations can result in hardware failure (1). Topology optimization (TO) could reduce peak stress by computing the most optimal material distribution in a patient-specific implant (PSI) for mandibular reconstruction (2). The objective of this study was biomechanical validation of a TO-PSI. A computer-aided design (CAD) model of a mandible with a segmental defect was created and a standard-PSI was designed. A TO-PSI was then designed with a maximum stress equal to the ultimate tensile stress of Ti6Al4V (930 MPa) during a loading condition of 378 N. Finite element analysis (FEA) was used to analyze stresses during loading. Both designs were subsequently produced in triplicate from Ti6Al4V, fixated to polyurethane mandible models with segmental defects identical to the CAD model, and subjected to continuous compression. Fracture of the TO-PSI occurred at a median peak load of 334 N (range 304-336 N). Fracture of the mandible model in the standard-PSI group occurred at a median peak load of 1100 N (range 1010-1460 N). Failure locations of TO-PSI and standard-PSI samples corresponded to regions in the FEA where stresses exceeded the ultimate tensile strength of Ti6Al4V and polyurethane, respectively. Failure occurred within a 30% range of the predicted peak load, demonstrating a successful preliminary biomechanical validation of TO in the design process of mandibular reconstruction plates. Future work will focus on refining the finite element model, to further optimize the design process of TO-PSIs.

We have designed a channeled device to facilitate supply of oxygen and nutrients throughout the engineered device in order to overcome the limitation in construct size due to oxygen diffusion. A channeled device mimicking a leaf was designed using CAD and the flow through the channels was optimized in simulation studies. The construct was fabricated by 3D bioprinting using Pluronic F-127 as sacrificial ink to print the channels. The actual leaf was bioprinted using tunicate cellulose nanofibers (TUNICELL) and alginate bioink and crosslinked in calcium chloride. The resulting device was a 35x18x3 mm leaf with one main channel connected to several side channels. Surface modification using periodate oxidation followed by laminin bioconjugation was performed to enhance cell adhesion. Time-of-flight secondary ion mass spectrometry (ToF-SIMS) analysis verified protein binding to the surface and Human umbilical vein endothelial cells (HUVECS) were used to show that endothelialization was possible. The device was perfused in a bioreactor developed under German Space Agency (DLR) contract for life science research missions under microgravity conditions. It was inherently developed for living cells and therefore is biocompatible and includes pumps and tanks to supply the cells with necessary nutrients as well as remove by-products of cellular metabolism. Media was successfully perfused through all the leaf hydrogel channels with periodic and continuous perfusion. The effect of flow rate on cell viability of stem cell laden hydrogel was evaluated. The biofabricated hydrogel leaf device shows great promise for the use as a perusable vascularized tissue engineered construct in various applications.

INTRODUCTION: Pulmonary arterial hypertension (PAH) patients ultimately die of right ventricular (RV) failure. To date there is no treatment because of no suitable pre-clinical models to study the RV.Therefore, we aim to develop a RV failure model to unravel the mechanisms that determine the fate of the RV by implementing the 3-dimensional engineered heart tissue (EHT) approach[1] with cardiomyocytes derived from PAH-patient induced pluripotent stem cells (iPSCs).

METHODS: iPSCs from PAH and healthy subjects were differentiated into cardiomyocytes (iPSC-CMs)[2], incorporated into the EHT, and cultured for 28 days (D). By changing stiffnes of the post we induced afterload [1]. Functional measurements (force, frequency, time and velocity) were achieved. Statistical analyses between normal and stiffer posts, and D14 or D28 were performed.

PRELIMINARY RESULTS:

We observed functional differences between control and PAH-EHTs with normal posts. After D14, PAH-EHTs generated higher force (P=0.001), contraction (P=0.013) and relaxation (P=0.002) times, and contraction (P=0.011) and relaxation (P=0.059) velocities compared to control EHTs. After D28, PAH-EHTs showed lower force (P=0.043), contraction (P=0.087) and relaxation (P=0.007) times, and contractile (*P=0.025) and relaxation (*P=0.038) velocities compared to control EHTs. There were no functional differences between normal and stiffer EHTs, except increased beating frequency (*P=0.017) on PAH-EHTs compared to control EHTs at D14, probably due to small group size (N=2).

CONCLUSIONS:

Under physiological conditions, control EHTs are more stable than PAH-EHTs, which force was drastically reduced at D28. Further optimization and profound characterization will be useful to unravel pathophysiological insights, as well as disease modeling and drug screening.

Abstract **#615**

EFFICIENCY OF MINIMALLY MANIPULATED BONE MARROW CELLS TO REGENERATE OSTEOCHONDRAL DEFECTS

Chaozong Liu[P][1], Maryam Tamaddon[1]
[1] *University College London*
Corresponding author's email: chaozong.liu@ucl.ac.uk

Bone marrow concentrate (BMC) is increasingly used as biological tool for the orthopaedic applications and it serves as a source of growth factors and mesenchymal stem cells (MSCs) [1] in a one-step procedure. This study is to investigate the efficacy of BMC in conjunction with an osteochondral (OC) scaffold for treatment of osteochondral defects in sheep knee joints.

Bone marrow was aspirated from iliac crest of the sheep in group 2 and was processed using NTL Biologica kit in the operating theatre. An osteochondral defect was created in medial condyle, scaffold with or without BMC was implanted in the osteochondral defect. The tissue was retrieved 6 months post-op, and bone integration and cartilage formation were examined to assess the effect of BMC on cartilage regeneration.

Large variations (up to 2 times) were observed between the TNC of different sheep. ICRS scoring of regenerated cartilage showed no statistically significant differences between the BMC and non-BMC groups ($p>0.05$). Histological staining of cartilage with Alcian Blue and Safranin-O showed similar cartilage formation in both groups qualitatively and quantitatively (Bern Score), there was no significant difference between the cartilage quality of the groups. Bone regeneration (%BV/TV) was higher in the BMC-containing group (62.78%±7.9 vs 58.62% ±13), however the difference was not significant ($p>0.05$). No

Collectively, these data suggest that BMC seems to have limited effect on regeneration of bone and cartilage in osteochondral defects. Although bone regeneration was slightly improved the improvement was not statistically significant.

Introduction: The formation of spheroidal multicellular aggregates for hepatocytes has drawn attention as it has been shown to closely mimic the natural environment found in vivo [1]. Due to many factors that influence the formation of aggregates/spheroids, coupled in-silico and in-vitro modelling of hepatocyte cell aggregation is important in order to reduce the number of experiments and optimize the necessary conditions to form the aggregates/spheroids.

Experimental methods: Differentiated human hepatocytes (HepaRG) and hepatic stellate cells (LX-2) have been used to form hepatic spheroids at a ratio of 4:1 similar to that of parenchymal:nonparenchymal cells in the liver tissue. Formation of the hepatic spheroids was achieved using 2 conventional methodologies i.e. low adherent coating surface to form spheroids and a high-density array of pyramid-shaped microwells, into which a suspension of single cells is centrifuged-AggreWell system.

Numerical methods: Partial differential equations explain the early stages of the cell aggregation process, starting from the principles of mass and momentum balance for cells, culture medium, and ECM production [2]. Based on many input parameters including different material characteristics for the low adherent coating and cells etc., the model predicts the cell volume fraction, velocity of the cells, and cell density as a function of time.

Results and conclusions: Developed model is able to predict formation of aggregates and how different parameters affect the number of aggregates, as well as their speed of aggregation. Developed model can be used for experimental planning and is a step towards improved biomaterial risk assessment.

Additive manufacturing Technologies have changed the way we design and fabricate structural components, especially for bioengineering applications (e.g., prosthetic replacements, biocompatible tissues for in vitro studies) (1). We present an in silico analysis of a 3D printing nozzle, investigating the best sagittal cross section to minimize the shear stress on the ink and, thus, improving the printing quality. We employ a synergistic approach based on a finite-element model elaborated with Comsol Software that provides labeled data for a deep learning model, developed with Jupiter Notebook (2). We build an axysimmetric model of the nozzle with linear features, whose dimensions fall in the range of commercial components. While the dye is modeled as a rigid fixed component, we model the ink as a deformable compound consisting of silk/hydroxyapatite, a composite that is used to mimic bone (3). The deep learning model is trained by thousands of samples that include several key features for 3D printing (e.g., final diameter of the nozzle, volume flow rate). The results show a good ability to predict the shear stress of the nozzle (≈75%), and we further extend this model with an evolutionary algorithm to obtain an optimal design of the nozzle based on the specific ink. This methodology can potentially change the way we currently design 3D printing nozzles by adapting the structural topology of the nozzle to the specific ink and printing applications, especially in those fields in which strict design requirements play a key role on the final product.

INJECTABLE HYPERBRANCHED POLY(B-AMINO ESTER) HYDROGELS WITH ON-DEMAND DEGRADATION PROFILES TO MATCH WOUND HEALING PROCESSES

Qian Xu[P][1], Sigen A[1], Wenxin Wang[1]

[1] *University College Dublin*

Corresponding author's email: qian.xu@ucdconnect.ie

Injectable hydrogels, with the ability to be introduced through minimal invasion and to fill any defect or cavity, have been extensively used for cell delivery in tissue regeneration in recent years. However, due to limited control of the material degradation process to match tissue integration, so far the developed injectable hydrogels have not fulfilled their potential.[1] Herein, an injectable hydrogel was developed with optimized degradation profiles to treat two different types of humanized excisional wounds (acute and diabetic).

Biodegradable hyperbranched poly(b-amino ester)s (HP-PBAEs) were newly designed and synthesized via "A2 + B4" Michael addition polymerization, and displayed fast gelation with thiolated hyaluronic acid (HA-SH) via a "click" thiol–ene reaction. Rheological measurements, degradation and water retention capacity tests, and dynamic/strain sweep tests were conducted on a series of HP-PBAE/HA-SH hydrogels.

The injectable hydrogels showed controllable and adjustable degradation profiles both in vitro and in vivo, using diamines with different alkyl chain lengths and poly(ethylene glycol) diacrylates with varied PEG spacers.

Two hydrogels with optimized degradation rates were used to encapsulate adipose-derived stem cells (ADSCs) and injected onto humanized excisional wounds (the humanized wound model can better mimic the human cutaneous healing process). Hydrogels with a faster degradation rate exhibited better wound healing in non-diabetic wounds, while hydrogels with a slower degradation rate showed a faster wound closure rate and significantly promoted the healing process as evidenced by histological assays for diabetic wounds.

The new HP-PBAE-based hydrogels in combination with ADSCs provide an alternative approach in accelerating the wound healing process.

In osteoarthritis, there is progressive damage of cartilage tissue. Because of the limited self-healing capacity of cartilage, it is important to investigate regenerative therapies. With their high water content, hydrogels are suitable for regenerative medicine applications. Chondroitin sulfate (CS) and hyaluronic acid (HA) are glycosaminoglycans found in native cartilage tissue. Therefore, hydrogels based on CS and HA are potentially useful for cartilage replacement therapies. However, such hydrogels usually lack mechanical properties when compared to synthetic hydrogels. Double network (DN) hydrogels are a class of hydrogel materials based on two interpenetrated networks, which often deliver promising mechanical properties. Here, we aimed to develop an in situ gelling, double network hydrogel, made out of CS and HA. The crosslinking chemistries were based on dynamic covalent interactions (Diels-Alder and hydrazone bonds). Two types of functionalized CS were prepared: a CS containing aldehyde groups (degree of functionalization DoF 10%), and a CS bearing maleimide moieties (DoF 15%). HA was functionalized with methylfuran groups (DoF 40%). In addition, adipic dihydrazide was used to crosslink oxidized CS. Gelation of the single networks was successful. These polymers were further combined to form a DN hydrogel (at 20 wt%), characterized by tunable viscoelastic and stress relaxation properties. It was shown that hydrazone-based network was shear-thinning, reversible and self-healing, which allowed for initial processing (e.g. extrusion), before the system was further crosslinked by Diels-Alder reaction. Cytocompatibility of the DN hydrogel is being investigated in order to assess suitability of the system to carry cells responsible for cartilage regeneration.

OSTEOCHONDRAL SCAFFOLD INNOVATION FOR EARLY INTERVENTION OF CARTILAGE DEFECT: FROM BENCH TO CLINIC

Chaozong Liu[P][1], Maryam Tamaddon[1]
[1] *University College London*
Corresponding author's email: chaozong.liu@ucl.ac.uk

The treatment of cartilage defects remains a challenge because treatments to date have failed to achieve a complete restoration of the joint cartilage surface and its properties. We have invented a novel osteochondral scaffold based on Titanium and PLGA matrix reinforced collagen/hydroxyapatite composite system for repair of large osteochondral defects, evaluated the in vivo performance using sheep condyle model, and has proceeded to first in man clinical study [1, 2].

Sheep medial formal condyle mode was used to evaluate the in vivo performance. The tissues were retrieved six months post-operation. The retrieved tissues were examined by histological and histomorphometry in terms of mechanical stability and biological fixation of the scaffold. A clinical dog shoulder model was used for preclinical study of the safety and efficacy of the osteochondral scaffold.

Retrieved tissue, from sheep condyle model, examinations revealed that good levels of defect fill, and formed hyaline cartilage-like tissue, and integrated well with the surrounding healthy tissues. Immunohistochemical staining revealed formation. pQCT and micro-CT examinations revealed bone ingrowth into Titanium matrix and form a strong integration with the surrounding bone. The bone-implant contact was calculated to be 61% (±15), and BV/TV ratio was significantly higher (p=0.01) in the scaffold group (~70%) compared to control group (~45%).

The sheep study has demonstrated the developed scaffold has the strength needed to bear the physical load of the joints and its patented biomedical structure encourages consistent cartilage fill. This novel scaffold would enable surgeons to intervene earlier, to prevent progression of the condition.

Aim: Many patients affected by end stage kidney disease depend on dialysis for survival. However, hemodialysis does not remove efficiently protein-bound uremic toxins (PBUTs), thus leading to severe comorbidities. Therefore, novel treatments, such as a bioartificial kidney (BAK), are needed. Here, efficacy and safety of a BAK device based on conditionally immortalized proximal tubule epithelial cells (ciPTECs) and hollow fiber membranes (HFM), are being evaluated.
Methods: Firstly, ciPTECs compatibility with PES/PVP HFM was determined. Subsequently, a prototype BAK was built to evaluate its capacity to remove PBUTs in vivo. Finally, stability of membrane coating was assessed by LC-MS/MS quantification.
Results: Collagen IV, L-DOPA [1,2] and the combination of these coatings were found to support cell attachment and formation of epithelial monolayers (F-actin staining). The polarization and tightness of monolayers were confirmed by increased expression of ZO-1, cilia presence and reduced FITC-inulin leakage by 70.7% ($p<0.0001$). The activity of OAT-1 transporter was determined by means of fluorescein uptake in absence and presence of probenecid (100±15.7% vs 64.9±15.1%; $p=0.18$). L-DOPA was found to be released from coated HFM only during the first 3 days (6.7±1.7 ng/ml, $p<0.005$). For in vivo efficacy studies, prototype BAK devices containing 10 HFM with surface area of 19.1 cm2 and blood and dialysate compartment volumes of 0.12 ml and 12 ml respectively, were prepared.
Conclusion: CiPTECs can be grown on L-DOPA coated PES/PVP HFM, to form functional epithelial monolayers. Prototype BAK device was successfully built to determine PBUTs clearance in rodents, and the results are expected soon.

Cells dynamically interact with their microenvironment via cell-matrix interactions. However, engineered biomaterials are often endowed with permanent and static adhesive moieties such as RGD motives. These adhesion strategies are associated with increased chronic inflammation upon implantation [1]. Here, we pioneer a novel cell binding technology, called 'Direct On-cell Crosslinking' (DOCKING), that directly tethers intrinsically non-adherent (e.g., RGD-free) biomaterials to cells via a universal and cytocompatible enzymatic crosslinking reaction between polymers and cellular proteins.

Specifically, we explored crosslinking of tyramine-modified biomaterials such as dextran (Dex-TA) to tyrosine residues on mesenchymal stem cells (MSCs). Subcutaneous implantation of Dex-TA hydrogel disks in C57BL/6 mice revealed significantly less fibrotic capsule formation as compared to Dex-TA-RGD. Adhesion of individually encapsulated cells within Dex-TA microgels via DOCKING was visualized by confocal and scanning electron microscopy. Mass spectrometry confirmed that DOCKING-targeted proteins associated with the cellular adhesome [2] and particularly connected to integrins alpha-5 and beta-1. Dynamically tuning the stiffness of cell-laden microgels via in situ enzymatic post-curing confirmed transduction of mechanical cues from the biomaterial to the encapsulated MSCs. For example, mechanotransduction as a direct result of DOCKING was indicated by upregulation of adipogenic and osteogenic genes as early as on day 1 of differentiation in soft (2.5 kPa) and stiff (45 kPa) microgels, respectively, and was likely mediated through nuclear lamin A/C.

In conclusion, enzymatic DOCKING provides a novel strategy that minimizes adverse host responses such as fibrous capsule formation to biomaterials, while enabling mechanical interactions with encapsulated cells to steer cell fate via mechanotransduction.

There is a dire need for a heart valve that grows with children. We fabricated tubes of biologically-engineered matrix previously shown to regenerate and grow as a pulmonary artery replacement in lambs, and implemented a novel valve design made from sewing three of these tubes together with degradable suture that confers growth potential. Seven lambs were implanted with tri-tube valved conduits in sequential cohorts and compared to bioprosthetic conduits. Valves implanted in two lambs of the first cohort of four animals functioned with only mild regurgitation and systolic pressure drops <10 mmHg up to 52 weeks post-implantation, during which the valve diameter increased from 19 mm to a normal ~25 mm. In a second cohort of three animals, an additional tube was used to create a sleeve around the tri-tube valve to counteract faster root growth relative to the leaflets. Two valves exhibited only trivial-to-mild regurgitation at 52-weeks with similar diameter increase and systolic pressure drops of < 5 mm Hg. The third animal exhibited moderate regurgitation at 52 weeks correlating to hyper-increase of valve diameter. In all explanted valves, the leaflets remained thin and pliable with only sparse, punctate microcalcification at most, and they contained interstitial cells and an endothelium progressing from the base of the leaflets. These results are superior in terms of calcification and hemodynamic function compared to reported studies for clinically-used pediatric bioprosthetic valves tested in the same model. The results demonstrate the potential for long-term valve growth of this “off-the-shelf” tri-tube valved conduit in children.

PSEUDOPOLYROTAXANE HYDROGELS FOR NEURAL TISSUE ENGINEERING APPLICATIONS

Emmanuel Kanelos$_P$[1], Rylie Green[1], Josef Goding[2]

Corresponding author's email: edk16@ic.ac.uk

Hydrogels are a cornerstone of neural tissue engineering, replicating extracellular matrix and supporting cell growth. An underexplored class of hydrogels are pseudopolyrotaxanes (PPRs) which possess a bead on a string supramolecular structure such as that formed between polyethylene-glycol (PEG) and cyclodextrin (CD). These systems possess desirable properties such as shear-thinning, easy biofunctionalization and tuneable mechanics for tailorable systems. Previous studies have not achieved degradability, used single biofunctionalisations and focused only on bone engineering. Here swelling, degradation and mechanics of PEGDA/CD gels are explored. Finally, we investigated the effect of dithiothreitol (DTT) on hydrogel degradation.

In PEGDA-CD rotaxane gels it is observable that swelling is decreased significantly with the addition of CD, due to the hydrophobic complex formed. Apart from initial sol-fractions, mass-loss does not occur over 28 days regardless of CD loading. Likewise, compression studies established the Young's modulus between 4-6 kPa and unaffected by CD loading. To address degradation, dithiothreitol (DTT) was introduced at molar ratios of 1:4,1:10, and 1:20 (DTT:PEG). A dose dependent response was observed, the highest concentration resulted in 75% mass-loss, whereas the lowest resulted in none. Thus, DTT is a low-cost method to control degradation. This is the first instance of thio-ether acrylate rotaxanes being investigated for neural tissue engineering.

Thio-ether PEGDA/CD gels are versatile systems with easy introduction of multiple functionalisations and tailorable mechanics. Coupled with shear-thinning properties there is great potential in injectable brain tissue engineering applications. Future work will investigate the biofunctionalization of CD for neural applications and full characterisation of mechanics.

Corresponding author's email: gfreund@ukaachen.de

Issue: Stem cells obtained from human fat tissue (ASCs) are multipotent progenitor cells, being able to differentiate into different mature cells, including osteocytes. Standard cultivation with fetal bovine serum (FBS) carries risks such as immunization and xenogeneic infection. Replacement of FBS is inevitable for future translation into clinics. However, altered media compositions could influence ASC proliferation and differentiation. In this study, ASCs were expanded and differentiated at decreasing concentrations of FBS on a 3D bromid free fibroin sponge to evaluate the effect on cellular vitality as well as on osteogenic differentiation.

Methods: We examined proliferation using PrestoBlue conversion (PB) and differentiation into the osteogenic lineage over a period of 14 days with 0-2% FBS concentration. Alkaline phosphatase activity (ALP), calcium deposition measured by cresolphthalein staining (CP) and the osteocalcin concentration through ELISA were taken for quantification of osteogenesis.

Results: The CP labelling, ALP activity and osteocalcin concentration increased with rising FBS concentration. However, osteogenic differentiation was also achieved at 0% FBS and showed significantly higher CP values in comparison to the control group. Osteogenic differentiation was still obtained on declining proliferation. Overall elevated measurements for ALP activity, cell numbers and osteocalcin secretion were observed for the 3D in comparison to the 2D culture.

Conclusion: Based on this data, it seems possible to achieve osteogenic differentiation of ASCs independently from xenogeneic serum supplements in a 3D culture by using silk fibroin scaffolds. This would lead to a reduction of xenogenic risks with a prospective in vivo and possible clinical translation.

Chronic venous insufficiency affects over 2 million patients in the US alone, with severe cases involving thousands of patients with chronic leg ulcers and potential amputation. A transcatheter vein valve made from a biologically-engineered matrix possessing the ability to regenerate has the potential to provide both valve function and long-term hemocompatibility and durability because the matrix becomes endothelialized and populated with host tissue cells. We developed a novel tissue-engineered transcatheter vein valve (TEVV) on a Nitinol stent1 and demonstrated function and durability in vitro. Tissue was grown from fibroblasts in fibrin gel so as to embed the stent, with a tubular extension of the engineered tissue from one end of the stent that was stitched along opposite sides and everted into the stent to form a bileaflet valve. Following decellularization, to create an “off-the-shelf” TEVV comprised of the resulting collagenous matrix, it was tested in a pulse duplicator to evaluate hydrodynamic properties. The TEVV was shown to have forward pressure drops in the range of 2-4 mmHg, low closing volume, and nil regurgitation. Further hydrodynamic tests were performed after crimping and then again after 1 million cycle durability testing, showing no degradation of valve performance or any visual damage to the matrix. The TEVV held over 600 mmHg backpressure after the durability testing, ensuring the valve would withstand pressure spikes well outside of the normal in vivo range. Catheter-based delivery into the ovine iliac vein demonstrated TEVV closing 2 weeks p.o. and endothelialization without thrombosis 8 weeks p.o.

Vascular calcification is a commonly occurring pathological process and is recognized as an independent prognostic marker for cardiovascular morbidity and mortality. Recent progress in developing novel therapies to modify vascular calcification is critically hampered due to the lack of reliable in vitro experimental models that recapitulate the structural and mechanical attributes of calcified arteries. In this study, we show the ability to model the behavior of diffuse vascular calcification in vitro using biologically-engineered grafts approximating the composition, structure, and mechanical properties of arteries.1 Transmural calcification was achieved by exposing the acellular grafts of collagenous ECM to complete medium containing elevated Calcium (Ca) and Phosphate (P) concentrations. It was found that increasing the serum concentration from 2% to 10% increased the extent and degree of calcification based on histochemical, ultrastructural, chemical and thermal analyses. The presence of variably-sized spherical calcific deposits within the matrix further confirmed its morphological similarity to pathologic calcification. Mechanical testing demonstrated up to a 16-fold decrease in compliance due to the calcification, consistent with prior reports for calcified arteries. The model developed thus has potential to improve the design and development of interventional devices and therapies for the diagnosis and treatment of arterial calcification.

Skeletal muscle tissue engineering has several applications such as the replacement of muscle tissue after volumetric muscle loss, the use as a 3D in vitro model system to study muscle physiology and in vitro drug testing. Selecting and expanding the proper cells as the starting source is an important factor to guarantee that engineered muscle closely mimics the in vivo situation. Satellite cell-derived myoblasts are often used because satellite cells are the native adult stem cell precursors for skeletal muscle. Obtaining these myoblasts in sufficient high numbers and with a high purity without compromising their myogenic potential is a challenge. In this work we tested specific coatings used to culture the myoblasts in vitro after harvesting the cells from human muscle biopsies. We monitored cell yield, cell morphology, myoblast percentage and myogenic differentiation capacity. Five different coatings were evaluated: collagen, gelatin, laminin, poly-L-ornithin/laminin and poly-L-lysine. The laminin and poly-L-ornithin/laminin coating resulted in improved myoblast attachment and proliferation compared to the other coatings. The percentage of myoblasts in the cell pool was evaluated with a desmin staining and the ability of the myoblasts to fuse into myotubes was assessed with a tropomyosin staining. The laminin-based coatings were found to maximize the myogenic versus non-myogenic ratio and resulted in the highest number of multinucleated myotubes. We conclude that the laminin-based coatings were best suited for expansion and support of myogenic capacity of satellite cell-derived myoblasts.

Human hepatobiliary LGR5+ organoids have great potential for tissue engineering purposes, as they can potentially regenerate damaged hepatobiliary tissue. However, the use of non-clinical grade mouse tumor extracellular matrix (ECM) extracts, such as Matrigel, is hampering clinical applications of these organoids. Furthermore, components of Matrigel hamper the differentiation towards mature cholangiocytes or hepatocytes. The aim of this study is to create clinical-grade tissue-specific hydrogels from human liver ECM for improving differentiation of hepatobiliary organoids.

Human livers (deemed unsuitable for transplantation, N=5) were fully decellularized in a pressure-controlled perfusion device using 4% Triton-X-100 + 1% ammonia. ECM components were extracted by pepsin digestion of the ECM to gain a viscous liver-based hydrogel. Subsequently, human liver organoids (N=15) were initiated in this hydrogel. Matrigel was used as control. Purpose-designed spinner flask were used to explore the large-scale expansion of organoids in liver ECM-hydrogel.

Liver-derived ECM hydrogels support initiation and proliferation of hepatobiliary organoids similar to BME controls. Gene expression of albumin was increased 142-fold, whereas expression of KRT-7 and KRT-19 decreased 2-fold in liver ECM hydrogel, indicating improved differentiation towards hepatocytes. Spinner flask cultures yielded up to 6-fold increase in cells/ml compared to static culture conditions.

This study shows the feasibility of creating liver-specific hydrogels, which supports differentiation of human hepatobiliary organoids. The spinner flasks were effective and allow for large-scale clinically relevant production of cells. The liver ECM hydrogels can provide an important step forward in applying these organoids in clinical settings for regenerative medicine purposes.

PHOTO-CROSSLINKABLE GELATIN-BASED HYDROGELS FOR ADIPOSE TISSUE ENGINEERING

Lana Van Damme$_P$[1]

[1] *University of Ghent*

Corresponding author's email: lana.vandamme@ugent.be

There exists a clear clinical need for adipose tissue reconstruction strategies to repair soft tissue defects which outperform the currently available approaches. In this respect, additive manufacturing has shown to be a promising alternative for the development of larger constructs able to support adipose tissue engineering. In the present work, crosslinkable hydrogels were developed which allowed cell encapsulation of adipose tissue-derived stem cells to be applied in extrusion-based bioprinting. To this end, norbornene-functionalized gelatin (Gel-NB) was combined with thiolated gelatin (Gel-SH) [1] enabling a thiol-ene click chemistry to develop a superior, cell compatible extracellular matrix (ECM) mimic.
First, the materials were synthesized and 2D sheets were characterized physico-chemically by performing gel fraction, swelling, mechanical and in vitro biodegradability assays while using conventional methacrylated gelatin (Gel-MA) [2] as benchmark. Next, both biocompatibility and the differentiation potential of encapsulated adipose tissue-derived stem cells (ASCs) were analysed via live/dead staining as well as Bodipy/DAPI and a triglyceride assay. In vivo experiments are currently ongoing assessing the differentiation potential and neovascularisation via ex vivo histology.
The results showed that the materials are able to mimic the physico-chemical characteristics of the natural ECM of native adipose tissue (viability >70%). Hence, the hydrogels could be of great interest towards future development of adipose tissue constructs and tissue engineering in general as it could offer a shift towards a patient-specific, 3D-printed, reconstructive approach, that can potentially be safer and more cost-effective compared to current clinical approaches.

Host immune response to medical devices and implantable biomaterials is key to their functional integration. Several cell types, proteins and extracellular components are involved in this innate response. Macrophages are essential in the regulation of the inflammasome and, thus, in the overall innate response, leading either to inflammation resolution or persistence. The development of biomaterial-based platforms to modulate the inflammasome and achieve favorable inflammatory responses is a promising strategy towards the promotion of implant integration and tissue regeneration. In the present work, we have developed macrophage-targeted biopolymeric-based nanocarriers for the controlled release of immunomodulatory metabolic drugs. Shikonin, a natural naphthoquinone with anti-inflammatory and inflammasome-attenuating properties, was encapsulated into zein-hyaluronic acid nanoparticles. These nanocarriers had hydrodynamic diameters near 200 nm and were efficiently taken up by human macrophages, showing no toxicity up to 1 mg/mL. The ability to modulate the cells inflammasome was also demonstrated through assessment of caspase-1 activity and IL-1β production. Moreover, NMR metabolomics was employed to monitor changes in the extracellular medium composition upon inflammasome activation and attenuation. This approach provided novel insight into how metabolites and metabolic pathways influence macrophage responses to biomaterials and immunomodulatory small molecules. Looking forward, this work is expected to foster the development of a novel class of versatile and cost-effective inflammasome-modulating biomaterials to mitigate implant-related chronic inflammation and promote tissue regeneration.

Information extraction is fundamental to scientific research, however, when done manually, it's extremely time-consuming and often comprises re-work. Alternatively, automated data extraction renders up-to-date, quick, and easy access to information. Nevertheless, there is little precedence of using automated text mining tools to extract information in the biomaterials domain[1].

Here, we compare the ability of contemporary text mining tools to extract useful information from biomaterials abstracts. As a topic, we selected 'polydioxanone' which, despite being a widely-used biomedical material, has a relatively limited literature, thus enabling manual validation of results.

We filtered abstracts using a machine learning classifier, utilising a Support Vector Machine algorithm trained on a previously-published gold standard set[2]. Following corpus definition and validation, we compared information extraction tools, including PubTator, text analysis methods, and DEBBIE, an open-access annotation pipeline of biomaterials, implants and medical devices.Results were analysed in conjunction with a manual review of the literature and existing systematic reviews.

Our findings show that lexical annotations of diseases and species by non-specific tools were accurate, but there were some inaccurate tags and categories. DEBBIE, as a biomaterial-specific tool, can annotate several domain-specific categories missing in general text mining tools. The unsupervised learner provided a quick, but computationally-expensive manner of clustering abstracts into topics.

We noted that indexing polymer-related literature is challenging, as naming is heterogeneous, and abbreviations are extremely versatile. Also, most of the tools required some degree of user proficiency, limiting their use. As such, we recognise a need for field-specific and user-friendly tools, such as DEBBIE.

THE MODIFIED HEDGEHOG TECHNIQUE TO REATTACH CHONDRAL FRAGMENTS IN THE YOUNG ADULT KNEE – FOLLOW-UP WITH 7.0T MRI AT 3 MONTHS AND 1 YEAR AFTER SURGERY

Marloes Peters[P][1], Ralph Jeuken[1], Esther Steijvers[2], Wiel WIjnen[1], Daan Loeffen[1], Pieter Emans[1]

The modified “Hedgehog” technique is a new surgical technique to reattach pure chondral fragments. The calcified side of chondral fragments is multiply incised and trimmed obliquely for an interlocking fit in the defect site. The technique was applied to young adults in this preliminary report, using high-field Magnetic Resonance Imaging (MRI) as outcome measure.

Three patients with a femoral cartilage defect and concomitant pure chondral corpus liberum were operatively treated by the modified Hedgehog technique. Age at surgery ranged from 20.6–21.2 years, defect size ranged from 3.8–6.0 cm2. Patients were evaluated at three and twelve months after surgery by 7.0T MRI, including a proton density weighted sequence to assess morphological tissue structure and gagCEST imaging, T2-mapping to measure the biochemical tissue composition in terms of glycosaminoglycans (GAG) and collagen structure respectively.

Twelve months after surgery patients reported no pain and showed full range-of-motion.
Over time, morphological MRI visualized improvements in integration of the cartilage fragment with the surrounding cartilage, which was supported by biochemical MRI showing increased GAG values and decreased T2-mapping values at the defect edges.

The modified Hedgehog technique has advantages over earlier used methods to reattach chondral fragments that use metalwork or absorbable biomaterials and involve both biomaterial-related drawbacks. Although the number of subjects in the present study was small, the preliminary results show potential. High-field MRI has the ability to follow-up the quality of reattached piece of cartilage itself as well as the integration of the edges of the defect with the surrounding cartilage.

THE MATRIX RELOADED: CREATING FUNCTIONAL HEPATIC CONSTRUCTS USING DECELLULARIZED HUMAN LIVER AND INTRAHEPATIC CHOLANGIOCYTE ORGANOIDS

Jorke Willemsep[1], Eric Safai[1], Luc J.W. van der Laan[1], Jeroen de Jonge[1], Monique M.A. Verstegen[1]

Liver transplantation is the only durable treatment for end-stage liver disease, but shortage of donor organs remains a limiting factor. Tissue engineered functional liver tissue could overcome this problem. LGR5+ intrahepatic cholangiocyte organoids (ICO), initiated from liver biopsies are an interesting cell source for hepatobiliary tissue engineering purposes. The aim of our study is to combine organoid technology with decellularization and recellularization techniques to make functional hepatic constructs.
Human livers (deemed unsuitable for transplantation, N=3) were decellularized using a pressure-controlled perfusion device with 4% Triton-X-100 + 1% ammonia. Circular sections were created using a dermal biopsy punch (Ø:8mm) and a cryotome (thickness:200µm). ICO were initiated from liver biopsies and added to the segments as a single cell suspension (25·104 cells/segment), which were cultured for up to 21-days (static conditions) or 7-days (microfluidic setup).
Under static conditions, organoids, incubated as single cell suspension, encapsulated the ECM, but did not infiltrate it. Phenotypically, these cells appeared to be columnar in shape, resembling cholangiocytes. Infiltration of ECM was achieved under flow conditions using a microfluidic setup. Gene expression and protein analysis revealed upregulation of hepatic (Albumin) and cholangiocyte (KRT-7) markers and downregulation of stem cell markers (LGR5) when compared to controls.
In conclusion, this study demonstrates that repopulation of decellularized human liver ECM with ICO is feasible and that these organoids exert self-organization and differentiation upon contact with the ECM. These initial results encourage further large-scale perfusion-based recellularization experiments in an effort to engineer functional and clinically relevant hepatic tissue in vitro.

Parkinson's disease (PD) is a neurodegenerative disease clinically characterized by motor disabilities. Current therapies are not being fully effective. Remarkably, the neuroregulatory molecules secreted by mesenchymal stem cells have been suggested as an alternative therapy. However, direct injection into the brain is the delivery approach that has been used in pre-clinical models [1]. Thus, the main goal of this work is to develop brain-targeting nanoparticles to deliver the secretome of MSCs and allow a systemic delivery treatment. For that, lipid-based nanoparticles were synthetized using different lipids and assembly approaches. The lipidic mesophase structures formed by mixing the lipid(s) with MSCs' secretome at different mass ratios were analysed by small-angle X-ray scattering (SAXS). The liquid crystalline phases were mechanically dispersed to produce nanoparticles. The particle size distribution and polydispersity index (PDI) of the final dispersions were evaluated by Dynamic Light Scattering (DLS). To determine the effect of the nanoparticles on cell viability, the MTS assay was performed using SH-SY5Y cells. SAXS analysis showed the formation of different liquid crystalline phases, depending on the lipid formulation used. Notably, these structures, which are promising self-assembled lipid systems for controlled release of drugs showed a high secretome ecapsulation efficiency. The DLS results showed hydrodynamic diameters smaller than 200 nanometers and relatively low PDI values. MTS assay revealed that the nanoparticles do not induce alterations on viability of SH-SY5Y cells at lipidic concentrations bellow 0.25 mg/mL. These results highlight the potential of lipid-based nanoparticles to encapsulate MSCs' secretome and to function as brain-targeting delivery systems.

Intra-articular (IA) injection with biologicals like cytokine neutralizing antibodies to treat osteoarthritis (OA) is challenging because of the rapid clearing of these biologicals from the joint space. To overcome these limitations, we developed a new concept that potentially can increase the therapeutic value of cytokine neutralizing antibodies in the management of OA. The concept is based on the use of injectable hydrogels functionalized with the variable domain of single chain heavy chain only antibodies (VHH) for cytokine capture. These hydrogels can either be pre-crosslinked in microgels before injection or injected as polymer-VHH conjugates that crosslink in a hydrogel in situ. To proof the concept of these so-called cytokine sinks we have selected a VHH that effectively neutralizes TNFα, which plays an important role in cartilage degradation in inflammatory arthritis. To achieve directed conjugation of the VHH to the polymer, recombinant DNA technology was used to introduce an unpaired cysteine in the C-terminus of the VHH. Hyaluronic acid was used as model polymer after substitution with tyramine and maleimide groups. We show successful conjugation of the VHH to the polymer backbone via thiol-maleimide chemistry. The VHH functionalized polymer could be used for making stable hydrogels after tyramine mediated crosslinking. Using an NF-κB luciferase reporter cell line we demonstrated that hydrogels functionalized with the VHH efficiently inactivated TNFα. Our results demonstrated that cytokine sinks have great potential for neutralizing inflammatory pro-catabolic cytokines after intra-articular injection by increasing the retention time of neutralizing antibody fragments in the joint cavity.

In osteoarthritis, increased proinflammatory cytokine production in damaged joints hinders the success of biomaterial guided regenerative strategies. Recent evidence links the Hippo (YAP/TAZ) pathway with IL1B signalling[1]. Meanwhile data suggests that connexin membrane channel proteins have roles regulating gene/ protein expression and activity[2], including YAP[3] and NFkB[4]. Therefore, we investigated connexin-43 (Cx43) activity in chondrocyte responses to proinflammatory cytokines and the link between Cx43 and YAP-NFkB signalling. Then, we functionalized previously optimised chondrogenic collagen I-hyaluronic acid (CHyA) scaffolds [5] to develop a non-viral Cx43-siRNA biomaterial delivery platform targeting Cx43. In human articular chondrocytes (hACs), Cx43 and YAP-mediated responses to IL1B were investigated using small molecule inhibitors and promotors. The effects of Cx43 and YAP on cell viability, migration, proliferation and anabolic/ catabolic marker expression with IL1B stimulation were determined. For siRNA-activated scaffolds, Cx43 siRNA was complexed with the cell penetrating GET-(glycosaminoglycan-binding domain) peptide[6] for transfection, incorporated into CHyA scaffolds and the effect of Cx43 knockdown in hAC responses to IL1B assessed. IL1B decreased cell proliferation, migration and promoted catabolic marker expression. Cx43-channel inhibition and YAP promotion were found to attenuate this effect. Catabolic marker expression was significantly reduced in IL1B samples treated with Cx43 siRNA or YAP promotion. Scaffold delivery of GET-Cx43 successfully knocked-down Cx43 expression in hACs and decreased catabolic responses to IL1B. This study highlights links between Cx43, YAP and proinflammatory signalling related to osteoarthritis and demonstrates the potential for YAP1-Cx43 signalling as a therapeutic target. Scaffold-mediated GET-siRNA delivery demonstrates the potential for this approach in cartilage regeneration.

INTRODUTION: Spinal Cord Injuries (SCI) affect both motor and sensorial functions of the body. One of promising approaches to tackle regeneration lies on the development of drug delivery systems that could increase bioavailability of therapeutic agents at lesion site, protecting it from degradation. Herein we propose the delivery of Adipose-derived stem cells (ASCs) secretome by in situ forming hydrogels made of star-shaped poly (ethylene glycol) (starPEG) crosslinked with heparin (Hep). Hep component provides affinity to cytokines, chemokines and growth factors and thereby prolonged release of secretome [1].

METHODS: ASCs secretome was loaded in a 1:1 ratio and the release profile evaluated by fluorescence intensity over 21 days as well as analytes detection by multiplex assay for 10 days. Moreover, mechanical properties of hydrogels were accessed such as rheology, mesh size and swelling ratio. Bioactivity effect of released secretome was evaluated by the capacity to promote differentiation of Neural Progenitor Cells (NPCs).

RESULTS: Fluorescence assays revealed that secretome was sustainably released for 21 days, being the highest amount released in the first 10 days. The multiplex assay allows the detection of Gal-1 released over 10 days. Regarding mechanical properties, hydrogels stiffness could range 500Pa-3000Pa, swelling ratio 1-2 and mesh size 10-20 nm. In vitro assays with NPCs show an increase of differentiated cells when loading secretome compared with vehicle.

CONCLUSIONS: Our reported data indicate that starPEG-heparin hydrogels are a suitable system to promote controlled and prolonged release of secretome. Hydrogel characteristics could be modulated to improve implantation, promoting SCI regeneration.

AUTOMATED GENERATION OF CUSTOMIZED ORGAN-ON-CHIP DEVICES

Pedro Costa[P][1]

[1] *BIOFABICS*

Corresponding author's email: pedro.costa@biofabics.com

Biofabrication is increasingly seen as the ideal solution for generating in vitro models. Not only it allows to accurately deposit and assemble specific materials (including cells) into complex 3D constructs but also allows to culture, stimulate, and analyze them into highly controlled and dynamic environments. Given the complexity of the human/animal body, it becomes necessary to develop tools which can automatically generate body-mimicking architectures and environments, particularly in a body-on-chip fashion. The purpose of this work was to demonstrate the limitless ability of newly developed software tools to generate body-like structures and environments and in this way democratize the access to organ-on-chip technologies.Parametric design methodologies were employed in order to enable automated generation of 3D device designs upon insertion of user-defined settings. Resulting parametrically designed shapes were then physically materialized by employing additive manufacturing and bioreactor know-how in order to produce fully functioning organ-on-chip devices fort testing under various conditions.It was possible to demonstrate that parametric design methodologies combined with additive manufacturing and bioreactor technologies may allow to easily, intuitively and automatically generate organ-on-chip devices with endless degrees of complexity, which may be employed in a wide array of applications.This project has received funding from the European Union’s Horizon 2020 research and innovation programme under grant agreement No 828835.

Introduction: Mesenchymal stem/stromal cells (MSC)-based therapies have been proposed for back pain and disc degeneration, despite limited knowledge on their action mechanism. Hence, we investigated the impact of a cell-free therapeutic approach with MSC secretome on AF organ cultures (AF-OCs) exposed to mechanical overload and proinflammatory environment [1].

Methods: AF-OCs were exposed to upper-physiological cyclic tensile strain and interleukin (IL)-1β (CTS+IL-1β) in a custom-made device [1]. A sub-group of stimulated AF-OCs was treated with human MSC secretome produced by preconditioned MSC (10 ng/mL IL-1β and 6% O2 for 48h). AF cells were characterized for gene expression changes. IL-6, MMP3 and collagen and AF adhesive strength were quantified in the tissue. Statistics: Kruskal-Wallis.

Results: A 4-days treatment of the CTS+IL-1β stimulated AF-OCs with MSC secretome downregulated the expression of inflammation markers (IL-6, IL-8), and metalloproteinases (MMP-1, MMP-3), but also of collagen type I ($p<0.05$). At protein level, it was confirmed that IL-6, MMP-3 and collagen content were decreased in the AF-OCs treated with the MSC secretome ($p<0.05$), as well as the annular adhesive strength ($p<0.05$).

Conclusion: The MSC secretome contributed to a decrease of the inflammatory and catabolic status of AF cells activated by CTS+IL-1β, and to the regulation of the complement system activation. However, it also contributed to a further decrease of collagen at gene/protein level and of the AF mechanical strength observed in the CTS+IL-1β group. The use of MSC secretome as therapeutic approach for disc-related diseases requires further mechanistic investigations before clinical trials.

The host immune response to an implanted biomaterial, particularly the phenotype of macrophages, is a key determinant of the downstream remodeling outcome [1]. Endogenous tissue restoration (ETR) is a process by which an acellular device becomes infiltrated by host cells, is gradually resorbed and remodeled into autologous tissue, and remains functional throughout [2]. Successful application of ETR requires a host response that supports appropriate tissue remodeling. Therefore, design of materials to support ETR is an important area of investigation. An electrospun polymer scaffold with the supramolecular 2-ureido-4[1H]-pyrimidinone (UPy) binding motif (ePC-UPy) based on the RestoreXTM material platform has been developed by Xeltis BV (Eindhoven, The Netherlands) for ETR-based repair of cardiovascular tissue [3–5].The present study compared the macrophage phenotype response, remodeling and calcification properties of the ETR-based ePC-UPy scaffold and a glutaraldehyde-fixed bovine pericardium (GF-BP) biologic scaffold, used widely in heart valve replacement.

The ePC-UPy material induced infiltration of mononuclear cells throughout the thickness of the scaffold within 2 days and neovascularization at 14 days. GF-BP elicited a balance of pro-inflammatory (M1-like) and anti-inflammatory (M2-like) macrophages, while ePC-UPy supported a dominant M2-like macrophage phenotype at all timepoints. Relative to GF-BP, ePC-UPy was less susceptible to calcification for the 180 day duration of the study. The results of this study highlight the divergent macrophage and remodeling response to distinct biomaterials. The favorable remodeling outcome induced by ePC-UPy (as indicated by a high M2-like:M1-like ratio) suggest that this material platform may be suitable for ETR-based heart valve replacement and other clinical applications.

Following spinal cord injury, trophic cells called astrocytes, become 'reactive'[1] and contribute to scar formation[2], preventing injured neurons from growing axons through the lesion site to restore sensorimotor function. Currently, no full therapeutic exists to facilitate cord repair due to the poor understanding of the underlying cellular mechanisms post-injury, and the lack of supportive environment to promote recovery[2]. Building on expertise in developing peripheral nerve guidance scaffolds[3] we aimed to create a biomimetic scaffold for 3D cord modelling and to provide a trophic environment for repair. Screening of native central nervous system (CNS) extracellular matrix (ECM) proteins revealed that collagen-IV and fibronectin combined, enhanced motorneuron (39%, $p<0.01$) and spinal cord astrocyte outgrowth (70%, $p<0.05$). Subsequent seeding of hyaluronic acid scaffolds functionalized with both ECM proteins, with mechanical properties and aligned microarchitecture similar to the spinal cord, with induced pluripotent stem cell (iPSC) derived astrocytes and neurons showed that soft scaffolds (1.9kPa) promoted viability ($p<0.05$), outgrowth/infiltration ($p<0.0001$) and differentiation compared to stiffer scaffolds (3kPa & 6.1kPa). Furthermore, soft scaffolds encouraged growth of iPSC derived sphereoids that subsequently formed extensive neuronal/astrocytic networks with distinct Beta-tubulin III+ (neurons) and GFAP+ (astrocytes) processes that connected with other spheroids. Here we show the creation of a novel scaffold environment that supports robust iPSC derived astrocytic and neuronal growth. These findings have implications for 3D modelling of astrocyte-neuronal interactions following spinal cord injury and further development of scaffold therapeutics for promoting spinal cord repair. Research funded by IRFU charitable trust, Anatomical Society UK and SFI-AMBER centre.

Poly-ether-ether-ketone (PEEK) and titanium, commonly used in orthopaedics often elicit a pro-inflammatory phenotype among cells of the innate immune system1. With the immune system playing a crucial role in modulating inflammation and bone homeostasis, alternatives that attenuate the pro-inflammatory environment and promote osseointegration are required2. The present study compares the in vitro response of (i) murine macrophages and (ii) SAOS-2 cells when cultured on a PEEK-zeolite composite material (ZFUZE) versus PEEK and Titanium substrates (DiFusion Inc, Austin, TX). Primary bone marrow-derived derived macrophages (2x106 cells) were seeded on each substrate and differentiated for 7 d. Macrophage phenotype was evaluated using RT-qPCR for pro-inflammatory (iNOS, IL1β and IL6) and anti-inflammatory (KLF4, Arg1 and Fizz1) markers, and confirmed with immunolabelling. To assess osteogenesis, SAOS-2 cells were seeded at a density of 1x104 cells/cm2. At confluence, gene expression was evaluated by RT-qPCR (BMP2, BMP4 and OCN), protein expression was assayed in the conditioned medium using ELISA (BNP2, BMP4, BMP7 and OCN) and alkaline phosphatase (ALP) enzyme activity was determined in cell lysates. The ZFUZE and PEEK materials reduced the gene expression of pro-inflammatory markers (IL1B & IL6) and anti-inflammatory marker, KLF4 compared to Titanium. Immunolabeling, indicated a pronounced (Fizz1+) M2-like phenotype in macrophages cultured around ZFUZE samples. Preliminary osteogenic data showed augmented BMP4 gene expression and BMP2 protein expression on ZFUZETM articles compared to all other groups. Taken together, the present study suggests that ZFUZETM represents a promising alternative orthopedic substrate that promotes a favourable host immune response, and could potentially enhance osseointegration.

INTRODUCTION

Attempted tracheal replacement efforts to date have had very little success, often succumbing to stenosis within poorly-vascularised constructs[1]. The major objective of this study was to redevelop a 3D in vitro collagen-hyaluronate scaffold[2] as an innovative tracheal medical device by increasing its mechanical properties and maximising submucosal blood vessel formation.

METHODS

A biodegradable, thermoplastic polymer was used to 3D-print (3DP) a tubular backbone for integration into lyophilised collagen-hyaluronate biomaterials, with scaffold design optimised via multimodal mechanical assessment. The construct's vascularisation potential was determined by using a previously established in vitro co-culture model[3] of HUVECs and human MSCs. Biocompatibility, vessel formation, and angiogenic marker expression were all analysed.

RESULTS

The 3DP backbone was successfully incorporated by lyophilisation into collagen-hyaluronate scaffolds, producing a composite with pores of 300µm for ideal vascularisation[3]. The backbone provided sufficient scaffold strength, with compressive moduli of 0.09-0.19 MPa, and flexural moduli of 0.13-0.29 MPa, all mimicking native trachea[4]. Cellular metabolic activity and live-dead staining indicated that the 3DP synthetic backbone did not have a detrimental effect on cellular viability. Furthermore, the 3DP scaffolds supported the expression of angiogenic markers vascular endothelial growth factor and basic fibroblast growth factor, as well as the formation of vessel-like structures in 3DP scaffolds.

DISCUSSION & CONCLUSION

By addressing both the mechanical and vascularisation requirements of a tracheal scaffold, this work has begun to pave the way for a new therapeutic option to resolve the shortcomings of current treatments.

ACKNOWLEDGMENTS

This study is funded by the SFI-funded AMBER centre (Grant 17/RC-PhD/3477).

AUTOMATION OF FIBRE PATTERNING IN 3D FOR CELL-CULTURE DEVICES PRODUCTION

Ruishan Liu[P][1], Elisabeth Lauren Gill[1], Yan Yan Shery Huang[1]
[1] *Department of Engineering, University of Cambridge, UK*
Corresponding author's email: rl614@cam.ac.uk

The electrospun fibrous scaffolds have gained popularity recently. Limited methods exist to apply low voltage and actual automation of patterning fibres in three dimensions. Hence, it is envisioned that automaton of patterning fibres in three dimensions with low electrospinning voltage would be realised, and thus mass production of fibrous scaffolds would be achieved. We have fabricated three-dimensional fibrous devices batch by batch via additive manufacturing (particularly fused filament fabrication technique) and electrospinning (particularly near field low-voltage electrospinning patterning technique). Consequently, polylactic-acid initiator and gelatine fibres (with 3-5 um diameter and 150 um inter-fibre pitch) could be integrated automatically without manual stacking. This integrated scheme would reduce capital and operating costs, and safety hazards while scaling up production. We have seeded cells (fibroblast cell line and brain cancer cell line) onto the three-dimensional fibres. Results have demonstrated the biocompatibility of the cell-culture devices since cell attachment and proliferation have been observed. We have applied machine learning (regression models) to find the correlations among operating parameters and product quality. Machine learning based on regression models could offer advantages, including accurate prediction and parameter optimization. Future work involving multi-functional fibres deposition is proposed to accelerate the application of fibrous devices in tissue engineering and drug discovery areas.

[2] *Keele University*

Corresponding author's email: I.Echevarria@bham.ac.uk

The clinical need for improving the limitations of the current tissue engineering approaches for OA repair could be addressed by the use of novel technologies and allogenic cell sources. Mechanical regulators are known to play a key role in osteoarthritis and present some key targets for modulation. The mechanotransductive potential of stem cells introduces the possibility of using external mechanical stimuli to promote cell differentiation towards a chondrogenic pathway and provide cues for tissue maturation. Our group has focused on the use of MNPs to remotely control the stem cell fate by modulation of the mechanical regulators of the cells1.

MNPs were functionalized with TRPV4 antibodies, to target the mechanosensitive ion-channel of human Umbilical Cord-derived stem cells (UC-SCs) from 3 donors. Labelled cells were cultured as pellets for 21 days in chondrogenic media and submitted to 1h daily magnetic stimulation regimes using the MICA magnetic bioreactor. Chondrogenesis was evaluated by histological staining showing enhanced deposition for all the chondrogenic markers on MICA activated groups, and immunohistochemistry that showed a sustained proliferation of MICA groups together with SOX9 and COL2 early expression and a low signal of COLX. These results were supported by gene expression analysis and biochemical tests.

MICA activation enhances chondrogenic response on UC-SCs by an increased matrix deposition and enhanced cell growth and proliferation. The mechanical activation on MSCs also induces an early response on COL2 production. TRPV4 is showed to be a specific mechano-inducible target that triggers a chondrogenic response when activated remotely with MNPs.

Injury to retinal ganglion cells (RGC) as a result of acute trauma or progressive insult such as occurs with glaucoma can lead to axon degeneration and irreversible loss of visual function [1]. The present study shows that Matrix Bound Nanovesicles (MBV), a distinct class of extracellular vesicles localized to extracellular collagen fibrils [2], mitigate the inflammatory response and preserve RGC viability and function following experimentally induced severe acute intraocular pressure (IOP) elevation in a rat model. Intravitreal MBV injection attenuated IOP-induced RGC axon degeneration and cell death, protected RGC axon connectivity to visual nuclei in the brain, and prevented loss of retinal functioning as shown by histology, anterograde axon labeling, manganese-enhanced magnetic resonance imaging, and electroretinography. In the optic nerve, MBV also prevented IOP-induced decreases in growth-associated protein-43, a neuron-specific marker up-regulated in regenerating axons [3], and elevations in levels of glial fibrillary acidic protein, suggesting decreased astrocyte activation consistent with RGC health [4]. In vitro studies showed MBV mitigated the pro-inflammatory phenotype of activated microglia and astrocytes, stimulated RGC neurite growth, and protected RGC from conditioned media generated by activated astrocytes while exhibiting no cytotoxic effects on RGC viability. Thus, MBV can modulate distinct signaling pathways (e.g., inflammation, cell death, and axon growth) in diverse cell types. Since MBV are naturally-derived structures and contain bioactive factors present in numerous FDA approved devices, MBV may be readily useful, not only experimentally, but also clinically as an immunomodulatory, neuroprotective approach for treatment of ocular trauma or disease and other CNS tissues.

Parkinson's disease (PD) is characterised by the loss of midbrain dopaminergic neurons within the substantia nigra, responsible for dopamine regulation via their projections through the nigrostriatal pathway that connects to the striatum(1). Thus, reconstruction of this crucial pathway is essential for improving cell transplantation therapies for PD. Wnt signalling is an important developmental pathway that regulates dopaminergic cell proliferation and differentiation(2). Here we propose methods to promote and study both neurite outgrowth, migration and Wnt activation(3) using magnetic nanoparticles in 2D and 3D experimental models to assess magnetic field stimulation as a remote activator.

Magnetic nanoparticles (MNPs) were functionalised and coated with a peptide, UM206 (which binds to Wnt Frizzled receptors), and used to label the dopaminergic neuronal cell line, SH-SY5Y. An oscillating magnetic field was applied and expression of dopaminergic markers were assessed via immunocytochemistry. MNPs were also coated with graphene-oxide and internalised in cells PC-12 and SH-SY5Y cells, using P21-8R(4), a transfection agent. 3D collagen-based hydrogel models were created and optimised in which neuronal differentiation of graphene-oxide MNP labelled cells was induced during the application of a static magnetic field. Neurite outgrowth and migration was investigated using confocal imaging and immunocytochemistry.

Results indicate that UM206 coated MNPs showed successful activation of Wnt signalling and subsequent increase of dopamine expression markers. The 3D hydrogel systems showed promising potential as useful and relevant models to investigate neuronal migration and outgrowth. The use of MNPs and their functionalisation can be considered encouraging tools in remote control of cellular functions and behaviour.

Engineering multiscale vascular networks is a key challenge in biofabrication. The hierarchical, microscale anatomy plays a crucial role in enabling connectivity to external perfusion sources and ensuring transplant's grafting success. Decoupling the multiscale problem of engineering vascular networks, i.e. directing the mesoscale vessel formation while providing for de novo formation of microscale vessels, is a viable strategy to reduce the necessary spatial resolution, processing time, and complexity of the biofabrication process. We focus on establishing a protocol for repeatable microfabrication of 3D cell-laden hydrogel scaffolds with arteriole and venule scale microvasculature, which can be further expanded into a capillary bed by conditioning with pulsatile perfusion on a microfluidic platform. We demonstrate the simple 3D bioprinting of vascularized cardiac patches with a custom digital light processing (DLP) bioprinter. The vascularized cardiac patches are composed of human coronary artery endothelial cells and cardiosphere-derived cardiac stromal cells. The vascularized cardiac patches are then conditioned in microfluidic device, which regulates pulsatile perfusion through the bioprinted vascular network, delivers growth factors, and monitors vascularity by the measurement of the hydrodynamic resistance of the tissue construct. These conditioned, vascularized cardiac patches are evaluated for efficacy in treating myocardial infarction. Integration with the myocardium, promotion of regeneration, and subsequent cardiac function are characterized.

Introduction: Calcium phosphate (CaP)–based biomaterials are widely used in bone regeneration applications [1]. Nevertheless, their properties and clinical performance remain inferior to their biological counterpart, i.e. autologous bone graft. Hence, there is a need for further improvement [2]. We propose that a lack of reliable in vitro screening methods for such biomaterials has hampered our ability to find an optimal material. Here, we present a multiplex protein assay as a high-throughput tool for screening the osteogenic properties of CaPs and for predicting their success in promoting osteogenic differentiation.

Methods: In order to establish the osteogenic differentiation programme of human mesenchymal stromal cells (hMSCs), they were cultured in basic medium and osteogenic medium with or without the addition of BMP-2, in basic medium supplemented with Ca2+ or PO43-, and on beta-tricalcium phosphate (TCP) discs. A multiplex protein assay to detect analytes related to bone formation, resorption, angiogenesis, and immunomodulation was performed at multiple time points. Osteogenic differentiation was confirmed by conventional methods such as Alizarin red stain, alkaline phosphatase assay, and qPCR.

Results and discussion: The protein profile for hMSCs cultured in the different medium conditions, with the addition of Ca2+ or PO43-, and on TCP discs varied over time. With a statistical model, we correlated the protein expression to the results of osteogenic differentiation for a descriptive panel of markers.

Conclusion: Here, we presented our efforts towards developing a high-throughput screening tool based on protein multiplex for evaluating osteogenic properties of CaP-based biomaterials.

The **Fraunhofer IPT** in Aachen has extensive experience in the development of automated production facilities for the manufacture of stem cell-based products and gene and cell therapeutics. Current project examples are: AutoCRAT, AIDPATH, JointPromise, BellaFactum and AIxCell. Since 2010, competencies in the field of automation of biopharmaceutical processes have been gathered, such as the development of concepts and systems for the automated production of therapeutics and the integration of measurement technology and sensors for adaptive process control. In addition, own solutions have been developed for "technology gaps", such as high-speed microscopy for automated quality control of cell culture processes. There is also deep knowledge in the field of process control (projects: AIMFREE, FreeMove, FabOS) as well as the connection of heterogeneous machine landscapes to a production platform in the GMP environment, the creation of digital concepts for model predictive monitoring and control of the process.

HMSCS RESPONSE TO POLYMER-CALCIUM PHOSPHATE COMPOSITE SCAFFOLDS CONTAINING ZINC PRODUCED USING ADDITIVE MANUFACTURING

Martyna Nikody[P][1,2], Jiaping Li[1,2], David Koper[1,2,3], Elizabeth Rosado Balmayor[1], Lorenzo Moroni[2], Pamela Habibovic[1]

Currently available options for treating critical-size craniomaxillofacial bone defects involve the use of either autologous bone or, alternatively, of a bioinert bone graft substitute. However, the use of autologous bone can result in complications including donor site morbidity, while bioinert materials lack osteointegration and have a high risk of implant failure (1). We propose the use of a novel bioactive composite with high ceramic content composed of poly(ethyleneoxide terephthalate)/poly(butylene terephthalate) (1000PEOT70PBT30, PolyActive, PA) and 50% beta-tricalcium phosphate (β-TCP) with the addition of zinc (Zn) in a form of a coating of the TCP particles. Several inorganic ions have been shown to affect biochemical functions important for different aspects of bone regeneration (2). Although Zn is found in the bone only in trace amounts, it plays an essential role in its metabolism by stimulating bone formation by osteoblasts and inhibiting osteoclasts differentiation (3). Therefore, we hypothesise that the addition of zinc to the β-TCP will result in enhanced osteogenic properties.

Overall, human mesenchymal stromal cells (hMSCs) cultured on all types of scaffolds showed cell growth and alkaline phosphatase (ALP) production. Higher cell growth and ALP production were observed on scaffolds containing β-TCP and β-TCP with the addition of zinc than on 1000PEOT70PBT30 scaffolds. Furthermore, extracellular matrix formation was observed on all scaffolds except for 1000PEOT70PBT30 scaffolds. The osteogenic properties of tested scaffolds will be further investigated by evaluation of cell differentiation at mRNA level by qPCR analysis for a set of specific osteogenic markers.

HYBRID BIOINKS CONTAINING LIQUEFIED BIOFACTORIES

Maryam Ghasemzadeh-Hasankolaei[1], Clara R. Correia[1], João F. Mano[1]

The aim of this work is the development of a natural-based bioink enriched with liquefied living microfactories. These living microfactories consist of liquefied compartments encapsulating stromal cells and surface-modified microparticles. Such a system has been proved as a suitable cell encapsulation strategy for tissue engineering [1]. Herein, the novelty consists in the combination of the liquefied encapsulation technology with an external and supportive hydrogel to confer bioprintability to the system and produce clinically relevant tissue engineered constructs. Using the electrospraying technique, alginate-microbeads containing adipose-derived stromal cells and surface-modified microparticles were produced. Then, alginate-microbeads were combined with gelatin methacryloyl or methacrylated hyaluronic acid or a combination of thereof, to produce hybrid bioinks. After bioprinting, results showed that we successfully developed stable hybrid bioinks even after the liquefaction process. Biological assays in all tested bioinks indicated that the viscoelastic structure of solid alginate-microbeads during the bioprinting process, as well as the liquid microenvironment provided after liquefaction, allowed cells to remain viable. More importantly, surface-modified microparticles offered proper support for cell interaction and structural organization. Overall, this study developed a proof-of-concept strategy which can be applied for bioprinting of any kind of anchorage-dependent cells. The versatility of this technique facilitates engineering of desired niches for encapsulated cells, while the developed bioink can be designed with optimal mechanical properties without cellular bio-performance constrains.

SELF-SUPPORTING LAMINARAN-BASED HYDROGELS

Mehrzad Zargarzadeh[P][1], Cláudia Nunes[1], Manuel A. Coimbra[1,2], Catarina A. Custódio[1], João F. Mano[1]

Hydrogels as Extracellular Matrix (ECM)-mimic systems have revealed exceptional promises to support the 3D encapsulation of cells towards the development of tissue-engineered constructs. However, in some cases, the use of bulk hydrogels is associated with the limitation in providing an adequate supply of oxygen and nutrients, in particularly glucose as the main source of energy and metabolic intermediate in living cells [1, 2].

Recently laminaran(laminarin), a β-glucan storage polysaccharide, have been applied for the development of photo-cross-linkable hydrogels [3]. Here we report a platform for cell culture that takes advantage of the degradation process of the laminaran hydrogels. The degradation mechanism of choice is enzymatic as it allows the release of glucose by gradual degradation of the polymer by specific hydrolyzing enzymes.

We fabricate the enzyme encapsulated laminaran hydrogels to obtain structural platforms for 3D cell culture but also achieving a satisfying release of glucose over a prolonged period in order to enhance the cells survival. We demonstrated that 3D encapsulated tumor cells (A549) and human mesenchymal stem cells (hMSCs), exhibited improved survival rate and proper functionality due to the beneficial properties of the glucose production.

We believe, this self-supporting bioscaffolds with enzyme-empowered degradation capacity can successfully overcome glucose diffusion limitation. Such innovation is expected to circumvent the limitations of the current hydrogels strategies that lack on nutrients diffusion and boosting the application of hydrogels in a variety of bioengineering applications including in tissue engineering.

Bilayer scaffolds based on gellan gum (GG) and nanoparticulate bioactive-glass (BAG) were developed by an integrative approach based on engineering principles and characterization in biomimetic bioreactors. The osteo-inductive GG-BAG layer containing 2 % w/w GG and 2 % w/w BAG (composition: 70 n/n % SiO2, 30 n/n % CaO) was produced by gelation followed by freeze-drying to obtain open porosity in axial and radial directions. The chondral layer was obtained by dispensing a warm 2 % w/w GG solution at 60˚C over the frozen macroporous GG-BAG layer at -25˚C. The temperatures were optimized by applying a one-dimensional unsteady-state heat transfer model so to obtain a thin integration zone, 0.5 – 1 mm thick. The scaffolds were evaluated regarding bioactivity in a biomimetic bioreactor with specially designed chambers to provide supply of two media relevant for chondral and bone tissues. In the present experiment, simulated body fluid (SBF) was supplied countercurrently continuously during 14 days of the experiment (1.1 ml min-1 flowrate), while dynamic compression (5 % deformation, 0.68 Hz frequency, 337.5 µm s-1 loading rate, 1 h / day) was applied on the chondral layer, from day 7 to day 14. SEM analyses have confirmed the retained integrity of the scaffolds, as well as formation of hydroxyapatite (HAp) uniformly throughout the osteo-layer of the scaffolds.Significantly higher bioactivity under biomimetic conditions compared to static controls resulted in slightly but significantly increased compression modulus. These results indicated a high potential of the applied integrative strategy for the development of biomimetic bilayer scaffolds.

Tissue engineered heart valves (TEHVs) are promising alternatives to non-living bio-prosthetic and mechanical valve prostheses, prospecting life-long replacement options that can adapt to a changing hemodynamic environment [1,2]. For truly safe translation to the clinic, some drawbacks need to be overcome [3], a major one being (micro)calcification of TEHVs.

In this systematic review, we analyzed calcification found in pulmonary TEHVs, implanted in large animal models. We studied the influence of tissue engineering methods on calcification and tissue-specific differences in histological differentiation of TEHVs. A total of 78 studies were included in data extraction, of which 38 studies containing 78 experimental groups could be included in meta-analysis. The overall calcification event rate (ER) was 0,35 (95%CI [0,28-0,43]), with a large heterogeneity between study outcomes. Calcification was more prone in the conduits (ER 0,34 [0,26-0,43]) than in the leaflets (ER 0,20 [0,16-0,26]). Some trends were observed, yet there were no significant differences in calcification between natural or synthetic scaffolds, cell-seeding methods, or different animal models and follow-up times.

This study showed that calcification is frequently found in large animal models for TEHVs. Control-based research could shed further light upon causes and solutions for calcification, bringing the field of TEHVs forward towards clinical use.

The aim of this study was to investigate possibilities for production of macroporous scaffolds based on alginate hydrogels with addition of hydroxyapatite (HAP) precursors and to evaluate the best candidates under biomimetic conditions in perfusion bioreactors for potential use in bone tissue engineering. HAP powders, undoped and doped with Mg2+, were synthesized using a hydrothermal method followed by calcination. Composite scaffolds with different fillers were prepared by an improved procedure including gelation and freeze-drying method. Scanning electron microscopy has shown uniformly dispersed mineral phase in all obtained highly macroporous composite scaffolds with open and connected pores. Biomechanical properties of all scaffolds were investigated in a biomimetic bioreactor with dynamic compression (0.28 Hz frequency, 10% deformation). Compressive strength of scaffolds increased with the increase in Ca2+ and the decrease in Mg2+ concentrations in fillers. The formation of HAP crystals within all scaffolds was examined in the simulated body fluid (SBF) during 28 days under static conditions, while the best candidate (Mg substituted HAP filler, precursor solution with (Ca+Mg)/P molar ratio of 1.52) was evaluated under physiologically relevant conditions in perfusion biomimetic bioreactors with the direct SBF flow at the superficial velocity of 400 µm/s. The continuous perfusion induced enhanced formation of HAP crystals throughout the scaffolds leading to improved mechanical properties as compared to the initial scaffolds. The results of this study have shown potentials of the macroporous scaffolds with incorporated nanostructured Mg substituted HAP fillers in conjunction with perfusion bioreactors as a biomimetic environment for application in bone tissue engineering

Spinal cord Injury (SCI) is a dramatic pathology with a high number of new cases emerging every year. The injury triggers several pathophysiological events which cause damage and supress axonal growth in the spinal cord tissue, causing motor, sensory loss and causing incapacitating conditions to the patients. In this work we have assessed the therapeutic value of adipose tissue derived stem cells (ASCs) secretome on two distinct models of SCI in rodents (transection and compression). In both models, the secretome was intravenously administered repeated times in acute and chronic phase with the animals showing improvements at motor, sensory and histological level . The locomotor performance evaluated in the BMS test shown a threefold increase in the groups treated with secretome over control in both injury settings. Moreover, the transection group treated with secretome significatively improved the sensory score evaluated in the Von Frey test compared with untreated animals. Reduction of inflammatory cells (microglia and macrophages) was also observed in the secretome treatment on both models compared with control, being the difference statically significant in the transection group. In this model the secretome also increased the expression of Gap-43 and beta-III tubulin markers when compared with control. This result translates in improved regeneration and axonal growth in the lesion site besides a decrease in the lesion cavities. Altogether, this provide evidences of the therapeutic potential of ASC secretome after SCI, supported by indications on the positive effects exerted on neuroinflammation, axonal outgrowth and regeneration, observed in two distinct models of SCI.

Corresponding author's email: yasarkemalerdogan@gmail.com

316L stainless steel was the material of choice for cardiovascular stent applications due to its mechanical properties, corrosion resistance and established manufacturing techniques. However, the use of bare stainless steel in clinics has been decreasing steadily. The leading factors for the decreased use of stainless steel include nickel ion release, limited endothelization, thrombus formation and restenosis. In this study, 316L SS surface were modified with anodization technique to obtained oxidized based nanopit structures with a size range from 25 to 250 nm in diameter. In addition, we altered the surface morphology of the nanopit features to have higher depths and thicker oxide layer on 316L stainless steel via two-step anodization. Surface topography of the samples showed that root mean square roughness (rms) value for non-anodized sample was 1.2 nm, while 200 nm surfaces had an rms value of 17.2 nm. XPS results showed that anodized surfaces were composed of Fe2O3, Cr2O3 and O1s. We observed Ni peak intensity to decrease as diameter of nanostructures increased. Also, nickel ion release from anodized and non-anodized surfaces at 37°C for 30 days were assessed with ICP-MS. The in vitro tests revealed that nanostructured surfaces promoted adhesion and proliferation of human umbilical vein endothelial cells (HUVECs). Especially, 200 nm of nanopit surface was promising for rapid re-endothelialization and could possibly minimize problems of bare metal for stent applications.

Failure rates of primary ACL reconstruction surgery approach 25%(1), necessitating new approach to improve outcomes. One promising strategy harnesses bioresorbable scaffolds to facilitate native ligament healing. Ideally, such scaffold should have a structure mimicking that of the natural ligament, provide adequate mechanical strength, and be fully biocompatible – supporting the appropriate cellular activity in order to drive tissue regeneration, while eliciting minimal local and systemic toxicity. With this in mind, we have developed a robust polycaprolactone(PCL) prototype scaffold, and have characterised it against a current market competitor as well as traditional suture materials. The prototype scaffold was produced by electrospinning of continuous PCL filaments(2), and by subsequently weaving these into a 10mm wide fabric. Uniaxial tensile testing was used to determine the mechanical properties of the prototype vs controls, and morphology was assessed via SEM. In compliance with ISO 10993-5:2009, cytotoxicity was evaluated with a neutral red uptake assay using NIH/3T3 cells. Cellular attachment and proliferation of ACL-derived primary fibroblasts, cultured on scaffolds for 14 days, were monitored using PrestoBlue™ assay and SEM. The tensile strength of the prototype patch was comparable to hamstring tendon allograft, the current gold standard for repair. The SEM images demonstrated a biomimetic morphology of the patch, with aligned nanofibers, similar to the ligament microstructure. The prototype showed an adequate cytotoxicity profile. Primary cells attached to the materials tested, demonstrating fibroblast-like morphology and increased metabolic activity from day 7 of culture. This study supports the suitability of a novel PCL electrospun scaffold for ACL reconstruction.

SELF-ASSEMBLED CONDUCTIVE NANOFIBERS FOR SPINAL CORD REGENERATION

Gillian Koehl[P][1], Josef Goding[1], Simone Di Giovanni[1], Rylie Green[1]

[1] *Imperial College London*

Corresponding author's email: gek13@ic.ac.uk

Spinal cord injury (SCI) is a severely debilitating chronic injury. Tissue repair remains a challenge due to the inability of severed axons to cross the injury site and form new connections. In vivo, injectable hydrogels have been shown to promote limited axonal growth through the lesion site, however they offer poor axonal guidance cues and connection to endogenous tissues. Cellular cues such as topography, mechanical properties, electrical stimulation and bioactive epitopes have shown promise in controlling neuroprogenitor differentiation, guidance, synapse formation as well as mediating inflammation. However, due to a lack of available materials, these cues have not been combined into an injectable aligned conductive fibre scaffold to foster regeneration after SCI.

Self-assembled peptides have shown promise as an injectable biocompatible hydrogel for SCI with aligned fibre topography [1]. Conductive polymers have shown potential for nerve tissue engineering applications due to their biocompatibility and conductivity. However, fabrication techniques have limited their incorporation into fibrous scaffolds to conductive coatings which limit cell adhesion and the incorporation of other bioactive cues.
In this work a pathway for the synthesis of a self-assembling amphiphilic peptide base VVAAEE functionalised with an alkyl tail and aniline monomer was designed. The effects on self assembly were assessed with circular dichroism and TEM. Future studies will investigate the trade-off between mechanical properties and conductivity, as well as the influence of fiber alignment on conductivity. The cellular response to this scaffold will also be investigated, through cytotoxicity studies, as well as differentiation and network formation.

PROXIMAL TUBULE INJURY PARACRINE FACTORS INDUCE THE DEPOSITION OF A COLLAGENEOUS EXTRACELLULAR MATRIX

Silvia M. Mihaila[1,2], João Faria$_P$[1], Laura Giordano[1], Rosalinde Masereeuw[1,2], Marta Valverde[3]

Aim: Acute kidney injury is a pathological condition in which ischemia or drug-induced damage contribute to loss of proximal tubule cells. Stem cells therapies were shown to contribute in the repair process via paracrine mechanisms [1]. However, little is known about their contribution to the local extracellular matrix (ECM). With stem cells being a remarkable source of ECM, we hypothesized that their exposure to injured proximal tubule-derived paracrine factors will results in phenotypical and ECM composition changes. Methods: Proximal tubule injury was induced by exposure of human conditionally-immortalized proximal epithelial cells (ciPTEC-OAT1) for 24h to tenofovir (50µM) and antimycin-A (10nM). Post-injury secretome was screened for TGF-β/ PDGF-BB. Human adipose-derived stem cells (hASCs/P6) were exposed to ciPTEC-OAT1s-derived secretome (1:1, medium:secretome) enriched with ascorbic acid (50µg/mL). After 7 days of culture, protein quantification and deposition were evaluated. Results: Different proximal tubule cells-derived secretome compositions were obtained. While the exposure to tenofovir (50µM) reduced the metabolic activity ($p<0.001$), exposure to antimycin-A, known to inhibit mitochondrial oxygen consumption [2], did not affect the metabolic activity of ciPTEC-OAT1, when compared to standard cultures. Levels of TGF-β1 and PDGF-BB were significantly higher ($p<0.05$) in injured ciPTECs-OAT1s. A library of hASCs-made ECMs was obtained by the exposure to variable secretome compositions. The injury secretome (tenofovir- and AA-derived, respectively) induced higher protein deposition, enriched in collagenous proteins ($p<0.05$). Conclusion: Our results highlight stem cells as efficient producers of ECM, in the context of renal tubule repair. Further analysis includes in-depth evaluation of secretome, ECM and phenotypical changes.

Articular cartilage (AC) is a graded tissue with three layers exhibiting differences in cell density: the superficial zone having the highest and the deep zone, the lowest [1]. Only a few studies have introduced a cell gradient into scaffolds [2] and, as far as we are aware, none have optimized the scaffold mechanical properties, hence failing to recapitulate a more biomimetic environment. In this study, we aimed to bioprint scaffolds with different zonal cell densities, assess the scaffold stiffness and the influence of the cell density on tissue deposition.

The scaffolds were bioprinted using an alginate-based bioink (Cellink) containing human articular chondrocytes and a poly-caprolactone (PCL) support structure. The design of the scaffolds included three cell densities: 20E6 (high), 10E6 (mid) and 5E6 cells/ml (low). Eight different PCL designs were assessed by compressive tests. The scaffolds were cultured in chondrogenic medium for 25 days and analysed by live-dead and histological staining (Alcian blue, Hematoxilin-Eosin, and Picrosirius-red).

The PCL design showing the closest stiffness to native AC (8.35 ± 0.35 MPa) was used for bioprinting of the zonal scaffolds. The live-dead analysis at day 14 revealed the ability to generate a zonal cell density with high viability. Histology showed a smooth transition between the zones and a higher sGAG deposition in the highest cell density zone.

This qualitative data demonstrate the generation of different zonal cell densities within bioprinted scaffolds recapitulating the tri-phasic organization of AC. Follow-up studies should look at the addition of a stiffness gradient along the cell gradient.

Aim: Protein-bound uremic toxins (PBUTs) accumulate in plasma of end-stage kidney disease patients. Recently, we have developed bioengineered kidney tubules capable of active PBUTs secretion via organic anion transporter-1 (OAT1)[1]. To accelerate their application as units for bioartificial kidney (BAK), a comprehensive assessment of their functional performance under clinical-like conditions is essential. Here, we evaluated the PBUTs clearance capacity in bioengineered tubules perfused with uremic plasma and directly exposed to dialysate.

Methods: Human conditionally-immortalized proximal tubule epithelial cells equipped with OAT1 (ciPTEC-OAT1) [2] were exposed to medical-grade dialysate fluid for 240min. Their metabolic activity (PrestoBlue), membrane integrity (LDH release), pro-inflammatory response (IL-6/IL-8 release), oxidative stress (ROS production) and OAT1 functionality (fluorescein uptake) were assessed. Further, ciPTEC-OAT1s grown on biofunctionalized hollow fiber membranes were extraluminally exposed to dialysate fluid and intraluminally perfused with human uremic plasma using a tailor-made flow system. Clearance of five representative PBUTs was assessed (LC-MS/MS).

Results: Exposure of ciPTEC-OAT1s monolayers to dialysate reduced their metabolic activity (80.4±4.0%,$p<0.001$) and OAT1 functionality (80.9 5.4%,$p<0.001$) and increased the release of LDH (15.0±2.7 %,$p<0.05$), without inducing the release of IL-6 or IL-8. After 30min exposure, a 3.4±0.9-fold increase in ROS production was noticed. Furthermore, exposure of ciPTEC-OAT1s-loaded bioengineered kidney tubules to dialysate enabled the concomitant clearance of multiple PBUTs, without compromising the membrane integrity (FITC-inulin paracellular leakage).

Conclusion: The demonstrated functionality of bioengineered kidney tubules advances the development of BAK. Further research is aimed at introducing flow at the dialysate side and evaluating the efficacy of a multiple-fiber mini-BAK-module in rodents.

DEVELOPMENT OF A HIGH-DENSITY SYSTEM FOR EXPANSION AND CARDIAC DIFFERENTIATION OF HUMAN INDUCED PLURIPOTENT STEM CELLS AS AGGREGATES IN SINGLE-USE VERTICAL-WHEEL™ BIOREACTORS

Usage of human induced pluripotent stem cells (hiPSCs) for Regenerative Medicine applications requires their expansion to clinically-relevant quantities. The novel Vertical-Wheel bioreactors (VWBRs) allow for homogeneous mixing while conveying less shear stress to cells compared to traditional alternatives. This work reports strategies to establish and optimize expansion and cardiac differentiation of hiPSCs as aggregates in VWBRs [1].

Cultures were performed in the PBS MINI 0.1 bioreactor with 60 mL of working volume. Two different expansion media were tested, mTeSR1 and mTeSR3D, as well as dextran sulfate (DS) supplementation. The generated hiPSCs were analysed by flow cytometry and qRT-PCR and their differentiation potential was assayed via EB formation and directed differentiation. Cardiac differentiation was performed adapting a previously-described protocol [2]. A maximum cell density of (2.3±0.2)×10^6 cells·mL^–1 was obtained after 5 days with mTeSR1+DS, resulting in aggregates with an average diameter of 346±11 µm, without loss of pluripotency. Cardiac differentiation resulted in over 70% cTNT+ cells after 15 days.

The results here presented suggest the VWBR as a promising technology for the development of hiPSC-derived products under Good Manufacturing Practices for biomedical applications.

BOOSTING NEUROGENESIS: A NON-INVASIVE DEEP BRAIN STIMULATION PLATFORM FOR NEUROREGENERATION THERAPIES

Sofia Peressotti[1], Josef Goding[1], Rylie Green[1]

Alzheimer's disease (AD), among all neurodegenerative diseases, encompasses one of the most pressing healthcare crises to date. Due to the brain's intrinsically low turnover, neural tissue regeneration is considered an essential prerequisite to reverse AD cognitive and physical symptoms [1]. However, the development of a viable therapy is hindered by the low efficacy and immunogenicity of cell transplants as well as the inflammatory response due to invasive treatments. Electrical stimulation is known to increase neural stem cell (NSC) proliferation and differentiation [2]. Thus, a deep brain stimulation (DBS) method based on temporally interfering electric fields is hypothesised to direct NSC behaviour non-invasively [3]. The study aims to engineer a regenerative therapy to promote intrinsic adult neurogenesis and to improve the efficacy of NSC transplants through the use of biomimetic stimulation patterns compatible with non-invasive DBS. Electrical stimulation patterns mimic developmental brain waves and clinical DBS parameters, expecting to trigger neurogenesis-related molecular pathways. An autoclavable stimulation device is developed to simulate the non-invasive DBS clinical setting, and the effect of biomimetic stimulation on NSC fate and function in vitro is investigated in both 2D and 3D culture. The effect of stimulation on epigenetic regulation of cell differentiation, activation of developmental pathways, synapse formation and electrophysiological function is investigated. Overall, this minimally invasive approach embodies an unprecedented intersection between regeneration effectiveness and ease of clinical application, creating a possible pathway toward the treatment and reversal of neurodegeneration.

SOFT ROBOTIC DEVICES FOR EMULATING VASCULAR MECHANOBIOLOGY

Cody Fell[P][1], Mia Woodruff[1], Mark Allenby[1]

[1] *Queensland University of Technology*

Corresponding author's email: cody.alexander.fell@gmail.com

Tissue-engineered vascular grafts (TEVGs) are expected to replace prosthetic and autologous grafts as the gold standard for treating severe cases of vascular stenosis and occlusions in various formats, such as peripheral arterial disease (PAD), which affects over 200 million people worldwide (1). The femoropopliteal artery (FPA) accounts for nearly 80% of PAD cases and is one of the most flexible arteries in the body, accommodating standing, walking, and crouching (1, 2). These complex biomechanics and hemodynamic forces are implicated in the frequent incidence of PAD in the FPA, leading to debilitating morbidities, such as limb-threatening ischemia (3, 4). Moreover, FPA disease management and surgical treatments exhibit dismal long-term success rates, as low as 39% after five years (5). The emerging field of soft robotics aims to emulate physiological locomotion and could provide a platform for enhanced TEVG development and disease modelling applications that more completely mimic vascular biomechanics. We fabricated bio-integrated soft robotic devices (BSRs) imbedded with pneumatic networks (PneuNets) that induce angular flexion, longitudinal extension, and radial distension upon pressurization. We developed a coated hyperelastomer for both soft robotic actuation and tissue culture. Then we employed simulation-based iteration to design PneuNets optimized for emulating FPA flexion during daily walking and sitting poses, the most extreme being a radial distension of 20% and angular flexion of 140°. Finally, these designed, manufactured, and programmed vascular BSRs were seeded with mesenchymal stem cells (MSCs) and conditioned for 24 hours to highlight the effect of FPA mechanobiology on MSC cell morphology and alignment.

Due the common dural damage occurrance on neurosurgery, a proper closure of the site must be done in order to prevent complications on recovery [1]. Above fulfill tasks as provide watertight closure and support for cellular migration. Therefore, we developed and evaluated a formaldehyde crosslinking allogenic collagen sponge (ACS) as an alternative for the synthetic and xenogenic dural substitutes on neurosurgical procedures. Acid soluble collagen was extracted from human tissue pre-treated on alkaly solution and acid/enzymatic hydrolysis. The obtained solution was salting out for separated collagen type I fibers and homogenized on an acid solution. Thus, the excess of salt were removed by a dyalisis system. Finally, after concentrated the fibers with a freeze-drying process, the fibers were resolubilizated, lyophilizated on a specific shape and crosslinked with formaldehyde vapor treatment.The soluble collagen present the three characteristic α1, α2 and β bands for collagen type I on a SDS-PAGE electrophoresis gel [2,3]. An ACS of 1 cm2 had a complete in vitro degradation within 2-4 hours[4], a wide pore size range from 20 to 170 µm and below 10 ppm of residual formaldehyde [5]. Moreover, the crosslinking process did not affect the cytocompatibility; this was confirmed by seeding Human Adipose Stem Cells onto the ACS and stained by DAPI and Phalloidine after 14 days in culture. Finally, we observed that the ACS supported and promoted cell growth and migration and could be a possible scaffold for dura matter with possible low immune response due to allogenic source.

DESIGN OF A TISSUE-ENGINEERED 3D SPINAL CORD MODEL TO BETTER UNDERSTAND AMYOTROPHIC LATERAL SCLEROSIS

Aurélie Louit$_P$[1,2], Marie Josée Beaudet[1], François Berthod[1,2]

Background: A mutation in the Superoxide Dismutase 1 (SOD1) gene has been identified as a cause of amyotrophic lateral sclerosis (ALS) in 5% of patients. Recently, studies have shown that non-neuronal cells could contribute to the development of ALS. Objectives: Our objectives are to develop by tissue engineering an in vitro murine 3D model of spinal cord reproducing the ALS phenotype, and to determine the role of each cell type in its development. Methods: Motor neurons (MN) have been extracted from spinal cord mouse embryos aged of 14 days of development and astrocytes, microglia, and Schwann cells (SC) from SOD1G93A or SOD1WT adult mice, overexpressing respectively the ALS mutant or the normal human SOD1 protein. These cells have been purified and co-cultured on 3D collagen/chitosan sponges. Results: When SOD1G93A MN were cultured with mutant astrocytes and microglia, there was a 25% reduction in TUJ-1 positive neurites length, compared to the control seeded with SOD1WT MN, astrocytes and microglia. A similar decrease in the neurite length was observed with non-transgenic MN grown in presence of SOD1G93A glial cells, compared to SOD1WT glial cells. Finally, when cultured with SOD1WT SC, axonal growth was enhanced. Conclusion: Axonal migration was found shorter in presence of SOD1G93A glial cells, recapitulating in part an ALS phenotype. However, adding SC to the model helps axonal growth. This 3D model, adaptable to other types of mutations involved in ALS, should lead to a better understanding of the disease mechanisms, and could serve as a platform for drug screening.

INJECTABLE POROUS DOUBLE-NETWORK HYDROGELS WITH VOCAL FOLD-MIMETIC VISCOELASTICITY

Healthy voice production has a significant impact on individual wellness, occupational function, and societal productivity. Intense mechanical stresses during speech can result in laryngeal dysfunctions, including vocal folds (VFs) scarring and tissue loss. The most common treatment in practice is to inject biomaterials to the wounded site; however, the mechanical properties of existing biomaterials for VF treatments are poorly matched to those of native VFs or they could be effective over only a short time period. We investigated a chitosan-based biocompatible and injectable double-network hydrogels to recapitulate both the structural and viscoelastic properties of VFs. Our porous double-network hydrogels comprise 1-2 % glyoxal-crosslinked glycol-chitosan (covalent network) and 1.5% physically crosslinked chitosan (sacrificial network). During gelation, the chitosan network exhibited pH-induced phase separation, resulting in the creation of micropores. We used confocal microscopy and micro-CT to characterize the pore size of the hydrated gels and found them to be within 10-20 µm. By varying the glycol-chitosan concentration, the stiffness (1-3 kPa) and stress relaxation time (20-120 seconds) were highly tunable to match those of VFs. The obtained relaxation time is significantly faster than that of most covalently crosslinked hydrogels (>10,000 seconds). This biomimetic viscoelasticity is attributed to the breaking of dissipative physical crosslinks and highly interconnected pores to facilitate water migration under strain. These hydrogels are also friendly to human vocal fold fibroblasts, yielding over 75% cell viability rates over a 7-day 3D fibroblast culture. The efficacy of this hydrogel system will be evaluated using a phono-mimetic bioreactor.

Pelvic Organ Prolapse impacts 1 in 4 women, due to weakening of vaginal wall due to childbirth [1]. Non-degradable synthetic mesh for treating pelvic organ prolapse (POP) have been banned in many countries due to the adverse events associated with transvaginal surgery [2]. To this end, we developed poly (L-lactic acid)-co-poly(ε-caprolactone) electrospun nanofibrous mesh bioengineered with SUSD2+ endometrial mesenchymal stem/stromal cells (eMSC) for POP repair. This study determines the impact and fate of our vaginal therapy with focus on tissue integration and foreign body response using our unique ovine model of POP (n=45). We compared our results to NanoMesh without eMSC and to current clinical native tissue repair procedure as a control. Following surgery, vaginal tissues were explanted and assessed at 7, 30 and 90 days. Firstly, we observed that surface modification of meshes had a significant impact on the foreign body response and giant cell formation. Surface modified nanomeshes with and without eMSCs integrated well with vaginal tissues revealing formation of new extracellular matrix (ECM) and blood vessels inside the meshes, confirmed by histology and scanning electron microscopy. We are currently assessing macrophage polarization, inflammation, elastin metabolism as well as tensile properties from vaginal explants from sheep. Our study highlights that eMSCs modulate immune response and thus impact the fate of implants used for POP treatment. From a tissue engineering perspective, such bioengineered constructs have a significant potential as alternative autologous surgical constructs for the treatment of POP.

MATRIX-BOUND NANOVESICLE-ASSOCIATED IL-33 MODULATES MACROPHAGE PHENOTYPE TRANSITION IN THE HOST RESPONSE TO SKELETAL MUSCLE INJURY

Arthi Shridhar[P][1,2], Joseph Bartolacci[3,2], Marissa Behun[3,2], Amrita Sahu[2], Gaelen Dwyer[1], Fabrisia Ambrosio[2,4], Heth Turnquist[1], Stephen Badylak[1,2]

Favourable tissue remodelling requires an appropriately-timed transition from a pro-inflammatory (M1-like) to a pro-remodelling (M2-like) macrophage response. Matrix bound nanovesicles (MBV) activate macrophages toward an M2-like phenotype, and are a rich source of interleukin-33 (IL-33). IL-33 can attenuate inflammation, and enhances satellite cell expansion for muscle regeneration. This study evaluated the effects of MBV-associated IL33 on macrophage phenotype and associated muscle regeneration. Bone marrow macrophages and MBV were isolated from C5BL/6 and C5BL/6-il33-/- (IL33 KO) mice1. Muscle stem cells (MuSC) were isolated from wild-type mice, and treated with (i) recombinant IL33, (ii) IL33-MBV or (iii) IL33+ MBV for 4 d (1 x 109 MBV/mL). Additional groups included supernatants from macrophages treated with the same. MuSC differentiation was evaluated through immunolabeling for myosin heavy chain. For in vivo studies, a muscle injury was induced using cardiotoxin in (IL-33 KO) mice2 and IL33+ MBV was delivered to the tibialis anterior. At 3, 7 and 14 d, cells were immunolabelled for M1-like (Cd11b/iNOS), M2-like (Cd11b/Fizz) macrophages, and satellite cells (MyoD). Muscle function was evaluated using in situ contractile testing at 14 d. Treatment with exclusively IL33+MBV promoted an M2-like macrophage phenotype, and enhanced myogenesis. The latter was observed solely in the indirect treatment group, suggesting a possible macrophage-mediated mechanism. Impaired functional recovery and reduced satellite cell activation in IL33 KO mice, was partially restored upon exogenous provision of IL33+ MBV. MBV-associated IL-33 plays a significant role in promoting a macrophage transition that is conducive for the functional repair of muscle following injury.

Tendon injuries account for the highest percentage of musculoskeletal clinical complaints [1]. Due to the replacement of the native structure by scar tissue the bone-tendon interface (enthesis) weakens, and full function is rarely restored. Tissue engineering is a promising strategy to increase understanding of enthesis formation and repair, a requirement of functional enthesis regeneration. In this study, we developed a tissue-engineered model with which to study enthesis development based upon the encapsulation of human bone marrow mesenchymal stromal cells (hBMSCs) in a biocompatible hydrogel.

Hydrogels were formed by 400-500 nm blue light photocrosslinking of methacrylated gelatin and a poly(D,L-lactic acid) and poly(ethylene glycol) co-polymer. Rheometry revealed a storage modulus of 1.93 ± 0.23 kPa with hydrogels showing a degradation time of >48 days. Biocompatibility was confirmed with encapsulated hBMSCs showing high cell viability (>80%), cell spreading (actin staining) and proliferation (Ki67 staining). We then formed separate blocks of tissue-engineered tendon and bone to study enthesis development at the tissue interface. Upregulation of tenogenic markers and tendon-like tissue formation showed optimized tenogenic differentiation under TGF-β3 and mechanical loading. High mineralization indicated osteogenic differentiation of encapsulated hBMSCs. This hydrogel platform was then used to study the influence of paracrine signalling on artificial enthesis formation.

Together, our findings support the utility of our system as a tissue engineering platform to study enthesis formation and development. This system enables further analysis of the influence of paracrine signalling at the enthesis and the mechanisms responsible for artificial enthesis development.

Cutaneous wound healing process leads to the formation of scar tissue rather than the restoration of functional and aesthetically satisfactory skin. Wound healing process consists in three precisely and highly programmed phases: inflammation, proliferation, and remodeling. In this work, a composite collagen hydrogel with tunable properties is proposed as a candidate for holding and releasing components intended to heal skin wounds. Type I collagen hydrogels were crosslinked with oligourethane and loaded with colloidal silica, and optionally, with anti-infection agents. The in vitro macrophages response to hydrogel was studied, as well as the physicochemical and mechanical properties. Composite collagen hydrogels were deposited in situ on the rat skin wounds and the formed skin was examined histologically. Hydrogels demonstrated to be suitable for injection reaching storage modulus around 500Pa after a 15min of gelation. The collagen crosslinking modulated in vitro degradation and water uptake capacity and did not prevent the viability of dental pulp stem cells and macrophages. Macrophages cultured within hydrogels produced IL-1β, IL-10 and TGF-β1; commonly associated with an immunoregulation response. This silica-doped crosslinked collagen injectable hydrogel accelerated wound contraction, reaching 90% in 10 days, compared to the 75% of controls. Wound healing was featured by a shorter inflammatory stage and accelerated angiogenesis, fibroblast ordering, and dermal maturation after composite hydrogel application. Altogether these results suggest that hydrogel components act synergistically to promote functional wound closure, suggesting a role in the inflammatory and proliferation phases.

In recent years, a cell spheroid system is considered as one of the most common and versatile way to culture cells in 3D. However, limited size, weak structural stability and heterogeneous cell differentiation of cell spheroid due to the insufficient supply of oxygen/nutrients into the central region, relatively weak cell-cell interaction, and different concentration of signaling molecules along the cell depth of the spheroid are still remained as critical challenges. In this study, we fabricated porous microparticles with leaf-stacked structure throughout entire matrix (ELSS particles) which can provide space for sufficient supply of oxygen/nutrients in cell spheroids, act as a filler for improved structural stability of cell spheroids, and allow sustained release of signaling molecules for effective induction of cell differentiation throughout whole cell spheroids. A cell spheroid system was prepared using the ELSS particles and human bone marrow-derived mesenchymal stem cells (hBMSCs). The morphology, release pattern of bone morphogenetic protein-2 (BMP-2) from ELSS particles, cell survival/structural stability/osteogenic differentiation of hBMSCs in cell/ELSS spheroid system were observed. We also evaluated cell/ELSS spheroid system for promoting bone regeneration in a SD rat (calvarial defect model).

Shortness of donor nerves for grafting peripheral nerve injuries has led to the development of nerve guidance conduits that connect sectioned stumps and thus help to prevent the formation of neuromas. Often, the standard diameters of these devices cannot be adapted to the diameter of the nerve injured at the time of surgery. In the present work, bi-zonal scaffolds were developed to form nerve conduits filled with an inner matrix made of unidirectional channels, which is covered by a multidirectional pore zone. Collagen type I dispersions (5 mg/g and 8 mg/g) were sequentially frozen using different methods to obtain six laminar scaffolds. Each of these scaffolds consisted of a unidirectional pore/channel zone adjacent to a multidirectional pore zone. Conduits with adjustable diameter were formed by rolling-up the scaffolds from the unidirectional to the multidirectional zone. Physicochemical, microstructural, and mechanical properties of the scaffolds, as well as their biodegradability, residual glutaraldehyde, and cytocompatibility were determined and compared. Based on the results of these comparisons, proliferation and differentiation of human adipose-derived stem cells were assessed in only one of the scaffolds. These cells adhered, aligned in the same direction as the unidirectional pore fibers, proliferated, and differentiated into Schwann-like cells. The results of this work highlight the potential ability of the tested scaffold to form adjustable nerve guidance conduits capable of interacting with cells in vivo when grafted onto a severed nerve.

Keywords

Bi-zonal scaffolds ; Collagen type I; Peripheral nerve regeneration

DECELLULARIZATION OF 3D BIOPRINTED TISSUES TO ENGINEER 'OFF-THE-SHELF' IMPLANTS FOR BONE REGENERATION

Pierluca Pitacco[P][1,2], Daniel J Kelly[1,2,3]

Decellularization of the ECM deposited by cells in vitro represents a promising strategy to develop bioactive biomaterials as its composition can be engineered to meet specific requirements. The capacity to generate patient-specific implants can be further enabled by emerging 3D bioprinting strategies. The goal of this study was to generate engineered-ECM scaffolds for bone regeneration by decellularizing 3D bioprinted tissues primed in vitro for endochondral bone formation.

A fibrinogen-based bioink [1] containing hMSCs was 3D bioprinted within a polycaprolactone scaffold generated by fused deposition modelling to create mechanically reinforced constructs, which were subsequently cultured within one of three different culture regimes (chondrogenic, hypertrophic, chondrogenic+BMP-2) and then decellularized using freeze/thaw cycles, a wash in Triton X-100 + NH4OH and DNase treatment. Biochemical assays and histological analyses were performed pre- and post-decellularization, and after reseeded osteogenic culture.

After decellularization, DNA content dropped for all the regimes to less than 35% of the pre-decellularization value. sGAG levels decreased, but constructs retained 60% or more of the initial values, while approximately 80% of the deposited collagen was always retained. Compared to the uncultured bioink controls, all the decellularized implants better supported the osteogenesis of reseeded hMSCs under minimal osteogenic culture in vitro, with cells depositing the highest values of calcium on the hypertrophic constructs. A subcutaneous implantation pilot study in mice showed that decellularized grafts supported robust vascularization in vivo.

An ongoing rat femoral defect study is now exploring the potential of these three promising decellularized engineered-ECMs to promote bone regeneration.

The human pluripotent stem cells (hPSCs) are a stable and limitless source of regenerative medicine due to hPSCs differentiation into all types of cells in our body. However, current differentiation process of human pluripotent stem cells into cardiomyocytes to enhance the purity of hPSC-derived cardiomyocytes requires some purification processes, such as Fluorescence-activated cell sorting (FACS) or Magnetic-activated cell sorting (MACS), which are laborious and expensive. In this study, we developed cell sorting plates, which were prepared from coating thermoresponsive poly(N-isopropylacrylamide) and extracellular matrix proteins on the cell culture plates. After hPSCs were induced into cardiomyocytes on the thermoresponsive surface coated with laminin-521 for 15 days, the temperature of the cell culture plates was decreased to 8-9 ℃ to detach the cells partially from the thermoresponsive surface. The detached cells exhibited a higher cardiomyocyte marker of cTnT than the remaining cells on the thermoresponsive surface as well as the cardiomyocytes after purification using conventional cell selection. The detached cells expressed several cardiomyocyte markers, such as α-actinin, MLC2a, and NKX2.5. This study suggests that the purification of hPSC-derived cardiomyocytes using cell sorting plates with the thermoresponsive surface is a promising method for the purification of hPSC-derived cardiomyocytes with inexpensive and easy operational way compared to conventional laborious purification processes.

While various types of injectable tissue adhesives have been developed, insufficient adhesion performance of these materials to load-bearing soft tissues, as well as their poor physiochemical properties remain a challenge in biomedical applications. Commercially available adhesives such as fibrin- and PEG-based adhesives present low adhesion, and cyanoacrylate adhesives could cause cytotoxicity. Moreover, most developed hydrogel adhesives impose limitations such as non-injectability, high polymer content, low mechanical properties, slow implementation and the need for the host tissue surface treatment.

By controlling the interfacial bondings and bulk mechanics, we propose an intrinsically-adhesive design platform for the development of hydrogels with multifaceted functionalities. Our single network (SN) hydrogels were fabricated with (a) a two-step modification of a polymeric backbone (e.g., hyaluronic acid, gelatin), including methacrylation of the chains and subsequent chemical conjugation of adhesive molecules, and (b) incorporation of a reinforcing component (e.g., fibrillar collagen, fibrillated cellulose). With the versatility of the design strategy, not only a high level of adhesion under a very fast curing time was achieved, but wide window of physicochemical properties was obtained for the target applications. The potent adhesion performance of our hydrogels was studied by ex vivo and in vivo (goat model) evaluations.

We have particularly targeted the treatment of meniscus tears with the developed adhesive hydrogel as an unmet clinical need. Current surgical techniques involve either highly invasive and complex suturing methods or permanent removal of the damaged regions. Our findings highlight the potential of hydrogel family for minimally-invasive treatment of the meniscus tears.

Vaginal childbirth causes significant maternal tissue injury, which can later lead to incurable disorders such as pelvic organ prolapse (POP). This study introduces an immediate vaginal tissue treatment using Aloe Vera (AV)-Alginate (ALG) hydrogel (Hyd) for delivering maternal endometrium derived Mesenchymal stem cells (eMSCs) to promote early healing in a rat simulated birth injury (SBI) model. Vaginal trauma after SBI was evidenced by increased vaginal diameter and inflammatory response. Untreated tissues showed a significant reduction of smooth muscle content, increased elastin and increased tissue stiffness, indicative of fibrotic healing. Local injection with hydrogel (Hyd T) or with eMSC in hydrogel (Hyd/eMSC T) had a significant impact on birth injury reversal. Hyd/eMSC T significantly improvement smooth muscle and elastin content, comparable to uninjured control vagina. At the nanoscopic level, injury caused disorganised structural collagen with increased D period but intervention with Hyd/eMSC T, normalised collagen structure and significantly reduced tissue stiffness. Hyd/eMSC injection showed significant immunomodulation evidenced by lowered M1:M2 ratio while restoring connective tissue composition after 6-weeks. Immediate treatment of severe vaginal birth trauma with therapeutic eMSCs delivered in AV-ALG hydrogel may be a potential new treatment strategy for healing birth injury and preventing future POP in women.

Introduction: Any material intended for bone tissue engineering requires having various properties in a single structure. This can be achieved by combining organic and inorganic materials with considerably different properties in the form of hybrids that retain the intrinsic properties of their constituents and acquire new, synergistic properties. Here, we have prepared spherical photoluminescent hybrid microparticles (MPs) from L-phenylalanine-derivatized poly(ester amide) (PEA) and tertiary bioactive glass (BG) and loaded them with two compounds.

Methods: Hybrid microparticles were synthesized using sol-gel process in the presence of PEA, with catalytic amounts of acid in a two-pot process. By adding Nile Blue and Orange G as hydrophobic and hydrophilic model compounds during synthesis, single- or dual-loaded MPs were obtained.

Results: Single-phase homogeneous hybrid microparticles were synthesized from PEA and BG. A nucleation-aggregation mechanism is proposed for the formation of the MPs. The homogeneity of the MPs was proven via EDX elemental mapping, while deposition of a layer of hydroxyapatite on the surface of MPs after a one-day incubation in simulated body fluid demonstrated their bioactivity. The MPs possess intrinsic photoluminescence properties owing to PEA. Nile Blue showed a sustained release profile for more than 14 days. The cytocompatibility of the MPs was demonstrated through culturing of mesenchymal stem cells embedded in a fibrin gel containing MPs for 2 weeks.

Conclusion: The bioactivity in cooccurrence with intrinsic photoluminescence and the possibility of dual drug release, all in a homogenous microparticle, offer a unique platform for bone tissue engineering, including both regenerative and pharmaceutical therapy.

Pelvic organ prolapse (POP) impacts 65% of women over 68 years of age. Recently non-degradable transvaginal meshes were banned owing to the chronic inflammation and foreign body reaction. This study proposes to overcome such clinical hurdles by designing optimal degradable 3D printed melt electrowritten (MEW) meshes as a promising alternative, that can minimize undesirable immune response. Meshes of MEW poly ε-caprolactone (PCL) with hierarchical geometry were fabricated by two-way stacking of the strands at spacing: 1 mm, 0.5 mm at 3 different interlayer angle of 90, 45 and 22.5 Deg. The mesh morphology study by electron microscopy reveals the strand thickness to be 18.86 ± 2.16 µm. The hierarchical mesh printed at 45 and 22.5 Deg showed better proliferation of vaginal fibroblasts and tensile strength at the dry condition. The meshes were implanted in a mouse model of POP to assess the foreign body reaction at 1 and 6 weeks. Explants revealed hierarchical 45 and 22.5 Deg angular meshes showed better tissue integration. We are currently assessing the expression of CCR7 and CD206 in tissues to understand the impact of geometry on macrophage polarization. This study profiles the immunobiology following MEW mesh implantation to provide an optimal alternative in urogynecological surgery.

Extra cellular vesicles (EVs) are a primary paracrine effector of cell mediated improvements in tissue healing. The mechanism underlying this therapeutic benefit is thought to result indirectly from the immunomodulatory abilities of EVs, via triggering the secretion of cytokines that promote alternatively-activated (M2) anti-inflammatory macrophages. Our hypothesis is that EVs can eventually be functionally incorporated into 3D printed scaffolds to direct macrophage polarization, improving the tendon healing landscape. Thus, the goal of this study was to determine the effectiveness of cell specific EVs to direct monocyte / macrophage polarization into an M2 phenotype. EVs were purified via size-exclusion filtration from enriched media of primary tenocytes from human and ovine rotator cuff tendons harvested 2-15 hours post-mortem. Human monocytes (THP-1 cells) were differentiated into a macrophage phenotype using phorbol 12-myristate 13-acetate (PMA) and co-cultured with: 1) 100ug/mL purified exosomes, 2) exosome depleted tenocyte enriched media, 3) fetal bovine serum, or 4) exosome depleted fetal bovine serum. Cultures were analyzed using an immunologic multiplex assay examining IL-6, 1L-12, and IL-10 macrophage markers. Cultures challenged with human tenocyte derived exosomes showed marked upregulation of IL-10 expression, a primary M2 phenotype indicator, in relation to pro-inflammatory macrophage markers including IL-6 and IL-12 as compared to all other culture groups. These data showed a significant alteration in macrophage signaling toward an M2 phenotype for this specific exosome cohort. Future work will strive to incorporate EVs into 3D printed scaffolds as an approach to improve the surgical repair of rotator cuffs.

Pelvic Organ Prolapse (POP) is the herniation of pelvic organs into the vagina. Despite broad acceptance of mesh use in POP surgical repair, the complication rate is unacceptable. Tissue engineering techniques involving a biologic or synthetic scaffold seeded with regenerative and immunomodulatory cells could provide a promising alternative. This study aimed to determine the Foreign Body Response (FBR) to nanofibrous degradable poly (L-lactic-acid)-co-poly(e-caprolactone) blended with gelatin mesh (PLACL/G) seeded with endometrial mesenchymal stem cells (eMSC) implanted in a mouse model of wound repair and tissue regeneration.

eMSC were isolated from endometrial biopsy by SUSD2 magnetic bead sorting. Electrospun PLACL/G nano-meshes with and without eMSC were implanted in a NSG mouse skin wound repair model for 1 and 6 weeks (n=7 mice/group). The expression of extracellular matrix (ECM), cell adhesion, angiogenesis and immune response genes were quantified using Fluidigm Biomark qPCR.

Our results show significant changes in ECM, angiogenesis and immune response genes in the presence of eMSC. We found a significantly reduced expression of the inflammatory gene Il-6 in eMSC seeded PLACL/G group compared to PLACL/G alone after one week ($P< 0.05$). The expression of ECM associated genes including Col-III, Cd44 and Cdh2 increased from one to 6 weeks in the PLACL/eMSC group. Constructs including eMSC showed an increased expression of angiogenesis associated genes including Pdgfa at 6 weeks ($P<0.05$).

This study shows that eMSC modulate the FBR to degradable PLACL/G nanofibre mesh through down-regulation of acute inflammatory markers and improved tissue regeneration through induction of ECM synthesis and vascularization.

Recent work highlights the potential of seeding spheroids in high resolution melt electrowritten(MEW) scaffolds to generate larger hybrid constructs with mechanical support. However, the structure to function relationships of these constructs are poorly understood. This study aimed to develop a hybrid MEW 3Dbioassembly platform to study interfaces in high throughput. We systematically investigated the effect of fibre thickness, spacing and hydrophilicity of MEW scaffolds on spheroid seeding efficiency, stability as well as cell-material, and cell-cell interactions.

Allylated gelatin (GelAGE:G1MM,20wt%) and thiolated heparin (HepSH,0.5wt%)[1,2] was biofabricated into cell-laden microspheres(15x10ˆ6 hACs/ml, 5x10ˆ6 hMSCs/ml) using oil-emulsion microfluidics[3] and photopolymerisation(450nm,30mW/cm2,3min,1/10mM Ru/SPS,60mM DTT). MEW scaffolds were 3Dprinted[4,5] with 5µm catching-fibres and tailored fibre diameter (5, 10, 50µm), +/-NaOH treatment. 3Dbioassembled MEW-constructs were cultured in chondrogenic (5w) or osteogenic medium (3w). Cellular health (live/dead®/alamarBlue®) and tissue formation (GAG/DNA, IHC:Safranin-O/Alizarin-red, Cx43/aggrecan/Col I/II) was characterized.

GelAGE-HepSH microspheres(Ø0.5mm,Ø1mm) were placed in MEW scaffolds with spatial accuracy. Both hydrophilic and 5µm diameter fibre MEW scaffolds were unable to retain spheroids. Thicker MEW structures supported fusion into larger tissue constructs, with high expression of Cx43 cell signalling, cell migration and ECM deposition, seen to support both chondrogenic (68.2±4.3GAG/DNA) and osteogenic (8.6±0.7ALP/DNA) tissue formation. Spheroids in NaOH-treated scaffolds displayed limited secretion of sGAGs(11.9±2.1GAG/DNA), highlighting the importance of optimising both scaffold design and post-treatment to guide cellular development through cell-material interactions.

In conclusion, 3Dbioassembly of microspheres into MEW scaffolds provides a facile conversion of two biofabrication strategies to achieve high-throughput shape control to support tissue fusion and deposition of tissue specific ECM proteins.

Cell spheroids represent a reproducible, high throughput strategy to generate miniaturised organs. However, the understanding of spheroid fusion and tissue integration remains a bit of an enigma. This study aimed to develop a 3Dbioassembly platform to study tissue-tissue interfaces in vitro. We systematically investigated the effect of cell source and biomaterial matrix components on biological functions including cell migration, signalling, fusion kinetics, tissue-quality and tissue-host integration.

Human mesenchymal stromal cells and articular chondrocytes were fabricated into Ø1mm spheroids using either biomaterial-free centrifugation[1,2] or 3Dbiofabrication of naturally derived hydrogels (vitreous humor;VH[3], allylated gelatin;GelAGE[4], and thiolated heparin;HepSH[5]). Thermoplastic cages(1x2x1mm) were 3Dprinted to hold two tissue spheroids adjacently (3w,TGF-β1). Cellular health (live/dead®/alamarBlue®) and tissue formation (GAG,DNA, IHC:Safranin-O,Cx43/Col I/II, PCR:Col I/II,Agg,Sox9) was characterized.

Coordinated migration was essential for MSC tissue fusion while HAC tissue-tissue interfaces were lacking both cells and collagen type II. Multicellular spheroids remodelled early fibro-cartilage to articular matrix. However, fusion between mature MSC and HAC tissues did not upregulate the chondrogenic capacity of HACs – highlighting the importance of direct cell contact over soluble cell signals (HAC-MSC:5.8±2.0 GAG/DNA, Multicellular:15.5±1.7 GAG/DNA). VH based spheroids offered relevant biomimetic cues to integrate with mature cartilage, while GelAGE-HepSH was enzymatically degraded with limited tissue forming - stressing the importance of optimising both bioactivity and degradation profiles of biomaterials for successful integrative repair strategies.

Overall, a facile 3Dbioassembly platform was introduced to study cartilage-cartilage interfaces, offering a powerful route to study both multicellular fusion mechanisms in developmental stages of organoid growth and tissue-host integrative repair strategies.

3D in vitro models of pathological adipose tissue (AT) are gaining tremendous interest for the possibility of fabricating in vitro AT equivalents useful for drug screening and new therapies development [1]. Nevertheless, the development of a scaffold able to healthy and/or pathological cell culture and mimic AT, to obtain a reliable in vitro model, is still challenging. Here, gelatine (Gel) and hyaluronic acid (HA) were investigated to realise an in vitro 3D model able to mimic AT extracellular matrix. Gel and HA were chemically modified via methacrylation to obtain GelMA and HAMA [2]. GelMA, HAMA and GelMA/HAMA hydrogels were obtained by photocrosslinking, exposing the polymeric solution to UV rays (Irgacure 2959) or to visible light (Ru/SPS as photoinitiator). The obtained samples were investigated by chemical, physical, mechanical and biological characterization.

H-NMR confirmed GelMA and HAMA methacrylation (DoF = 40.42% and 52.5%). The hydrogels showed good stability at 37°C up to 3 weeks and mechanical properties comparable to native AT. In vitro tests (3T3-L1 preadipocytes) revealed no cytotoxic effects of GelMA and HAMA obtained by UV or visible light exposure. Preadipocytes embedded in GelMA and GelMA/HAMA hydrogels were cultured up to 14 days. Alamar Blue and Live&Dead proved an increase in 3T3-L1 viability and metabolic activity for samples obtained by UV exposure or visible light exposure (0.1/1 [mM/mM] Ru/SPS concentration).

The results demonstrate the suitability of GelMA and HAMA hydrogels as 3D AT models and the potential of visible light photocrosslinking as a promising alternative to UV light exposure.

Sustained release of signaling molecules from delivery systems is a common strategy for ensuring their prolonged bioactivity and for minimizing safety issues. However, residual toxic reagents, the use of harsh organic solvents, and complex fabrication procedures in conventional delivery systems are considered as critical challenges toward clinical use. In this study, we developed microparticles with leaf-stacked structure throughout entire particle (ELSS) which can allow sustained release of the growth factor [i.e., bone morphogenetic protein-2 (BMP-2)] as well as enhance bone regeneration due to their unique morphology. The ELSS particles can be prepared by clinically feasible materials and procedures. The morphology of ELSS particles, BMP-2 release from ELSS particles; and proliferation and osteogenic differentiation of human periosteum-derived cells (hPDCs) on BMP-2-immobilized ELSS particles were investigated.

3D PRINTING OF DOUBLE-POROUS PLA SCAFFOLDS FOR BONE TISSUE ENGINEERING

Davide Vandoni$_P$[1], Davide Pellegatta[1], Nicola Contessi Negrini[2], Silvia Fare'[1]

[1] *Department of Chemistry, Materials and Chemical Engineering G. Natta, Politecnico di Milano, Milan, IT*

Additive manufacturing allows fabricating scaffolds with a single porosity level, obtained by spacing the filaments during printing (fused deposition modelling, FDM), that only allows for cells colonization and ingrowth in the porous structures [1]. We developed a novel technology to print double-porous PLA scaffold for bone regeneration by combining FDM (i.e., 3D scaffolds porosity) and a chemical blowing agent (CBA), to obtain microporous 3D filaments [2].

PLA and CBA were extruded (TTCBA-degradation, to form microporosity on filaments. Scaffolds were characterized by morphology, pore size and distribution, in vitro degradation, CaP nucleation, compressive tests, in vitro cytotoxicity (L929) and cytocompatibility (MC3T3-E1) tests.

SEM showed a correlation between CBA content and microporosity. 1 and 3% CBA scaffolds exhibited small pores amount; 5% CBA scaffold showed the lowest pores number with the smallest diameter; 7.5% samples had the highest pores number; 10% samples had the largest diameter (10-90µm). Compressive elastic modulus decreased increasing the microporosity. Degradation tests showed a significant weight loss for 10% CBA scaffolds, due to the higher pores content. The 1.5SBF treatment showed the scaffold ability to promote CaP nucleation. In vitro biological test showed high viability for all scaffolds.

FDM and CBA were coupled to fabricate double-porous PLA scaffolds. The 7.5% CBA content was found optimal and it allowed obtaining promising results, without compromise the mechanical properties and degradation kinetics.

AbstractBackground and Aim: Cryopreservation of tissues and germ cells is a way to maintain the fertility and reproduction of valuable and endangered species the aim of this study was to cryopreserve the testicular tissue and cells of different species while maintaining the quality of these samples. Materials and Methods: In this experimental study, Samples of human testicular tissue and various animal species (Mouse, Rat, Bovine and Sheep) were prepared and stored in small pieces or after enzymatic digestion and extraction of cells by slow freezing method. The quality of frozen tissues and cells after post freeze was assessed by their viability and culture.Results: The results showed that after thawing, an acceptable percentage of the cells were alive and cultured. Also, the study of gene expression in different stages of spermatogenesis by Real-time PCR method in human sample showed that the sex cells are well preserved in different stages of maturation.Conclusion: In this study, the quality and viability of testicular tissue and cells after thawing, was well preserved by the used method. The results of this research could be a way to preserve fertility in human and a way to preserve and reproduce valuable species.

Micro confinement cues can direct cellular interaction. Combining cancerous and non-cancerous in co-cultures contributes to cellular motility, localization, and organization. However, it is unclear how this milieu of signals influences the assembly of co-cultures on confined geometries. Pancreatic cancer is enriched with a cancer-associated fibroblast or stellate cellular population that when activated coordinates the deposition of extracellular matrix and can comprise over 90% of patient tumours. To observe the activity and coordination of stellate cells with pancreatic cancer, we confined an equal ratio co-culture population to protein-micropatterned hydrogels. We find that interfacial cues of the pattern edge influence stellate migration and corralling of cancer cells, especially in circle shapes. Surprisingly, enhancing convex curvature further activates and coordinates stellates yet the cells are free to migrate throughout the micropatterned region. Using computational modelling, we show the cellular localization is curvature-stress dependent for both cancer and stellate co-cultures. We also find that inhibiting mechanotransduction pathways decreases stellate activation and associated corralling. Our model also indicates interfacial cues influence collagen I production a key component of the stromal/desmoplasia reaction that decreases chemotherapeutic response in diseases such as pancreatic, breast, and liver cancers.

Aim of the study was to develop optimal wound covering based on tissue-engineering technology using decellularized porcine skin matrix. Two decellularization protocols were examined: protocol No.1 based on the using of Triton X-100 and sodium deoxycholate, protocol No.2 based on sodium deoxycholate only. After characterization by histology, DNA quantification and in vitro cytotoxicity tests the protocol No.1 was chosen for further experiments. In vivo study was carried on 1 pig of the Landrace breed. A deep skin wound was created on the back by a dermatome. For closure the decellualrized and recellularized by dermal fibroblast matrices were used, and samples from wound were assessed histologically by retrieving those during early and long-term postoperative period.

Both matrices, decellularized and recellulatized, showed the tissue biocompatibility, the development of weak inflammatory reaction and the absence of a connective tissue capsule. The decellularized matrix was detached by day 12 revealed the connective tissue covering the wound. The recellularized scaffold underwent progressive in vivo remodeling resulted to form a full-layer skin. The main feature was the existence of healthy skin with growth of hair and developed skin appendages observed during the long-term period.

Finally, we present the approach of wound covering, based on decellularized dermal matrix, which was effectively recellulatized by fibroblasts, and subsequently promoted the formation of full-thickness skin that did not require additional coating.

Somatic cells can be inefficiently and stochastically reprogrammed to pluripotent cells by exogenous expression of reprogramming factors, which are mostly transcription factors. Transcription factors cooperatively bind closed parts of the DNA to regulate downstream genes and to change epigenetic status toward reprogrammed cell states. However, current stagnation of reprogramming technology accounts for such drawbacks as a poor and slow yield of high-quality reprogrammed cells from primary somatic cells, which results in delays of medical applications. Natural transcription factors have bee used as reprogramming factors, but the effective functional alteration of reprogramming factors remains unexploited overall. Low competence of natural reprogramming factors might prevent the majority of cells to successfully and synchronously reprogram. Among reprogramming factors, Kruppel-like factor 4 (KLF4) plays central roles in reprogramming toward pluripotent state and other cell types.

Here we screened amino acid residues in the zinc-finger domain of KLF4 for enhanced reprogramming efficiency. Identified KLF4 mutant accelerated and stabilized reprogramming to pluripotency in both mouse and human somatic cells. Further, from all the amino acid residue variants of defined position, smaller amino acid residues in that position showed enhanced reprogramming activity. ChIP-seq and RNA-seq experiments revealed that the identified mutant bound to promoters of several pluripotency genes more and drove the gene expression of these genes during reprogramming. Molecular dynamics simulations predicted that this mutant formed additional interactions with DNA. Our study demonstrates that modifying amino acid residues of DNA-binding domain enables next-generation reprogramming technology with engineered reprogramming factors.

A BIOINSPIRED BOTTLEBRUSH POLYMER FOR ARTICULAR CARTILAGE REGENERATION

Articular cartilage is a hydrogel-like tissue, which enables humans to resist high repetitive loading cycles painlessly. The characteristic resilience arises from the bottle brushed glycosaminoglycan (GAG) organization and extruding of water by the tissue, which increases the strength during compression. Afterwards, the organized negatively charged GAGs rehydrate the tissue again for joint lubrication. During aging articular cartilage often loses both its GAG content and its ability to remodel. Therefore, the tissue's resistance to repetitive loading is diminished making it more susceptible to damage and osteoarthritis. Tissue engineers could recapitulate the lost biomechanical properties in newly developed hydrogels. However, hydrogels often suffer from low mechanical properties. Smartly designed bottle brushed polymers have interesting water uptake and mechanical properties for cartilage applications such as lubrication1 or strain-stiffening effects2. Therefore, we hypothesized that for cartilage applications a bioinspired bottle brushed polymer could offer a solution to resist cyclic loading and simultaneously maintain its lubrication function. We have designed a biohybrid polymer based on a hyaluronic acid backbone to which short RAFT polymerized side arms were coupled. Initially, we attached hydroscopic side arms to the backbone. To improve modularity of the hydrogel platform, we then switched towards designing activated side arms, which allows for facile customization of the platform for attaching cross-linkers or peptides. The bottlebrush polymers were characterized chemically, mechanically and physically. Furthermore, we tested injectability and cell viability of chondrocytes. Our results show that the design of the bottle brush and hydroscopicity have great impact on the mechanical properties and cell viability.

THE DEVELOPMENT AND APPLICATIONS OF MILK DERIVED PROTEIN BASED SCAFFOLD FOR BONE REGENERATION

Hee Seok Yang$_P$[1]

[1] *Dankook University*

Corresponding author's email: hsyang@dankook.ac.kr

Recently, a number of studies have reported that bioactive peptides of food proteins induced positive biological activities. One of these candidates, casein is a well-characterized protein representing 80% of total milk proteins. The β-casein possesses various multifunctional biopeptides such as casein phosphopeptide, β-casochemotide-1 that bind metal ions including calcium and magnesium with high affinity and induce macrophage chemotaxis which is crucial for bone homeostasis and repairing bone fracture by improving the differentiation of mesenchymal stem cells (MSCs). Thus, we hypothesized that the reparation of a casein-based scaffold could be enhanced bone regeneration by various biopeptides. We designed a scaffold that casein was cross-linked with biocompatible polyvinyl alcohol (PVA) via a simple freeze-thaw method (milk-derived protein, MDP). Also, the MDP coated with 3,4-dihydroxyphenylalanine (L-DOPA) (MDP-DOPA) which had been known as a mussel adhesive protein for immobilizing adhesive proteins and cytokines for recruited cells. The MDP and MDP-DOPA groups proved indirectly the contribution of macrophages migration that RAW 264.7 cells were highly migrated toward MDP-DOPA which were contained biopeptide. To demonstrate in vivo bone regeneration via biological interactions between recruited cells including macrophages and MSCs by biopeptides, we transplanted both MDP and MDP-DOPA on mouse calvarial defect model (ø=4 mm). We confirmed new bone formation using a live micro-CT and histological study, MDP-DOPA group showed faster mineral deposition and higher bone density compared to MDP group. For these results, we demonstrated the effect of multifunctional biopeptide in casein that had great potential as biomaterials via the synergetic effect of casein and L-DOPA.

Mesenchymal stromal cells (MSCs) are characterized by a regulatory phenotype and respond promptly to the environmental signals modulating their secretory activity. An appropriate preconditioning may induce MSCs to release secretomes with an enhanced regenerative potential. Secretomes are composed by both soluble factors and extracellular vesicles (EVs), whose functions could be altered differently by the preconditioning approach. Here we demonstrate that the MSC secretome is strongly modulated by the simultaneous stimulation with hypoxia and pro-inflammatory cytokines, used to mimic the harsh environment present at the site of injury. We observed that the environmental variations strongly influenced the angiogenic potential of the different secretome fractions. Upon inflammation, the pro-angiogenic capacity of the soluble component of the MSC secretome was strongly inhibited, regardless of the oxygen level, while the EV-encapsulated component was not significantly affected by the inflammatory stimuli. These effects were accompanied by the modulation of the secreted proteins. On one hand, inflammation-activated MSCs release proteins mainly involved in the interaction with innate immune cells and in tissue remodeling/repair; on the other hand, when MSCs are not exposed to an inflamed environment, they respond to the different oxygen levels modulating the expression of proteins involved in the angiogenic process. The cargo content (in terms of miRNAs) of the corresponding EV fractions was less sensitive to the influence of the external stimuli. Our findings suggest that the therapeutic efficacy of MSC-based therapies could be enhanced by selecting the appropriate preconditioning approach and carefully discriminating its effects on the different secretome components.

INTRODUCTION: Mesenchymal stem cells (MSCs) regulate cell processes by secreting growth factors, cytokines, chemokines, hormones and extracellular vesicles, known as secretome. This secretome has successfully exhibited therapeutic properties.1 Although secretome can be directly administered in the target site, its fast clearance is still challenging. Therefore, new efforts have been made to develop delivery platforms,1 that sustain secretome release and increase its retention time.

The aim of this work is to encapsulate secretome into nanoparticles (NPs) for achieving a sustained release and to evaluate their potential in wound healing.

EXPERIMENTAL METHODS: Secretome was obtained by culturing human umbilical cord MSCs under hypoxic conditions. Protein content was determined using a protein array. Secretome was encapsulated in poly(lactic-co-glycolic) (PLGA) NPs by double emulsification. NPs size and zeta potential were measured using a Zetasizer. The loading content and release was evaluated using a microBCA. The secretome integrity was also assessed. NPs cellular cytocompatibility was studied using human dermal fibroblasts and keratinocytes.

RESULTS: The most expressed bioactive molecules detected in the secretome were TIMP-2, TIMP-1, IL-6, IL-8, RANTES. NPs encapsulate between 7.2-13.5 μg/mg NPs, having sizes of 300-400 nm and zeta potentials below -20 mV. NPs were biocompatible and sustained the release for 7 days.

DISCUSSION AND CONCLUSIONS: The secretome composition evidenced its potential in wound healing. Secretome was successfully encapsulated in the NPs, showing a sustained release. Our results indicate that these nanoplatforms are promising wound healing agents.

Recent progresses in Tissue Engineering are directed towards the development of technologies able to provide patient specific scaffolds. Additive manufacturing (AM) techniques combining with suitable materials are able to create a physiological milieu for cell growth. As the development of bio-based biocompatible and sustainable photocurable materials for 3D printing is a stringent request to employ these techniques in biomedical applications, methacrylate biopolymers has been synthetized and exploited as photocurable materials for different AM approaches [1][2]. Commercial chitosan (CS) and carboxymethyl cellulose (CMC) were chemically modified using methacrylic anhydride reagent. Methacrylated CS was then mixed with β-glycerol phosphate salt to impart a thermally-induced phase transition and produce a chitosan-based hydrogel as bioink for cell encapsulation and 3D bioprinting of well-defined scaffold architectures. In vitro tests performed using different cell lines (NIH/3T3, Saos-2, SH-SY5Y) confirmed the absence of cytotoxic degradation products and the excellent biocompatibility of the developed hydrogel. Cellularized 3D structures were then obtained through 3D bioprinting technology confirming the hydrogels processability and its unique biological properties.

Aqueous formulations based on methacrylate CMC were easily 3D-printed through a Digital Light Processing (DLP) apparatus to produce 3D shaped hydrogels with excellent swelling ability and mechanical properties. Envisaging the application of the hydrogels in the biomedical field, cytotoxicity is also evaluated. The light-induced printing of cellulose-based hydrogels represents a significant step forward in the production of new DLP inks suitable for biomedical applications.

Here, a platform of photocurable biopolymers were then proposed as promising materials to recreate complex living tissues through AM techniques.

In situ heart valve tissue engineering utilizes the regenerative response of the human body to create a living, functional replacement valve from a resorbable, synthetic and off-the-shelf available graft. Recently, preclinical studies using electrospun supramolecular elastomeric valvular grafts have shown that this principle, also known as Endogenous Tissue Restoration (ETR), enables in situ regeneration of pulmonary valves with sustained long-term functionality in vivo1,2. However, detailed knowledge on the underlying mechanisms of the material-driven endogenous regenerative response remains elusive. Therefore, the goal of the present study was to gain a mechanistic understanding of these processes by combining immunohistochemistry, using a comprehensive sheep-specific antibody panel3, and Raman spectroscopy for spatiotemporal analysis of in situ tissue-engineered heart valves with follow-up up to 24 months. Detailed knowledge on graft resorption, neo-tissue formation, as well as the involved cellular influences was obtained. Spectral changes of graft material 2 months post-implantation, indicated starting degradation in the arterial conduit and base region of the leaflet, correlating with the presence of foreign body giant cells at these iNOS-rich, tissue remodeling sites. Interestingly, in the base region giant cells were located within the graft whereas in the conduit material giant cells remained on the outer layers with only limited infiltration into the scaffold material. Extracellular matrix components, such as collagens and elastin were formed in a highly heterogeneous fashion. Taken together, these findings enhance the understanding of material-driven regeneration and highlight the importance of the micro-environment and hemodynamic loading on the cellular response towards a biomaterial.

Mullerian Anomalies (MA) comprise all congenital disorders that affect the development of the Mullerian duct into the female reproductive tract in the fetus. It manifests itself as defect in organogenesis, vertical or lateral fusion and septal resorption causing this congenital uterine malformation. Tissue engineering for female reproductive organs using various biomaterials might help to overcome this complex anomaly. The study aims to engineer a bilayer scaffold using combinatorial approach of electrospinning on a printed structure utilizing silk fibroin (SF) and Polycaprolactone (PCL) in homogenous blend form. Briefly, different polymer ratio was chosen and optimized to fabricate scaffold by direct printing followed by electrospinning of nanofibrous layer. The electrospun substrate presented nanofibrous architecture ranging from 150 nm to 600 nm similar to native extracellular matrix (ECM) structure. 3D printed substrate supported the structure in terms of size/ shape retention that eventually facilitated enhancement in mechanical properties of the scaffold. SEM microscopy images showed nano and microstructural analysis of scaffold as well as pore distribution. Physico-chemical characterization using XRD, FTIR, and Raman spectroscopy confirmed the presence of SF and PCL. Lysozyme degradation assay showed 16% degradation after 30 days (with specific composition of SF/PCL x/y). Contact angle measurement evidenced hydrophilicity with contact angle value of 40 degree supporting 80% water absorption in less than 10 hrs. In vitro studies using fibroblast cells demonstrated enhanced cell viability, cell anchoring, migration and proliferation. It is envisioned that the developed scaffold would be beneficial to improve women reproductive health, especially those who suffer from MA

Ordered mesoporous carbons (OMCs) have been proven to be excellent drug carriers, thanks to their high loading capacity, good cytocompatibility and easy surface functionalization. However, OMCs need to be appropriately incorporated in dosage forms to allow their retention in target tissues for the requested time to completely release their cargo. To overcome this drawback, we embedded ibuprofen (IBU)-loaded spherical and rod-shape OMCs (approx. 120 and 500 nm, respectively, 100% IBU loading) into thermo-sensitive hydrogels (15-20% w/v, up to 10 mg/ml OMC concentration) based on a custom-made amphiphilic poly(ether urethane) (PEU) containing Poloxamer®407 blocks (Mn 72kDa)[1]. OMC incorporation did not worsen the overall gelation potential of PEU aqueous solutions, which still exhibited fast sol-to-gel transition under physiological conditions (few minutes). Rheological characterization highlighted that OMC geometrical features and surface coating with sodium dodecyl sulfate (SDS, 1% w/v to improve OMC dispersibility in aqueous media) played a key role in influencing the progressive organization of the polymeric chains into a gel network. Indeed, spherical OMCs better integrated into the gel network, whereas SDS heads took part to the gelation process through the formation of hydrogen bonds with PEU chains. The developed hybrid formulations released IBU at a slower rate compared to gels loaded with IBU as such (85% vs. 100% IBU released within 3 weeks), thus effectively working as injectable depots progressively releasing their cargo in loco and improving OMC residence-time in the target tissue. Hence, the engineered platform could effectively solve issues related to multiple dosing providing a long-lasting therapeutic device.

Given their effectiveness in improving patient health and quality of life, the use of silicone-based medical devices significantly increased over the years. Unfortunately, they can also act as a substrate for microbial colonization and biofilm development. Biosurfactants have recently emerged as a new generation of anti-adhesive and anti-biofilm agents [1][2]. In this work, an approach via plasma technology was proposed to covalent graft BSs on medical grade silicone substrates. Argon plasma treated silicone samples were aminolized using 3-aminopropyltriethoxysilane (APTES) to provide amino-functional groups exploited to covalently graft BSs via carbodiimide chemistry. Various characterization techniques (contact angle analysis, XPS and colorimetric assay) were used to confirm the success of each functionalization step.
The anti-adhesive/anti-biofilm activities of BS covalent grafting on modified silicone were tested against Candida albicans and Staphylococcus aureus strains. The evaluations were carried out after 1.5h (fungal adhesion phase) and 24h, 48h, 72h (intermediate and mature phases of fungal and bacterial biofilm formation). C. albicans adhesion was inhibited of 86% whereas biofilm formation was reduced in term of biomass and metabolic activity of 80% and 78% respectively, at the last time-point (72h). Biomass and metabolic activity of S. aureus biofilms were respectively reduced of 98% and 93% at 72h.The effect of these modified surfaces resulted to be constant, or even incremental, over time. In conclusion, a strategy to covalently graft BS on silicone substrates has been proposed and the anti-adhesive and anti-biofilm activity of the coating was demonstrated.

Introduction

Epithelial tissues such as skin, intestine and the oral mucosa share a common, highly conserved structure however, amongst different tissue types the surface epithelium differs and is highly specialised according to its function.

We hypothesise that signalling from the fibroblasts within the submucosal compartment is critical to the differentiation of the overlying epithelial layer. Using advanced 3D tissue culture and tissue engineering technologies we propose to investigate whether these signals are tissue-specific and assess the paracrine and juxtacrine influences between these cell populations.

Methods

Reconstructed human full-thickness skin, intestinal and oral mucosal models have been developed utilising both primary cells and existing cell lines; fibroblasts are seeded in Alvetex® Scaffold inserts forming a robust submucosa on top of which epithelial cells are seeded, which subsequently differentiate.

Results

Our tissue models demonstrate structural morphology resembling the structure of native skin, intestine and buccal mucosa. Fibroblasts produce endogenous extracellular matrix proteins which provides support for the overlying epithelia. Extensive characterisation of the models shows evidence of basement membranes and multiple other structural and functional features shared by the native tissue. When epithelial cells were cultured with non-tissue matched fibroblasts this had a significant influence on the differentiation and morphology of the overlying epithelia. Intestinal epithelial cells showed greater polarisation. Oral epithelial cells underwent a more epidermal-like differentiation pathway producing a terminally differentiated stratum corneum.

Conclusion

We provide preliminary evidence that tissue-specific fibroblasts are required for the formation of fully-differentiated mucosal tissue constructs and alternative fibroblasts sources can alter epithelial cell differentiation.

INTRODUCTION: The alpha phase of tricalcium phosphate (α-TCP) is often used as a main constituent of calcium phosphate bone cements (CPC) [1]. One of the main advantages of CPC is their application through minimally invasive surgical procedures. Even through, post-surgery infection risks are possible, usually precluded through systemic antibiotic therapy [2]. Gentamicin sulphate (GENTA) is commonly antibiotic of choice due to its wide antibacterial spectrum [1]. The aim of the current study was to prepare controlled release GENTA delivery systems based on the CPC. For this purpose, GENTA was microencapsulated in poly-L-lactic acid (PLA) matrix and prepared vehicles were dispersed within the CPC matrix.
METHODS: Microcapsules were prepared by water-in-oil-in water (W1/O/W2) double emulsion technique. CPC composites were prepared through mixing α-TCP powder and GENTA/PLA microcapsules with sodium containing salt solutions.
RESULTS: Analysis of the prepared microcapsules showed that upon encapsulation of GENTA in the PLA matrix it is possible to obtain microcapsules in which the total GENTA content equals up to 3.27±0.2 wt.%. Drug release profiles from CPC/microcapsule composites indicated that GENTA has substantial affinity to the CPC matrix, influencing the active substance release in the water medium.
DISCUSSION & CONCLUSIONS: During the research it was established that only part of the drug could be extracted from the CPC, suggesting that sulphate ions of GENTA most likely bind to the cement via van der Waals interactions.
ACKNOWLEDGEMENTS: The authors acknowledge financial support from the H2020 BBCE project under grant agreement No. 857287 and DD-SCAFF project under grant agreement No.1.1.1.5/ERANET/18/01.

3D in vitro tumor models bioengineering in ECM-mimetic hydrogels that recapitulate the tumor microenvironment provide a unique opportunity for accelerating therapies preclinical screening [1,2]. During ECM-biomaterials design stages, the selection of cell-laden hydrogel or hydrogel-3D tumor spheroid platforms remains however to be fully elucidated. Investigating the effect of differential cellular arrangement within hydrogels is paramount for robust anti-cancer therapeutics evaluation is such platforms [3]. To evaluate this, herein we bioengineered 3D spheroid microtumors or cell-laden osteosarcoma models in viscoelastic GelMA or Matrigel ECM-mimetic hydrogels, and evaluated cancer cells/microtissues maturation, as well as their response to an ALK targeted chemotherapeutic.

3D microtumors laden in ECM-mimicking hydrogels exhibited spheroidal morphology, exhibited the characteristic necrotic core found in vivo and presented significant sprouting in all ECM-mimetic hydrogels tested, thus mimicking metastases occurring at advanced disease stages. Cell-laden hydrogels did not exhibit cellular sprouting nor the formation of dense solid microtumors with necrotic core. Additionally, cell-laden hydrogels exhibited higher susceptibility to Lorlatinib treatment than 3D spheroid-laden hydrogels models. Hence, during in vitro maturation, osteosarcoma spheroid-laden hydrogels better recapitulated key features of native tumors and exhibited increased resistance to chemotherapeutics. These responses demonstrate that hydrogel-laden 3D tumor spheroids may provide a more suitable 3D microenvironment for in vitro tumor modelling and drug screening than their cell laden counterparts. Such findings highlight the importance of carefully evaluating different cellular aggregation states and microenvironments when designing ECM-mimetic hydrogels for in vitro disease modeling and for screening candidate anti-cancer therapeutics so as to extrapolate more realistic performance data.

We attempted to develop a new treatment for bronchial fistula using regenerative therapy including autologous platelet lysate and allogeneic dermal fibroblasts.

METHODS:This study included 34 patients with bronchial fistula after lung surgery. The regenerative product, consisting of human allogenic dermal fibroblasts suspension and autologous platelet lysate, was injected into the cavity of the fistula through a bronchofibroscope every second day totally five times. Hystological examination of cells from biopsies was performed after each bronchoscopy.

Human allogeneic dermal fibroblast were obtained from GMP laboratory. The total number of cells used in the one injection was 2 million per ml.

Platelet rich plasma was obtained by two-step centrifugation the patient's blood and collecting platelet concentrate suspended with plasma of total volume 10 ml. Freeze/thaw cycles were used for activation platelet. The aliquots of 2 ml platelet lysate were stored at −80oC until use.

RESULTS: The bronchial fistula was localized in main bronchus in 23 (67%) cases, in peripheral bronchus – 8 cases. From 34 patients 29 had the diameter of fistula less 10 mm, and in 5 cases the full failure of bronchial stump was determined.

All patients underwent bronchoscopy after treatment. All fistulas closed within 1 months after beginning of regenerative therapy. Bronchoscopic image confirmed fistula healing. No recurrence developed after definitive treatment. There were no adverse events. The histological examination revealed the formation of granulation tissue, metaplastic squamous epithelium.

CONCLUSIONS:Based on the results of this study, a regenerative therapy of bronchial fistula appears to be a promising treatment modality.

Key angiogenesis steps imply fine tuning of endothelial cell activities: proliferation, differentiation and migration to settle new vessel growth. Physiologically, platelets and endothelium, through their proximity, interact to support angiogenesis. In tissue regeneration, platelet-derived products can trigger therapeutic angiogenesis through autologous growth factors, cytokines and chemokines delivery. In this study, we evaluated and compared the angiogenic modulation achieved by three different platelet-derived preparations: platelet-rich-plasma (PRP), PRP-hyaluronic acid (HA) or platelet lysates (PL) at various concentrations (5-40%).

We first evaluated their biological activities on HUVEC metabolism, viability, senescence and tube formation capacities on a 2D matrigel. PRP and PRP-HA exhibited comparable biological stimulation while PL showed the lowest activity. To mimic the complexity of sprouting angiogenesis, we used a 3D angiogenic model: the fibrin bead assay (FBA). PRP and PRP-HA stimulated all steps of the angiogenic process to promote a massive sprouting of a branched microvessel network (from 4.0 (control) to 13.6-fold stimulation of total microvessel length for PRP and from 2.2 (control) to 12.6-fold stimulation for PRP-HA. PL show a milder angiogenic response (from 2.2 (control) to 9.0-fold stimulation). PL did not allow proper microvessel formation but rather promoted a stimulation of cell proliferation. Secretome profiling revealed modulations of 26 human proteins (angiogenic cytokines and chemokines, pro and anti- angiogenic growth factors and their receptors, matrix metalloproteinase and serine protease receptor) upon platelet-derived products treatment.

These in vitro experiments present PRP and PRP-HA as safe and effective cell therapy systems when a sustained therapeutic angiogenesis is needed.

The atrioventricular heart block is a pathological situation that constitutes a significant burden in pediatric heart surgery. The aim of the project is the replacement of technical pacemaker systems with biological pacemaker systems made from the patient's own cells with the potential of growing along in the child's organism to reduce the repetitive operations. A mixture of human iPSC-derived cardiomyocytes and human umbilical vein endothelial cells are embedded in fibrin gel using a dual injection head system. Accordingly, fibroblasts are embedded in fibrin gel and the extruded fiber is coupled with the cardiomyocyte- endothelial cell fiber. Both fibers are twisted and cultivated for 14 days while conditioned in a cyclic strain bioreactor. During the cultivation the 2 fibers fused forming a mechanically stable construct. Connexin 43 staining showed the conductive capacity and electrical coupling of the fiber in the aligned cardiomyocytes. The endothelial cells formed capillary-like structures, as indicated by CD31 staining. Furthermore, the collagen deposition by fibroblasts mechanically strengthened the construct. Last but not least, the electrophysiological recordings suggested that the Biopacer construct could accomodate a transition up to 180 bpm which is very promising for the future ex vivo implantation and animal studies. To fulfill this aim, our future steps include the development of a multifunctional protective shield around the Biopacer which will mechanically support the construct during the implantation. In addition, the encapsulation of immunosuppressive and endothelialization promoting factors are about preventing the patient fibrotic response and contributing to the Biopacer connection to the blood circulation respectively.

Patients diagnosed with unresectable airway stenosis often face limited treatment options. In previous studies, a biohybrid airway stent has been invented to treat stenoses caused by bronchotracheal cancer [1]. A nitinol stent is combined with a polymer cover to avoid tumor ingrowth. To maintain the mucociliary clearance throughout the luminal stent surface, the aim of this study was the exploration of different stent cover materials to promote differentiation of autologous respiratory epithelial cells inside the stent.

We examined differentiation of human respiratory epithelial cells (HREs) on different scaffold materials based on polytetrafluoroethylene, polycarbonate urethane (PCU), polyamide, polycarbonate, a collagen-elastin mixture (Cartimaix, Matricel) and a Cartimaix-PCU combination. PET-inserts were used as positive control. After one week of proliferation on different scaffolds in a liquid-liquid-interface, cell differentiation was stimulated in air-liquid-interface (ALI) for four weeks prior to analysis by electron microscopy, PAS reaction and immunohistochemistry. Furthermore, PC-9 tumor cell migration through Cartimaix-PCU was examined. We could prove mucociliary differentiation on Cartimaix, Cartimaix-PCU and controls whereas cells formed a confluent monolayer without ciliation on pure PCU. Other materials did not lead to formation of confluent cell layers. Tumor cells did not migrate through Cartimaix-PCU. In our study, we could show that Cartimaix provides suitable properties to be used as scaffold for epithelial cell differentiation. This evaluation of potential stent cover materials regarding their ability to encourage epithelial differentiation features a first step towards engineering biohybrid constructs for treatment of airway stenosis comprising ciliated epithelium that can support an improved mucociliary clearance in vivo.

SOUND-INDUCED MORPHOGENESIS FOR RAPID ORCHESTRATION OF MULTICELLULAR SYSTEMS

Tiziano Serra[P][1]

[1] *AO Research Institute Davos*

Corresponding author's email: tiziano.serra@aofoundation.org

Morphogenesis, a complex process, ubiquitous in developmental biology and tissue regeneration, is based on self-patterning of cells. Spatial patterns of cells, organoids, or inorganic particles can be forced on demand using acoustic standing waves, such as the Faraday waves. This technology allows tuning of parameters (sound frequency, amplitude, chamber shape) under contactless, fast and mild culture conditions, for morphologically relevant tissue generation. We call this method Sound Induced Morphogenesis (SIM). In this work, we use SIM to achieve tight control over patterning of endothelial cells and mesenchymal stem cells densities within a hydrogel, with the endpoint formation of vascular structures. Here, we first parameterize our system to produce enhanced cell density gradients. Second, we allow for vasculogenesis after SIM patterning control and compare our controlled technology against state-of-the-art microfluidic culture systems, the latter characteristic of pure self-organized patterning and uniform initial density. Our sound-induced cell density patterning and subsequent vasculogenesis requires less cells than the microfluidic chamber. We advocate for the use of SIM for rapid, mild, and reproducible morphogenesis induction and further explorations in the regenerative medicine and cell therapy fields.

Self-assembling hydrogels hold potential to revolutionise the way we deliver therapeutics which are not orally available, as they can be injected directly to the desired location and provide their cargo protection from clearance. The porosity and stiffness of a hydrogel are critical to its function as a depot for therapeutic molecules, as they influence the release profile and potential location of injection, respectively. Control of porosity and stiffness are typically achieved through covalent crosslinking; however this can be damaging to delicate cargo and unsuitable for injection in situ.

According to previously described methods, N-acetylated lipidated tripeptide monomers were synthesised and purified[1, 2]. Peptide monomers of different compositions were mixed before hydrogel gelation, stiffness and injectability were measured with an Anton-Paar MCR 302 Rheometer.

We have developed a self-assembling hydrogel with controlled stiffness in the absence of crosslinking, by making subtle changes to the peptide composition. We hypothesise that pore size can be manipulated in a similar fashion, and we aim to characterise the relationship between peptide composition, stiffness and pore size. Preliminary results suggest that pore size and stiffness can be controlled independently in this system, which is unique amongst self-assembling hydrogels, Independent control of hydrogel porosity and stiffness without covalent crosslinking substantially broadens the scope of potential applications, such as tissue engineering, mechanobiology studies and controlled drug delivery.

The tissue microenvironment contains a complex assortment of multiple cell types, matrices, and vessel structures. Emulating this complex and often hierarchical organization in vitro has proved a considerable challenge. Recently, the method of bioprinting into granular materials has emerged with tremendous potential for tissue fabrication. Here, we demonstrate the first example of tumor microenvironments formed through direct writing of both vasculature channels and tumor cell aggregates, within a cell-laden microgel matrix. Photocrosslinkable microgels provide control over local and global mechanics, while enabling the integration of virtually any cell type. Using computational fluid dynamics, we show that removal of a sacrificial Pluronic ink defines vessel-mimetic channel architectures for endothelial cell linings. Pairing this vasculature with 3D printing of melanoma aggregates, we find that tumor cells migrated into the prototype vasculature as a function of spatial location, thereby providing a measure of invasive potential. The integration of perfusable channels with multiple spatially defined cell types provides new avenues for modelling development and disease, with scope for both fundamental research and drug development efforts.

The aim of the study was to evaluate the biological compatibility of the tissue-engineered trachea based on a polyethylene terephthalate (PET) scaffold and allogenic mesenchymal stem cells (MSC) in experimental non-human primates.
METHODS:The study was carried out on 6 nonhuman adult male primate Papio hamadryas at Research Institute of Medical Primatology. The tissue-engineered trachea had composed of synthetic PET 3D-scaffold seeded with primate allogenic MSCs.
After 72 hours cultivation in the rotating bioreactor the samples of tissue-engineered trachea was used for subcutaneous heterotopic implantation into the scapular area of the back for local reaction. The samples existed from heterotopic position were removed after 30 days and histological examination was done.
RESULTS:The surgical intervention proper had no negative effect on animal status. Before the implantation cell viability on scaffolds was 73.4±10.2%. Morphological analysis of tissue-engineered samples showed chaotically located synthetic filaments to which cells adhered. The morphological evaluation of implanted samples showed a fine capsule, which enveloped the implanted scaffold; the capsule was presented by compact fibrous connective tissue. Aseptic inflammation was detected in the samples, no demarcation roll from neutrophils was found. Immunohistochemical reaction with antibodies to vimentin detected cells of mesenchymal origin in the tissues adjacent to the scaffold and inside.
CONCLUSIONS:In vitro studies of tissue-engineered tracheal samples detected the scaffold biocompatibility at the cellular level. The presence of a fine connective tissue capsule without manifest fibrosis, no signs of microcirculatory disorders and immune disorders indicate the biocompatibility at the tissue level and absence of toxicity.

Cells can perceive complex mechanical cues from their microenvironment, which in turn influences their development. Although our understanding of these intricate mechanotransductive signals are evolving, the precise roles of substrate microtopography in directing cell fate is still poorly understood. Here we use nanoimprint lithography to generate micropillar arrays ranging from 1 to 10 µm in height, width, and spacing to investigate the impact of microtopography on mechanotransduction. Using this library, we aimed to determine how precise modulation of surface topography can regulate changes in nuclear architecture, chromatin organization, gene expression and cell fate determination. Using Mesenchymal Stromal Cells (MSCs) as a model, we demonstrate how subtle changes to the substrate topography impacts nuclear architecture, leading to prominent DNA re-origination, changes to nuclear envelope protein expression and decreased heterochromatin presence. Additionally, we observe that those micropatterns which stimulated maximal nuclear deformations correlated with the highest degree of osteogenesis, which we demonstrate is dependent on myosin-II-generated tension. We further demonstrate that these effects also translate to the in vivo scenario, in which select micro-topographical features present enhanced cranial wound defect closure. The outcomes of this study determine new insights into nuclear mechanotransduction by demonstrating that force transmission across the nuclear envelope can be modulated by substrate topography, and that this can alter chromatin organization and impacts upon cell fate. These findings have potential to inform the development of microstructured cell culture substrates that can direct cell mechanotransduction and fate for therapeutic applications in both research and clinical sectors.

Tissue engineered vascular graft (TEVG) have good potential to replace and repair demanded blood vessels. Here, we proposed a novel method to create three-layered TEVG on biocompatible glass fiber scaffolds starting from flat sheet state into tubular shape and to train the resulting tissue by our developed bioreactor system. Constructed tubular tissues were matured and trained under 3 types of individual flow programs, and their mechanical and biological properties were analyzed. The strength of scaffold after cell seeding was 2.83 N which is enough to withstand the pressure of blood flow and the use of sutures. Fluorescent imaging and histological examination of trained vascular tissue revealed that each cell layer has its own individual response to training flow rates. Fluid flow simulation model was created based on experimentally measured tissue geometries; its analysis suggested a correlation between local flow rate fluctuations and fibroblast layer infiltration depth into the scaffold. Concluding: a three-layered tissue structure similar to natural can be created by seeding different cell types in succession, and the following training of the forming tissue with increasing flow by a bioreactor is effective for promoting cell survival, and cell layer formation of desired geometry.

Substrate mechanics is a well-known modulator of stem cell fate. However, the effect of substrate stiffness on somatic cell reprogramming to induced Pluripotent Stem Cells (iPSC) remains largely unexplored. We assessed the influence of ECM-conjugated polyacrylamide hydrogels of varying stiffness on mouse and human fibroblast reprogramming. Mouse embryonic fibroblasts (MEFs) containing a Dox-inducible reprogramming transcription factor (OKSM) cassette with endogenous Oct4-driven GFP expression were first investigated. Among the hydrogels assessed, a specific stiffness produced up to a 4-fold increase in Oct4 GFP+ miPSC colonies compared to the TCP 'gold standard' control. This hydrogel was then assessed for its efficacy in improving Sendai virus-based human dermal fibroblast reprogramming, confirming that the same hydrogel produced much larger, tighter dome-shaped ALP+ hiPSC colonies compared to the TCPS, and resulted in 10-fold higher yields of hiPSCs. Cell growth, phenotype evolution, and gene expression analysis of cells undergoing reprogramming (by FACS) indicated significant differences in reprogramming kinetics on hydrogels. Time-course RNA-Seq and subsequent bioinformatic analysis revealed differentially-regulated signaling pathways at early and late time points on hydrogels, including many known (but also new!) to reprogramming. This analysis further confirmed that our 'soft' culture environment produced higher quality, more naïve iPSCs faster, offering a novel approach to address some critical deficiencies in current iPSC-manufacturing.

Introduction. Generation of functional vascular networks is an unresolved challenge for 3D engineered tissues. Physiological growth of vascular networks depends on controlled signaling from morphogenic factors like VEGF. Physiological VEGF signaling requires interaction with the extracellular matrix. Here we used an engineered VEGF protein to decorate fibrin hydrogels and rapidly and robustly generate self-assembled micro-vascular networks in vitro.

Methods. Fibrin matrices contained 10mg/ml of human fibrinogen, 3U/ml of thrombin, 3U/ml of factor XIIIa, endothelial cells (HUVEC) and/or adipose stromal cells (ASC) for support. VEGF164 was fused to the transglutaminase substrate peptide NQEQVSPL (TG-VEGF) to enable its covalent cross-linking to fibrin.

Results. Only HUVEC/ASC co-culture generated physiologically differentiated vascular networks, with apico-basal polarization marked by basal laminin and luminal podocalyxin, and open lumens. Vessel formation was influenced by cell density and TG-VEGF: 5x106 cells/ml with 0.1µg/ml of TG-VEGF resulted in a 2.5-fold improvement in vascular density, compared to no VEGF controls, after both 7 and 14 days. Vessel diameters remained similar to controls, with a median of 17µm and therefore compatible with micro-circulation. When injected in vivo, human-derived vascular structures rapidly formed and connected to the host mouse vasculature and were perfused by the systemic circulation, proving their ability to support blood flow.

Conclusions. We identified optimized in vitro conditions, namely 5x106 cells/ml of HUVEC/ASC with 0.1µg/ml of TG-VEGF, to efficiently form a 3D, perfusable, lumenized and physiologically differentiated micro-vascular network within 7 days.

There remains a substantial unmet clinical need for tissue engineered strategies to heal large volume bone defects. The delivery of microRNAs(miRs) induces cells to produce multiple therapeutic proteins with a physiologically relevant release profile and limited side-effects(1-3). Here, we investigate the potential of a scaffold-based approach, for sustained delivery of miRs to enhance bone repair. Collagen-nanohydroxyapatite(coll-nHA) scaffolds(1,2,4) were coupled with a cell-penetrating peptide(5) to establish a miR-activated scaffold system which co-delivers miR-26a-mimic(3) and miR-133a-inhibitor(1,2) for bone repair.

Coll-nHA scaffolds were fabricated using freeze-drying techniques and cross-linked with EDAC/NHS. miRs were complexed with RALA peptide and incorporated into scaffolds. The human mesenchymal stem cells(hMSC) were seeded and evaluated in terms of miR-26a-mimic and miR-133a-inhibitor expression, metabolic activity, DNA content, ALP activity and calcium content. Calcium and H&E staining were evaluated at day 28.

The miRs were homogeneously incorporated into scaffold which retained approx.60% of miR-cargo up to 28 days and transfected the hMSCs. Importantly, the dual-delivery miR-26a-mimic/miR-133a-inhibitor scaffold effectively delivered both cargoes to hMSCs. The miR-activated scaffolds enhanced cellular proliferation of approx. 40%. The miR-26a-mimic and miR-133a-inhibitor scaffolds stimulated ALP activity and the mineralization of hMSCs. The dual-delivery system enhanced osteogenesis to greater extent compared to miR-26a-mimic and miR-133a-inhibitor alone.

Coll-nHA scaffolds were successfully used for delivery of miRs demonstrating potential to be used as next generation of therapeutics for bone regeneration. A novel dual-microRNA scaffold system could be used as a feasible and universal template for delivery of any therapeutic miRs tailoring for a myriad of applications beyond bone repair.

Brain tissue repair and regeneration represents an exceptional clinical challenge. Acute brain insults such as traumas, strokes, infections, tumors, post-neurosurgery complications as well as chronic neurodegenerative diseases and mental disorders are a major cause of mortality and disability worldwide. Currently available neurorehabilitation strategies required for these patients rely on naturally slow mechanisms as neuroplasticity and adult neurogenesis. We explored an alternative approach to stimulate brain reparation via the rapid effects of non-invasive magnetic stimulation on glial cells. We examined the effects of 18 regimes of the spatially-patterned strong (0.6 – 2 T) pulsed (0.5-50 Hz) magnetic fields (SPMFs) generated by commercially available equipment on human astrocytes and microglial cells cultured in vitro in the conventional and 3D engineered (scaffold-based) models of the brain tissue.

We found that SPMFs can directly control the proliferation and viability of human astrocytes and microglia (frequency- and pulse number-dependent up- and downregulation), selectively modulate the functional polarisation of immune-stimulated microglia with an especially strong shift towards pro-regenerative “M2-like” type in a frequency/intensity-dependent manner. With short exposure to the continuous high-frequency SPMFs, we also achieved ≈70% magnetoporation and the magnetofection of the microglial cells cultured in a monolayer by the commercial iron oxide nanoparticles loaded with GFP plasmid. Finally, with the same SPMF mode, we demonstrated the triggering of the drug release from biocompatible polymer nanoparticles.

Our pioneering findings demonstrate the exceptional potential of SPMFs as a tool for brain repair and regeneration.

At present time the number of works devoted to the decellularization of various organs has significantly increased. There are many techniques and methods for the preparation of acellular extracellular matrix (ECM), whether based on the physical, chemical and enzymatic effects on the interest.

METHODS:The work was performed on 10 male Wistar rats weighing 210 ± 40 g. Decellularization of the lung and rat heart was performed by modified protocols. The samples were implanted subcutaneously in the interscapular region. Rats were derived from experiment on days 7 and 14. We made a qualitative assessment of the composition of the cellular infiltrate around the implant using immunohistochemistry.

RESULTS:The histological evaluation of rat tissue response to subcutaneous implantation of the decellularized heart matrices was performed. The qualitative cellular composition of the inflammatory infiltrate was studied with an assessment of the dynamic changes in the macrophages, T- and B-lymphocytes amount on days 7 and 14 after the beginning of the experiment.

DISCUSSION & CONCLUSIONS:The results obtained revealed a different tissue response of the recipient organism to ECM implantation. The least expressed was the response to the lung ECM, which successfully integrated into the tissues and did not undergo significant changes. It is shown that the tissue response to implantation depends not only on the quality of decellularization and the efficiency of antigen molecules removal, but also on the initial histological architectonics and quality of preimplantation preparation of the sample.

Acknowledgements: The work was performed as part of a complex research (№АААА-А16-116042550089-5 from 25.04.2016)

Metastatic disease remains a leading cause of cancer-related deaths. Metastatic sites are frequently found in cases of neuroblastoma (NB), a malignancy of the developing sympathetic nervous system. Particularly alarming are neoplastic cell invasions of the bone marrow and the bones that strongly correlate with tumor aggressiveness and poor prognosis of patients with NB. In order to improve our current knowledge of metastatic NB biology and improve treatment success, we need appropriate in vitro and in vivo models that more closely approach the native metastatic niche. In this study, we examined how the microstructure of β-tricalcium-phosphate (β-TCP) scaffolds, which contained interconnected microchannels of defined size, affects the interaction of tumor and stromal cells with the extracellular matrix. We confirmed that the tumor microenvironment is dynamically shaped by stroma, which sustain the growth of NB cells inside the metastatic niche. With respect to flat 2D counterparts, cells on 3D β-TCP structures produce more cytokines and define Connexin-43 intracellular localization. Our data confirmed the 3D growth conditions as a determinant factor for the type of cell response to conventional chemotherapy drugs. Together, we confirmed that both, geometry and chemistry, are relevant for translating realistic mechanobiological cues to the metastatic NB. In turn, they assist tumor cells to form spheroid-shaped arrangements facilitating their pro-migratory and pro-invasive patterns.

Differentiation of corneal limbal stem cells (LSCs) from human pluripotent stem cells (hPSCs) represents an attractive therapeutic option for patients suffering from bilateral LSC deficiency (LSCD). We have previously established an effective production method for clinical grade hPSC-LSCs. Here, our aim is to identify the most potent cell phenotype for corneal tissue engineering and clinical applications.

For the deep phenotyping of the hPSC-LSC populations, quantification of the protein and gene expression studies were conducted. In addition, identity of the cells was further confirmed with whole mount immunohistochemical stainings of human and porcine corneas. Further, the functionality of the identified cell populations where analysed in 3D bioprinted corneal structures, by transplantation to an ex vivo porcine cornea model as well as with the preliminary in vivo studies in LSCD rabbit model.

As a result, we can produce a cell population highly expressing clinically tested corneal progenitor marker p63α/p40 and these cells are able to keep their stemness properties in 3D bioprinting of corneal structures. Interestingly, we also identified an early arising ABCG2-positive cell population and these cells represented a noticeably different LSC-like phenotype as compared to later arising progenitor cell population (ABCG2-negative/p63α-positive). With whole mount immunohistochemical stainings, we confirmed relevant stem cell marker expression in corneal limbal crypts. Furthermore, both ex vivo and in vivo transplantations propose that this newly identified ABCG2-positive cell populations could provide better efficacy in clinical application.

As a conclusion, these two limbal cell populations may represent functionally different stem/progenitor populations with implications in their regenerative efficacy

Glioblastoma (GBM) is the most common brain tumour in adults[1], but current treatments are limited due to its invasiveness, risk of damage during surgery, and the restricted transport of drugs into the brain[2]. One promising treatment method is the use of biocompatible self-assembling peptide (SAP) hydrogels as localised delivery vehicles. SAPs provide similar properties to the native extracellular matrix (ECM) and are easily administrated[3]. For GBM, they can be implanted post-operatively and provide sustained drug release at the resection site. Here, we investigate SAP-mediated delivery of the anti-cancer drug CX-5461[4].

Fmoc-SAP hydrogels were prepared as described previously, via a pH switch[3]. CX-5461 was encapsulated during assembly, and human GBM cells were cultured on drug-containing gels or with free drug in solution. Target inhibition was determined by RT-qPCR, and cell viability and proliferation were quantified by flow cytometry and live cell imaging.

Stable, shear-thinning hydrogels were formed with and without drug inclusion, with rheology confirming stiffness similar to the brain ECM, and FTIR and CD spectroscopies confirming the expected π-β assembly mechanism. In vitro trials with human GBM cells demonstrated that the two drug groups achieved comparable drug target inhibition and consequent decrease in cell viability at shorter timepoints. However, a significantly prolonged effect (>7 days) was observed for the drug-loaded SAPs compared to the free drug alone.

These programmable SAP hydrogels may improve therapeutic outcomes in GBM by increasing local drug accumulation and efficacy, while also providing easy implantation, high biocompatibility, and helping to support surrounding healthy tissues.

Worldwide cancer remains the second-most common cause of death, despite the advances in prevention, early detection, treatment; among the bone cancer Osteosarcoma (OS) is the most common type diagnosed especially in children and young adults1.
The failure of the osteosarcoma conventional therapies leads to the growing need for novel therapeutic strategies. The lack of specificity for the Cancer Stem Cells (CSCs) population has been recently identified as the main limitation in the current therapies2. Moreover, the traditional two-dimensional (2D) in vitro models, employed in the drug testing and screening as well as in the study of cell and molecular biology, are affected by a poor in vitro-in vivo translation ability3. To overcome these limitations, this work provides two "tumour engineering" approaches as new tools to address osteosarcoma and improve therapy outcomes. In detail, two different hydroxyapatite-based bone-mimicking scaffolds4,5 were used to recapitulate aspects of the in vivo tumour microenvironment, focusing on CSCs niche. The biological performance of human osteosarcoma cell lines (MG63 and SAOS-2) and enriched-CSCs were deeply analysed in these complex cell culture models. The results highlight the fundamental role of the tumour microenvironment proving the mimicry of osteosarcoma stem cell niche by the use of CSCs together with the biomimetic scaffolds, compared to conventional 2D culture systems. These advanced 3D cell culture in vitro tumour models could improve the predictivity of preclinical studies and strongly enhance the clinical translation, with the ultimate goal to be applied in personalized medicine.

ELUCIDATING THE INFLUENCE OF LYSOSOMAL STRESS ON SCHWANN CELLS

Karen Libberecht$_P$[1,2], Tim Vangansewinkel[1,2], Ivo Lambrichts[1], Ludo Van Den Bosch[2], Esther Wolfs[1]

INTRODUCTION: Endo-lysosomal-autophagy alterations have been demonstrated to play an important role in neurodegenerative diseases1. In myelinating cells this pathway is crucial for transporting newly synthesized myelin proteins towards the plasma membrane. This renders myelinating cells to be particularly sensitive for lysosomal stress and autophagic failure, resulting in altered myelinating activity as seen in Charcot-Marie-Tooth disease2. However, the role of lysosomal dysfunction in defective myelinating cells and neurodegeneration remains poorly understood.

Here, we aim to mimic the effect of lysosomal stress on the peripheral myelinating cells: Schwann cells (SC). Isolation of SC is challenging and the use of clinically relevant animal models is limited in neurodegenerative diseases3. Therefore, an alternative is needed to elucidate underlying pathomechanisms. Here we aim to use human dental pulp stem cells (DPSC) as an alternative, as they can be differentiated towards SC-like cells (DPSC-SC)4.

METHODS: Lysosomal damage was induced in DPSC-SCs using chloroquine in different concentrations and incubation times. Lysosomal alterations and membrane permeabilization were visualized using Lysotracker Deep red® live imaging and a GAL3-LAMP1 puncta-assay, respectively. To elucidate the influence of lysosomal enzyme activity upon lysosomal stress, a Cathepsin B activity assay was performed. Finally, cell viability was monitored using Alamar blue and PI assays.

DISCUSSION & CONCLUSIONS: Our data indicate a dual effect of chloroquine on the lysosomal integrity of DPSC-SC, and a concentration-dependent loss of cell viability.

Further research will compare the lysosomal integrity in healthy stem cells after chloroquine incubation versus stem cells derived from patients with Charcot-Marie-Tooth disease.

Hydrogels, made from biological tissues, are gaining more and more importance in tissue engineering and regenerative medicine due to their natural composition and broad applicability. Beside in vitro application for 3D cultures or as a surface coating, recent preclinical and clinical studies demonstrated that injectable materials facilitate functional tissue remodeling in wounds and necrotic tissues. However, the underlying protective mechanisms are largely unknown, although the modulating effect of hydrogels on immune cells during injury and repair may play a role.

The use of human placental tissue was approved by the ethics committee of the Medical University of Vienna (EC No. 1602/2018). ECM hydrogels were produced from different parts of the human placenta and porcine cardiac tissue by decellularization, followed by an enzymatic digestion for solubilization of the ECM matrix. ECM hydrogels were characterized thoroughly to be compared to each other in molecular composition, immunogenicity and biomechanics. Cytocompatibility was investigated by performing cell seeding experiments on ECM hydrogel coated tissue culture plates. ECM hydrogels showed low DNA residues and preservation of cell interacting and structural ECM proteins. Rheology revealed clot formation of ECM hydrogels in reproducible biomechanical strength dependent on respective hydrogel type and concentration. All tested ECM hydrogels supported cell proliferation and survival of human endothelial cells, fibroblasts and smooth muscle cells. Human macrophage cultures showed reduced survival rates by ECM-hydrogels in vitro. First in vivo experiments to investigate the promotion of cardiac tissue repair in respect to infarct healing and remodeling in association with inflammation are ongoing.

Scaffolds are three-dimensional porous structures designed to, temporally or permanently, replace a critical bone volume loss, and act as a structural support for adhesion, proliferation and differentiation of osteoblasts, which is the main precondition for healing and regeneration of damaged tissue. For this purpose, hydrogels are particularly attractive due to high porosity, swelling ability, structural similarity to extracellular matrix and potential drug deliverability. However, the soft nature and lack of bioactivity limits its application in bone tissue engineering (BTE). In this study we synthesized composite hydrogels based on double network of gelatin and poly(methacrylic acid) (PMAA), and nano-particles of hydroxyapatite (HA) and β - tricalcium phosphate (β−TCP) as a reinforcement phases. Gelatin-PMAA double network is composed of covalently crosslinked PMAA network and physically crosslinked gelatin, and is characterized by improved mechanical and biological properties in comparison to single network hydrogels. Moreover, the incorporation of nano-sized inorganic fillers HA and β−TCP, created bone-mimicking structure with optimized mechanical and biological properties. The optimization of mechanical and morphological properties, as well as bioactivity, was performed by variation of filler content and HA/ β−TCP ratio. Composites were characterized by FTIR, SEM, mechanical testing, MTT assay and in vitro bioactivity. The loading and release of anti-inflammatory drug oxaprozin was also investigated in vitro. SEM images revealed macroporous structure and compressive strength values confirmed favorable mechanics of the obtained composite scaffolds. The increase of HA content led to improve physical-mechanical properties, while increase of β−TCP favored bioactivity and cell metabolic activity.

Coupling of angiogenesis and osteogenesis is crucial to generate vascularized bone grafts. Semaphorin3a regulates bone formation through the Neuropilin-1 receptor (Nrp1). We previously found that Vascular Endothelial Growth Factor (VEGF) dose-dependently: 1) impairs osteogenesis by increasing bone resorption; 2) inhibits endothelial Sema3a expression in muscle. Here we investigated whether: a) VEGF impairs bone formation by inhibiting endogenous Sema3a expression; b) Sema3a treatment could couple angiogenesis and osteogenesis in engineered bone grafts.

VEGF or Sema3a proteins were engineered with a transglutaminase substrate peptide (TG-VEGF and TG-Sema3a) to allow cross-linking into fibrin hydrogels. Osteogenic grafts were prepared with human BMSC and hydroxyapatite granules in fibrin hydrogels containing TG-VEGF, TG-Sema3a or both (ratio 1:1) and implanted ectopically in nude mice. Sema3a/Nrp1 signaling was blocked with a specific antibody.

High TG-VEGF caused severe bone loss and downregulation of Sema3a expression. Low TG-VEGF preserved both bone formation and Sema3A expression. Blocking of Sema3a/Nrp1 signaling: 1) impaired bone formation, increasing osteoclasts recruitment and reducing human progenitor survival; 2) decreased vascular invasion; and 3) impaired endogenous Sema3a expression, recruitment of Nrp1-expressing monocytes and phospho-SMAD2/3 activation in both human progenitors and host endothelium, consistently with a positive feed-back loop we previously described between Sema3a and TGF-β1.

Conversely, TG-Sema3a co-delivery prevented bone loss by high TG-VEGF, while preserving vascular growth. TG-Sema3a alone (without TG-VEGF) significantly promoted both bone formation and vascularization.

These data show that Sema3a is a key molecular link coupling angiogenesis and bone formation, and a promising target to generate vascularized bone grafts in a clinical setting.

AGE-DEPENDENT CHANGES IN PERIVASCULAR STEM CELLS AND THE IMPACTS OF ALTERED SENSING ON VASCULAR AGEING

Justin Cooper-White[P1], Mahfuz Chowdhury[1], Ernst Wolvetang[1], Desi Veleva[1]

[1] *The University of Queensland*

Corresponding author's email: j.cooperwhite@uq.edu.au

Perivascular niches exist throughout all tissues, forming an interconnected and highly responsive 'maintenance and repair' system across our body, and their decline in function is central to many age-related diseases. Perivascular stem cells (or pericytes, PCs) within these niches are expected to be exquisitely more sensitive to changes in their local microenvironment than other tissue-resident cells. However, little is understood as to what intrinsic changes these cells undergo with ageing and how this affects their ability to maintain the niche and support tissue repair. This work aimed to investigate the intrinsic changes in human pericytes as a function of age, and thereafter the impacts of any changes on their function within an in vitro perivascular niche model. We show that fat pad-derived adult pericytes exhibit minimal changes in gold-standard phenotype markers or morphological traits with increasing age, but show substantial changes in global gene expression, protein and growth factor production. Functionally, PCs change their extent and types of interactions with endothelial cells (ECs) as they age, but in contrast, are more 'activated' and 'angiogenic', based on their secretome profile. We show that the addition of pro-angiogenic factors was insufficient to overcome these functional deficits, and moreover, that these changes are a result of altered cell-cell communication and mechano-signalling. These results provide new insight into how age-related changes in pericyte function may contribute to increased refraction of microvessel networks as we age, and suggest a number of new options for therapeutic targeting to potentially reduce age-related decline in perivascular niche function.

Three dimensional (3D) in vitro culture systems are important to mimic the heterogeneous complexity of human tissues [1]. The development of additive manufacturing technologies allows to fabricating accurate and precise in vitro models [2]. Here we focused on melt electrowriting (MEW) which serves an excellent control of fiber resolution and helps to mimic the heterogeneous complexity of native tissues in synthetic scaffolds.

The capacity to fabricate complex and microscale structures using MEW provides new opportunities in in vitro culture systems. Three types of MEW designs were investigated; 1) reinforcing matrices, 2) guiding structure, 3) migration assays (competitive assays). MEW structures printed with poly(ε-caprolactone) (PCL) (Purasorb PC-12) were used in different in vitro models stated above.

Lattice scaffolds were utilized for reinforcement purposes increasing the compressive modulus of ultra-soft hydrogel to allow manipulation during culture. A migration assay was established, where the presence of various chambers enabled a 3D competitive cell migration assay. Furthermore, peptide coated scaffolds were used as a model for studying the impact of the design and dimensions on glioblastoma cells and astrocytes. The coating of MEW scaffolds were developed based on six-arm star-shaped NCO-poly(ethylene oxide-stat propylene oxide) (sP(EO-stat-PO)) [3]. The IKVAV and RGD peptides were linked covalently to MEW fibers through a reaction with isocyanates. The results demonstrate that the coating improved cell attachment and enhanced biomimicry of native ECM.

Cardiac remodeling entails the modification of ventricle 3D architecture as a result of the deposition of de novo synthesized non-compliant extracellular matrix (ECM). While the impact of the biochemical changes associated with pathological ECM deposition has been described in animal models, the basis and impact of structural changes due to collagen assembly and alignment in heart failure (HF) are poorly described. We combined SEM, AFM and 3D two-photon microscopy imaging, with the aim of characterizing the alterations occurring in human cardiac ECM biophysical properties at end-stage HF. By this approach, we generated a comprehensive, high-resolution map of the modifications occurring in the collagen network organization during pathological cardiac ECM remodelling.Next, we adopted a multi-omics approach coupled to bioinformatics analysis to identify novel mechanosensitive proteins whose function is perturbed in pathological heart. We demonstrate the reactivation of mechanosensitive YAP in the pathological heart occurs in a cell-specific fashion, thus contributing to the establishment of fibrosis, while being involved in the increased contractility of hypertrophic cardiomyocytes.More importantly, we provide evidence that the localization and function of RNA-binding proteins can be controlled by the increased biomechanical stress generated by cardiac ECM remodelling and propose their role as mechanosensitive switches affecting RNA splicing and maturation in the pathological heart. Altogether, we identify the dysregulation of known and novel mechano-regulated proteins in the heart, thus defining the mechano-pathological pathways controlling cell contractility and RNA homeostasis to shape cardiac cell response to the ensuing biomechanical stress caused by ECM pathological remodelling.

Glycosylation is a post-translational modification that attaches glycan receptors to cell surface proteins and lipids. Glycans are a major component of the extracellular matrix and are highly important in cell-cell interactions. Abnormal glycosylation is evident during multiple chronic brain pathologies including brain cancer, making glycan receptors excellent biomarkers for selective targeting of affected cells. Lectin proteins are widely used to identify many glycan residues. Here, we investigated in vitro targeting of sialic acid (wheat germ agglutinin), fucose (Aleuria aurantia lectin), and N-acetylglucosamine (tomato lectin) glycan moieties in glioblastoma astrocytes, normal neurons and microglia cells cultured in conventional monolayers and in 3D brain scaffold-based organ-specific models.

We bio-conjugated three different types of lectin proteins to 120-nm fluorescent nanodiamond particles with nitrogen vacancy centres. The binding of conjugated nanodiamonds to the glycan receptors of astrocytes, neurons and microglia cells in standard 2D cell cultures was evaluated. Next, we developed tissue engineered constructs combining the decellularized brain scaffolds and the brain cells of choice a 3D culture system, including the unique brain scaffold-based immunoids containing microglia cells. These models helped us better assess cell targeting in each cell type in a biologically accurate models reconstructing natural-like microenvironments.

In 2D and 3D cell cultures we found that Aleuria aurantia lectin, targeting core fucose glycan receptors, binds to glioblastoma cells with the highest affinity. Our findings indicate that the bio-conjugated nanodiamonds developed in this study could be used in future studies as a drug delivery vehicle for targeting human brain cancer and immune cells.

The human amniotic membrane (hAM) is successfully used for therapeutic applications, yet mostly in a decellularized form. Since amniotic cells display stem cell characteristics, recent research has initiated a paradigm shift towards the use of hAM with its original viable cell population. However, sustaining cellular viability of hAM is challenging. It has been suggested that in vivo, the apoptosis of amniotic cells is connected to loss of tissue tension. Therefore, our study addressed the question whether tissue distention impacts the cellular viability of hAM in vitro and whether mitochondria play a critical role in this process.

hAMs biopsies were incubated for 7–21 days, either distended on CellCrown(TM) inserts, or non-distended. In non-distended hAMs B-cell lymphoma 2-associated X protein (BAX) and B-cell lymphoma (BCL)-2 ratios were increased at day 7, followed by increased caspase 3 expression at day 14. At day 21, decrease of mitochondrial respiration and ATP was observed and consequently, loss of cell viability. In distended hAMs, mitochondrial function and cell viability were largely maintained.

Our data suggest that tissue distention prolongs the life span of hAM cells in vitro. Loss of tissue tension leads to an unknown tension-driven mitochondrial pathway (TDMP), resulting in mitochondria impairment, induction of caspase 3-mediated apoptosis and loss of viability of hAM cells. Further exploration of this mechanism will bring more understanding in the hAM physiology and support the optimization of hAM tissue cultures.

The study was funded by the Austrian Research Promotion Agency (FFG grant number 867674).

Intra-articular injection of Mesenchymal Stromal Cells (MSCs) has been recently proposed as a promising treatment for osteoarthritis (OA); yet, cell therapies still suffer from limitations (e.g., cell death upon injection, cell leakage). To overcome these drawbacks, MSCs could be encapsulated in injectable, cytoprotective hydrogels to support their viability and bioactivity. However, for successful intra-articular delivery, hydrogels should also be able to bear loads and absorb shocks. In this context, we envisioned to develop new, injectable and self-healing, boronic acid-based hydrogels to improve OA cell therapy.

Polysaccharides were first successfully functionalized with either boronic acid derivatives or diol-containing molecules via single-step syntheses, as confirmed by NMR or elemental analysis. A vast screening of boronic acids and diols led to the discovery of an innovative couple that allows the instantaneous formation of dynamic hydrogels under physiological conditions of pH and temperature, and is applicable to a variety of polysaccharides (e.g., hyaluronic acid, alginate, carboxymethyl cellulose). These hydrogels are stable for at least 2 months under physiological conditions with a shear elastic modulus ranging from 100 Pa to 1000 Pa. Due to their dynamic nature, the resulting hydrogels are injectable and can self-heal instantly after network disruption, making them suitable for intra-articular applications.

MSCs encapsulated in the newly designed hydrogels displayed excellent viability (> 90%) after 7 days of culture. The evaluation of the paracrine activity of encapsulated MSCs, as a function of hydrogel composition and mechanical properties, is now under investigation, laying the foundations for a new generation of OA cell therapy.

COACTIVATION OF ENDOGENOUS WNT10B AND FOXC2 BY CRISPR ACTIVATION ENHANCES BMSC OSTEOGENESIS AND PROMOTES CALVARIAL BONE REGENERATION

Mu-Nung Hsu[P][1]

Corresponding author's email: peter5552345@hotmail.com

CRISPR toolbox has been wildly expanded nowadays to accomplish precise, robust and easy genetic manipulation, but its potential for tissue regeneration has yet to be fully explored. The nuclease-dead Cas9 (dCas9) proteins are programmable transcriptional regulators that can be reconstructed with transcriptional activation domains for multiplexing gene regulation[1]. To promote BMSC differentiation toward osteogenesis and improve calvarial bone healing by BMSCs, we constructed a hybrid baculovirus vector (Bac-CRISPRa) that harbored a synergistic activation mediator (SAM)-based CRISPRa system to activate Wnt10b (that triggers the canonical Wnt pathway)[2] and forkhead c2 (Foxc2) (that elicits the noncanonical Wnt pathway)[3] in BMSCs. qRT-PCR revealed that Bac-CRISPRa enabled CRISPRa delivery and potently activated endogenous Wnt10b and Foxc2 expression in BMSCs for >14 days. Furthermore, the robust and prolonged coactivation of both Wnt10b and Foxc2 additively enhanced osteogenic differentiation while inhibiting adipogenic differentiation of BMSCs. Implantation of CRISPRa-engineered BMSCs into the calvarial defects remarkably improved the bone healing in rats. These data underscore the potentials of CRISPRa system for tissue engineering.

EFFECT OF BIOMATERIAL COMPOSITION ON MSC CHONDROGENESIS EMBEDDED IN A HYALURONAN COMPOSITE CONTAINING COLLAGEN FIBRILS

Andrea Schwab[P][1], Flurina Staubli[1], David Eglin[1], Matteo D'Este[1]

[1] *AO Research Institute, Davos*

Corresponding author's email: andrea.schwab@aofoundation.org

Biomimetic properties of biomaterial-inks, induced via 3D-bioprinting, allow mimicking the architecture of microfibrillar components in extracellular matrix 1. Aim of this study was to investigate the effect of collagen (col) concentration and col source in combination with a HA biomaterial on hMSC chondrogenesis.

Tyramine-modified HA was mixed with col from rat tail or from Jellyfish (J) (HA–col in mg/ml): 12.5-2.5 (1:1) and 16.6–1.7 (2:1). hMSC micropellets were embedded into biomaterials (5 mio/ml), enzymatically crosslinked for 3D-bioprining (3D Discovery RegenHu) or casting and light-crosslinking. hMSC pellets served as control group. Samples were cultured in chondrogenic media containing TGF-β1 (21 days) and analyzed for cartilaginous matrix synthesis (histology, proteoglycan quantification, PCR).

hMSCs migrated throughout biomaterial and differentiated towards chondrogenic lineage in HA-col marked by increased proteoglycan content (5000ugGAG/ugDNA), which was not observed for HA and HA-J. Upregulation of cartilage markers col II and aggrecan and SOX9 (100/300; 50/100; 4/4 fold-change) confirmed MSCs differentiation in HA-col (2:1/1:1), accompanied by little upregulation of col-I (0.6/0.6 fold-change), RunX2 (<2/2 fold-change) and col X that was more pronounced in pellet control (15 fold-change) compared to HA-col. hMSC embedded in HA and HA-J had low expression of cartilage markers. Col fibrilswith anisotropic orientation after 3D-bioprinting was shown by fluorescence imaging. Micropellets showed deformation in circularity in HA-col (0.96±0.02) upon printing (0.81±0.13, 18G needle) .

HA-col composite has proven to support hMSC migration and chondrogenesis with stronger chondrogenic response at higher col content. Shear induced col fiber orientation of THA-col bioink allows to control and direct cell migration.

3D SCREENING PLATFORM OF CELL-ADHESION PEPTIDES: GOING BEYOND RGD

Aurelien Forget$_P$[1]

[1] *Institute for Macromolecular Chemistry*

Corresponding author's email: aurelien.forget@makro.uni-freiburg.de

Cell-adhesion peptides (CAPs) such as the ubiquitous arginine-glycine-aspartic acid (RGD) sequence have allowed the functionalization of synthetic materials to mimic macromolecules of the extracellular matrix (ECM). However, the variety of ECM macromolecules makes it challenging to reproduce all of the native tissue functions with only a limited variety of CAPs. Screening of libraries of CAPs, analogous to high-throughput drug discovery assays, can help to identify new sequences directing cell organization. Challenges to this approach include the automation of cell seeding in three dimensions and characterization methods.[1]

Here, we report a method for robotically generating a library of 16 CAPs to identify microenvironments capable of directing a chain-like morphology in olfactory ensheathing cells (OECs), a cell type of particular interest for spinal cord injury to guide axon growth. This approach resulted in the identification of two CAPs not previously reported to interact with OECs to direct their morphology into structures potentially suitable for axon guidance.[2]

Following a similar approach, we are extending the screening to a broader variety of cell lines. With this new work, we are now equipped to better understand the cell interactions with the ECM. Screening of cancer cell lines will help us to investigate the progression of cancer as a function of the ECM biological adhesive properties and ECM mechanical properties Similar screening with mesenchymal stem cells will help us to discover new CAPs responsible for directing the organization of cells into structures pertinent for tissue regeneration.

Pharmacological compounds that selectively eliminate senescent cells and are termed "senolytics" were found to extend the healthspan of mice, to prevent or delay the occurrence of senescence-associated diseases and the development of frailty.

Here we discovered an altered lipid metabolism in senescent human dermal fibroblasts (HDF), which was centered on an elevated phospholipase A2 (PLA2) activity generating elevated levels of intracellular lysophosphatidylcholines (LysoPCs) and arachidonic acid (AA). These LysoPCs were significantly elevated in replicative senescence (telomere dependent) as well as in doxorubicin-induced premature senescence (SIPS; telomere independent) and correlated well with the senescence markers p21 and SA-β-galactosidase activity.

High intracellular levels of AA can induce apoptosis, which is usually prevented by conversion of AA into eicosanoids by cyclooxygenases (COX) and lipoxygenases (ALOX) or by reacylation and degradation processes after activation of AA by acyl-CoA synthases (ACSL). By blocking AA conversion with inhibitors against COX, ALOX and ACSL we achieved a senolytic effect in SIPS HDF, as well as lung fibroblasts and renal epithelial cells, where the EC50 value for senescent cells was up to 700-fold lower for senescent cells compared to quiescent control cells. The senolytic effect could be rescued with either an activator or inhibitor of cPLA2 and was thereby confirmed to be dependent on the elevated PLA2 activity of senescent cells. In line with previous reports, AA-induced apoptosis was ATP sensitive suggesting the involvement of ADP/ATP translocases.

Taken together, our data suggests, that the inhibition of AA conversion is a promising strategy for the development of senolytic therapies.

Abstract **#763**

LONG-TERM LOW-MAGNITUDE FLUID SHEAR STRESS DIRECTS BONE MARROW MESENCHYMAL STEM CELLS TOWARD OSTEOGENIC LINEAGE

Growing evidence indicates that the modulation of environmental factors alone is sufficient to regulate mesenchymal stem cells (MSC) fate to certain lineages although differentiation is commonly induced chemically in vitro. When it comes to clinical translation, however, it is to be induced without chemical treatment in order to overcome concern over unexpected adverse impacts. Recently, we have developed a perfusion bioreactor specifically for bone tissue engineering where MSC on three-dimensional scaffolds receive controlled fluid shear stress (FSS) for long term. In this study, by applying the bioreactor, biological responses of MSC to FSS including osteogenic differentiation were evaluated. MSC from Lewis rat bone marrow (rBMSC) were seeded on microporous scaffolds of a synthetic copolymer, Poly(L-lactide-co-trimethylene carbonate), and were subject to low-magnitude FSS (approximately 1.0-3.5e-4 Pa) up to 21 days. FSS induced by the system was characterised by an in-silico model. While FSS supressed cell proliferation, the expression of early and late osteogenic markers including Runt-related transcription factor 2, Alkaline phosphatase, Osterix, Osteopontin and Osteocalcin were significantly upregulated by FSS over the period of 21 days compared to a static counterpart. Similarly, mineral formation was observed on day 21 in the FSS group. Interestingly, FSS induced the upregulation of a definite and direct gene target of canonical Wnt signalling pathway, Axin2, which suggests the active role of the pathway in FSS-induced osteogenesis. Taken together, we have demonstrated that long-term low-magnitude FSS alone can direct the rBMSC fate toward osteogenic lineage, which can potentially improve the efficiency of bone regeneration after transplantation.

The use of non-covalent self-assembly to construct materials has become a prominent strategy in biomaterials science offering practical routes for the construction of increasingly functional materials for a variety of applications ranging from cell culture and tissue engineering to in-vivo cell and drug delivery.[1] A variety of molecular building blocks can be used for this purpose, one such block that has attracted considerable attention in the last 20 years is de-novo designed peptides.[2] The β-sheet motif is of particular interest as short peptides can be designed to form β-sheet rich fibres that entangle and consequently form very stable hydrogels. These hydrogels can be easily functionalised using specific biological signals and can also be made responsive through the use of enzymatic catalysis [3-4] and/or conjugation with responsive polymers [5]. Through the fundamental understanding of the self-assembly and gelation of these peptides across length scales [6-8] we have been able to design hydrogels with tailored properties for a range of applications including for the culture of a variety of cells[9-11], injectable and sprayable hydrogels for cell and drug delivery [12-13] as well as shear thinning hydrogel for 3D bio-printing [14-15]. The intrinsic biocompatibility [16] and low immunogenicity [17] of these materials makes them also ideal for TERM applications. Recently we have demonstrated their potential in a range of TERM applications including, oesophagus [18], nerve [19], intervertebral disk [20] and cardiac [21] regeneration.

Mechanophysical and microbiological assessment of poly(epsilon-caprolactone)/poly (ethylene glycol) based electrospun nanofibrous mats loaded with an antibacterial for wound tissue engineering applications

Husam M Younes P[1], Sandi Ali Adib [1]

[1] *Office of Vice President for Research & Graduate Studies, Qatar University, Doha, Qatar.*

Corresponding author's email: husamy@qu.edu.qa

PURPOSE

The purpose of this study is to fabricate and characterize mechanically optimized biodegradable electrospun nanofibrous scaffolds (BENS) prepared using the hydrophilic Poly (ethylene glycol) (PEG35000) with the hydrophobic Polycaprolactone (PCL) co-polymers and assess the impact of loading them with Amoxicillin Trihydrate (AMX) on their mechanophysical and microbiological.1,2

EXPERIMENTAL METHODS

Blank and AMX-loaded BENS were fabricated using PEG35000 and PCL. Morphology of BENS was assessed using SEM. FT-IR was used to identify the interaction between PEG35000 and AMX. DSC was used to determine BENS crystallinity and thermal behavior. The XRD analysis was utilized to identify the changes in the BENS crystalline pattern. The prepared BENS were also subjected to mechanical testing and their in vitro antibacterial activity against common skin pathogens was also tested

RESULTS AND DISCUSSION

Various weight percentage ratios of PCL75%: PEG25%, PCL50%: PEG25%, PCL25%: PEG75% in chloroform were prepared. The DSC and FT-IR analyses showed that the polymers and AMX structures were not affected by the electrospinning. The PCL75%: PEG25% mix resulted in the optimal mechanical strength and used for preparing the AMX-loaded BENS. The DCS, FT-IR, and XRD studies confirmed the existence of AMX in the BENS and its dispersion and transformation into an amorphous state. The in vitro antibacterial assay confirmed the efficiency of the drug-loaded fibers against the common skin pathogens.

CONCLUSION

Our findings showed that PEG & PCL based BENS possessed enhanced mechanical and microbiological properties that made them promising candidates for wound healing applications.

LOCAL ACTIVITIES OF THE MEMBRANES ASSOCIATED WITH GLYCOSAMINOGLYCAN-CHITOSAN COMPLEXES IN BONE CELLS

Hsin-I Chang[P][1], Min-Fang Yang[1]

[1] *National Chiayi Univesity*

Corresponding author's email: hchang@mail.ncyu.edu.tw

Chitosan is a cationic polysaccharide derived from the partial deacetylation of chitin. Hyaluronic acid (HA), chondroitin sulfate (CS) and Heparin (HP) are anionic glycosaminoglycan (GCGs) which can regulate osteogenic activity. In this study, chitosan membranes were prepared by glutaraldehyde crosslinking reaction and then composited with three different types of GCGs. 7F2 osteoblast-like cells and macrophages Raw264.7 were studied in vitro for the effect of chitosan membranes on osteometabolism. Although chitosan membranes are highly hydrophobic, the membranes associated with GCG-chitosan complexes have showed about 60-80% cell attachment. Furthermore, the membranes associated with HP-chitosan complexes could increase ALP activity, up-regulate OPG/RANKL mRNA ratio and inhibit COX-2 mRNA expression in comparison with chitosan films only. All membranes could also inhibit MMP-3 mRNA expression. On the other side, three types of the membranes associated with GCG-chitosan complexes could significantly inhibit LPS induced-Nitric Oxide expression. In addition, chitosan membranes associated with HP and HA can down-regulate Tartrate-resistant acid phosphatase (TRAP) activity but not CS-chitosan complexes. Based on these results, we conclude that chitosan membranes associated with HP can increase ALP activity and up-regulate OPG/RANKL ratio in osteoblasts and chitosan membranes associated with HP and HA could reduce TRAP activity in osteoclasts.

VVolumetric muscle loss (VML) decreases muscle regeneration capacity and lacks treatments. Injectable hydrogels are promising therapeutic candidates but their potential strongly relies on the presence of porosity allowing cell infiltration and vascularization. Therefore, this study aimed (1) to create injectable and porous hydrogels based on poly-lysine dendrimers (DGL)/NHS-polyethylene-glycol (PEG) through an effervescent approach and (2) to evaluate its ability to sustain muscle cells progenitor differentiation for skeletal muscle regeneration.

We found that effervescent porous hydrogels (EPHs) of modular mechanical properties could be prepared by dissolving acetic acid and potassium carbonate to DGL and PEG solutions, to create a spontaneous, homogeneous and interconnected porosity, remnant of the stabilized CO2 bubbles entrapment in simultaneously cross-linked hydrogels. The use of sole precursor solutions allows to inject the formulations with a dual syringe and a static mixer, leading to porous hydrogels that were proven biocompatible by subcutaneous injection in mice.

As a striking result, primary human myoblasts[1] (phMs) seeded into 3D EPHs showed extensive myotube formation and visible striation after 6 days in serum-depleted medium with spontaneous contractions. Quiescent satellite cells presence inside EPHs was confirmed with myogenic regulatory factor Pax7 up to 14 days after differentiation, consolidating EPHs potential to support tissue formation by replenishing stem cell niches.

In conclusion, we describe a novel porous hydrogel with potential as scalable solution for VML treatments within a swift and straightforward injectable delivery, which provides an optimal support for muscle cells progenitors to differentiate into contractile myotubes while maintaining a pool of muscle stem cells.

Introduction

Osteoarthritis (OA) is a multi-tissue disease in which the excessive infiltration and accumulation of monocytes in the synovium contributes to joint damage. Here, we created an organotypic microfluidic model recapitulating monocyte extravasation under inflamed OA-like conditions to investigate this dynamic process.

Methods

Synovium and cartilage were mimicked using hydrogel-embedded human OA synovial fibroblasts and chondrocytes. A perfusable endothelialized channel intervened in the synovium to mimic a post-capillary venule. Another channel was dedicated to synovial fluid injection. The endothelial monolayer was subjected to fluid flow and TNF-α before monocyte injection. Monocyte extravasation in response to a chemokine mix or OA synovial fluid was quantified and compared to a control group (culture medium).

Results

TNF-α and fluid flow synergistically induced the expression of ICAM-1 and VCAM-1 in endothelial cells. Validation experiments proved that monocyte extravasation was significantly higher in the presence of chemokines compared to the control group. Finally, we demonstrated that synovial fluid from OA patients induced a significantly higher number of monocytes to extravasate compared to the control group. Monocyte extravasation was enhanced by endothelium pre-activation.

Discussion & Conclusions

Our microfluidic OA joint model was successfully used to study monocyte extravasation in OA-like conditions, providing the first direct evidence that OA synovial fluid acts as a chemoattractant and induces monocytes to cross the endothelial barrier and invade the synovial compartment. We are currently assessing the effect of several molecules in modulating monocyte extravasation in obese and normal-weight OA patients.

KEYWORDS: Cell-derived matrix, Tumor modelThe use of cell-derived matrices (CDM) is a promising alternative to decellularized tissues/organs consisting of a complex assembly of macromolecules. 3D cell-cultured PLA microparticles combined with macromolecular crowding (MMC) effect, hold a great potential to develop bioactive materials for disease modeling applications. We propose CDMs as colorectal tumor models for personalized medicine by mimicking tissue microenvironment properties1.CDMs are produced by seeding human mesenchymal stem cells on fibronectin-coated PLA microparticles2 and cultured in presence of MMCs. Obtained CDMs are biochemically characterized by immunostaining and mass spectrometry; gene expression by qRT-PCR and RNA-sequencing; and mechanical properties by atomic force microscopy. Decellularized and particle-free CDMs are recellularized with colorectal cancer cells and cancer associated fibroblasts (CAFs)3 to further characterize cell-cell interactions, gene expression and CDM-remodeling potential. Obtained CDMs are compared with human colorectal tumor samples from patients.MMC effect enhances protein deposition in CDMs. Collagen types I, III and fibronectin are CDMs' main constituents, resembling colon tumor extracellular matrix. Decellularized and particle-free CDMs were recellularized with colon cancer cells and CAFs. Cancer CDMs' characterization is taking place to develop an in vitro tumor model to understand cancer promoting mechanisms, develop patient-specific drug screening platforms and to identify potential therapeutic targets.CDMs composition and the tunable matrix stiffness provides reproducible tissue microenvironment. By repopulating CDMs with cancer and stroma cells, we pretend to mimic native tissue structure and properties to obtain a promising platform for in vitro tumor model generation.Authors thank MINECO (MAT2015-68906-R) and RTI2018-096320-B-C21 for funding

Metastatic colonization of the organs is the main cause of cancer-related deaths. The patterns of cancer cells dissemination of the in different organs are not completely explainable by the blood circulation and vascularization, implying that local and organ-specific factors may contribute to the observed metastatic phenomena. In this work, we applied tissue engineering methodology to explore the effect of organ-specific extracellular matrix (OS-ECM) on cancer colonization rates and strategies.

Twelve types of OS-ECM scaffolds with preserved composition and histoarchitecture were prepared by mild decellularization, seeded with various types of cancer and cultured in vitro. The model tumors were assessed by pathology methods, digital image analysis, and machine learning approaches. In a separate experiment we seeded breast cancer cells on collagen I-coated silicone surfaces with controlled stiffness (from 0.2 to 64 kPa) and examined stiffness-induced phenotypical changes to correlate with our 3D culture observations.

Most OS-ECMs contained two compartments, originating from the organ parenchyma and stroma, respectively. They had different roughness/stiffness but similar chemical composition. Cancer cells revealed alternative attachment, migration and morphology in these OS-ECM compartments during the first 3 weeks in vitro, followed by spongification and total colonization of the matrix. The breast cancer cells phenotypic plasticity was upregulated across various stiffness levels. OS-ECM also significantly decreased sensitivity of cancer cells to chemotherapy.

This work demonstrated that virgin OS-ECM provides a dual morphogenetic niche which induces alternative cellular behaviour and enhancing adaptiveness of cancer cells. The implications of our findings for cancer diagnosis and treatment will be discussed.

YAP is a pro-fibrotic co-transcriptional activator which promotes extracellular matrix (ECM) deposition. While it is now credited of acting in a positive loop controlling cytoskeleton tension (1), the interplay between ECM and cytoskeleton through YAP is not completely clear. By combining decellularized matrices (dECM), RNA sequencing and immunostainings, with CRISPR/overexpression techniques, we defined YAP contributes to ECM generation in different cell types. We described how YAP controls the expression of individual matrisome components, and the deposition, remodeling and degradation of surrounding ECM. YAP mutant cells presented reduced cellular stiffness, that was mirrored by a deranged nucleoskeleton and decreased nuclear tension, inducing morphological abnormalities and alterations in the levels and distributions of several components of the nuclear envelope such as Nesprins and Lamins. Cell stiffness and nucleoskeletal organization were partially restored by growing cells onto dECM produced by cells expressing pathologically high YAP levels, with a significant recovery in Lamin A/C levels and nucleoplasmic retention of its phosphorylated forms. This rescue was independent of actomyosin tension and microtubular structures. In conclusion, we describe a mechanoparacrine effect of YAP by which cells, through the control of ECM production, can affect the cellular and nucleoskeletal mechanics of neighbor cells, independently of their own YAP intracellular activity. Our results suggest that combined therapies targeting simultaneously YAP and ECM could be potentially more beneficial in cancer therapeutic approaches.

Pelvic organ Prolapse (POP) is a condition effecting 1 in 4 women caused by injury and subsequent weakening of the vaginal wall during childbirth. Until recently reconstructive surgery augmented by synthetic non-degradable meshes were commonly used, however these meshes have been now banned owing to complications arising from severe foreign body responses (FBR). To promote tissue regeneration and mesh integration, we have developed nanostructured degradable meshes using electrospinning of polymer poly (L-lactic acid)-co-poly (ε-caprolactone) blended with Aloe Vera (PAV) boosted with endometrial mesenchymal stem cells (eMSCs). PAV meshes with and without eMSCs were implanted into a mouse model of POP and evaluated for mesh integration, fate and FBR response after 1 and 6 weeks. Our results show that meshes with eMSCs reduced cell adhesion and capsule formation at the mesh-host interface by 6 weeks compared to PAV alone. Scanning electron microscopy (SEM) revealed formation of neo blood vessels, ECM as well as improved mesh integration at the mesh interface. We are currently investigating the macrophage mediated FBR response with focus on M1 and M2 polarization. Our results highlight the potential of such meshes as an alternative POP treatment that may address a major unmet women's health need.

DESIGN, TOOLS AND BIOMATERIALS FOR SYNTHETIC MORPHOGENESIS

Aurelien Forget$_P$[1]

[1] *Institute for Macromolecular Chemistry*

Corresponding author's email: aurelien.forget@makro.uni-freiburg.de

Answering the question of how organs develop has been driven by focusing on the cell's gene expression. However, during the development of organs, materials surrounding the cells play a key role in guiding their organizations by presenting information in the form of gradients. By adapting novel design strategies and manufacturing tools with biomaterials, we now have the capacity to reproduce graded architectures needed to achieve synthetic morphogenesis.

Endeavours to create synthetic organs have been focusing on reproducing the cellular organization of mature tissue using diverse biofabrication techniques. Away from the technical race aiming to achieve faster and more precise cell deposition to reproduce the complex cell organization observed in adult tissue, we would like to present an approach where a synthetic environment would be programmed to direct the organization into a mature organ following the design rules of organ development.

In this talk conceived in three parts, we will first present our most recent work on how we can apply architectural tools to adopt design theory based on developmental principles.1 We will then proceed to showcase our manufacturing advances for the creation of graded objects mimicking developmental gradients. Finally, we will present our clickable biomaterials that can be functionalized with peptides during 3D printing, allowing us to create 3D patterns of biological information.

We envision these technological advances as a cornerstone to create multiple morphospaces where the principle of organ development can be tested in vitro to shape the future of regenerative medicine.

There is an increasing evidence that the tissue architecture has a strong influence on cell behavior and it is key to obtain functional tissue replicates (1). Hence, future improvements in the tissue engineering field will encompass tailoring three-dimensional (3D) cell microenvironments with the precision required to mimic in vivo features.

3D printing techniques have been positioned as a feasible alternative to conventional manufacturing techniques to achieve proper spatial resolution in a high-throughput manner, mainly due to high adaptability and reduced costs, becoming one of the current hot topics in applied research (2,3). However, requirements in terms of resolution, mechanical properties, or biocompatibility to obtain biomimetic 3D tissues demand further innovative approaches.

Here we present a fast, low cost and versatile printing method based on visible light polymerization for the fabrication of 3D bioengineered substrates and cell-friendly interfaces using photopolymerizable hydrogel-based bioinks. These bioinks are highly transparent and have low molecular content, mimicking the soft mechanical properties of the tissues.

With the appropriate combination of bioink composition, accurate selection of the printing parameters, and optimized designs we succeeded with prints for different applications, including cell culture substrates, microfluidic channels and tissue constructs for in vitro assays, compatible with the standard cell culture techniques. As a proof-of-concept, we developed functional scaffolds mimicking the 3D microstructure of the small intestine, containing both the epithelial and stromal compartments, using cell-laden bioinks.

Through this versatile top-down technique we demonstrated the potential of the light-based 3D bioprinting technology, contributing on providing alternatives beyond tissue engineering state-of-the-art.

INTRODUICTION: Fragility of osteoporotic bone is challenging, while the patients in most cases also possess the age-related disorders, highly influencing the fracture healing around the surgical sites [1]. Strontium ranelate (SrRan) has been found as an effective drug able to increase and stabilize the bone mineral density. Hyaluronic acid (HA) and calcium phosphates (CaP) have attracted an interest due to their biocompatibility and osteoconductivity, respectively. Most frequently HA based hydrogels consist of randomly interconnected polymer chains and drugs when incorporated in such structures without any covalent linkage to the HA network are released rapidly not serving as a prolonged release systems [2]. The aim of the current study was to evaluate the potential of HA/CaP/SrRan composite hydrogels as prolonged release drug delivery vehicles.

METHODS: HA/CaP/SrRan composite hydrogels were pepared mixing all components with 0.25M NaOH and BDDE. Prepared systems were crosslinked for 24 h at 45 °C, neutralized in 0.9% NaCl solution and used for the determination of SrRan release via UV-VIS.

RESULTS: All prepared hydrogels were characterized with active substance burst release (>30%) within the first 24 h, followed by up to 77% of SrRan release in dissolution media within period of 75 days.

DISCUSSION & CONCLUSIONS: During the research it was established that SrRan release from prepared compositions strongly depends on the route of CaP nanoparticle introduction into the hydrogel systems as well as on interactions between HA and drug molecules.

Control of cellular behaviour using external stimuli is a concept widely adopted in many biomedical applications, including regenerative medicine. Within these applications there is either a desire to control differentiation or preserve a particular phenotype, including stem cell culture and its applications. Material surface manipulation facilitates the replication of tissue anatomic structures through the creation of wrinkles across biomaterial surfaces (1). The underlying principle governing wrinkle formation is that the surface stiffness must be greater than the underlying bulk, when this stiffness is great enough the surface wrinkles upon physical deformation of the body. Therefore creation of polymer laminated elastomer blocks and O2 plasma treatment of elastomer are feasible techniques to achieve controllable and tuneable wrinkles (1). Previous work in the regenerative medicine field has featured static substrates for cellular topography replication, however a dynamic topography system is required as well. In this study, multiple parameters have been optimised to generate wrinkles with defined frequency, width and depth. To facilitate the generation of tuneable surface wrinkling, spatially and temporally, the laminated block method was combined with a small-scale bioreactor system fitting within a conventional cell culture vessel was developed. Using the laminated block system, a dynamic returnable wrinkled topography was achieved. The wrinkled surfaces generated by both methods have demonstrated the ability to align/ localise cells in discrete regions and alter their morphology. From these developments and utilising further optimisations, these methods will be useful studying cell response to the dynamically tuneable topography, including mimicking epithelial degenerative diseases.

THE EFFECT OF PORE SIZE ON OSTEOGENIC DIFFERENTIATION OF BONE MARROW MESENCHYMAL STEM CELLS IN SILK FIBROIN SCAFFOLDS

Chengchong Ai[1,2], James Goh[1,2]

[1] *NUS Graduate School for Integrative Sciences and Engineering, National University of Singapore*

Porous silk fibroin (SF) scaffolds have been widely used for bone tissue engineering (BTE), and the pore structure of scaffolds plays an important role in osteogenesis. The pore size of SF scaffolds reported in literature for BTE is quite varied, ranging from 60 to 700 µm[1, 2]. This study aimed to investigate the effect of pore size on osteogenic differentiation of bone marrow mesenchymal stem cells (BMSCs) in vitro. HFIP-derived SF scaffolds with pore diameters in the ranges of 355-400, 250-315, 160-220 µm were prepared by salt leaching methods, named as Large, Medium, and Small group. Porcine BMSCs were seeded on scaffolds and cultured in osteogenic medium for 21 days to evaluate cell proliferation, alkaline phosphatase (ALP) activity, calcium deposition, gene expression of osteogenic markers, and histological performance. Cell metabolic rate in each group increased significantly with time, but there is no statistical difference on the reduction rate at each time point among three groups. On day 21, ALP/DNA and calcium/DNA in Small group was significantly higher than that in the large group. Col I mRNA expression on day 7, OPN mRNA expression level on day 14, and OCN mRNA expression level on day 21 in Small group is higher. Immunohistochemical staining results on day 21 showed that Col I and OCN in Small group were more highly expressed. In conclusion, the HFIP-derived SF scaffolds with a mean pore diameter of 0.19 µm was optimal for osteogenic differentiation of BMSC in vitro.

Introduction

Osteoarthritis (OA) is characterized by cartilage degradation and alterations in subchondral bone remodeling and angiogenesis. Here, we exploited a microfluidic device to model the osteochondral interface for investigating the expression of factors involved in these processes in healthy and OA-like conditions.

Methods

The cartilage compartment was modeled by fibrin-embedded human articular chondrocytes. The cellular components of the bone part namely osteoblasts, osteoclasts, and endothelial cells were embedded in fibrin hydrogel enriched with calcium phosphate nanoparticles [1]. To induce OA-like conditions, the experimental group was treated with IL-1β. The expression of markers related to cartilage degradation, bone remodeling, and angiogenesis was assessed.

Results

Matrix metalloproteinases expression by osteoclasts was evident in both groups, being slightly higher in IL-1β treated samples. Differently, chondrocytes expressed matrix metalloproteinases only when treated with IL-1β. The expression of RANK as a factor regulating osteoclastogenesis was higher in the IL-1β treated group. Regarding angiogenesis, vascular endothelial growth factor was highly expressed only by endothelial cells in control samples, whereas its expression by osteoclasts was strongly upregulated when the samples were treated with IL-1β.

Discussion & Conclusions

We developed the first microfluidic vascularized osteochondral model in which cartilage and bone compartments are in direct contact. We demonstrated that inflammatory conditions stimulate the expression of matrix degradation factors, regulate bone remodeling, and involve osteoclasts in angiogenesis augmentation. We are currently analyzing the response of the model to an anti-inflammatory drug, Dexamethasone, in terms of all the aforementioned factors.

Bile secreted from hepatocytes has function to assist digestion and absorption of lipids. However, excessive accumulation of bile acids in hepatocytes causes necrosis. Therefore, bile must be transported from bile canaliculi, which are formed by hepatocytes, to bile ducts, which are formed by cholangiocytes. From the viewpoint of liver tissue engineering, it is important to construct bile canaliculi and bile ducts in vitro. Although previous studies reported construction of each tissue, little is known about a coculture in which bile canaliculi and bile ducts are connected. Here, we induced connection of bile canaliculi and bile ducts by the coculture of rat primary small hepatocytes and cholangiocytes. Specifically, we cultured cholangiocytes on collagen gel for 3 days, then started coculture by adding small hepatocytes. The cells were then overlaid with collagen gel and dimethylsulfoxide was added to culture medium for inducing bile duct formation. We confirmed that small hepatocytes and cholangiocytes jointly formed a luminal structure at the junction of bile canaliculi and bile ducts. We also investigated the CYP activity of small hepatocytes in the coculture. The results showed that the CYP activity of small hepatocytes in the coculture was comparable to that in the single culture. Finally, this coculture model was reproduced in a small culture device for miniaturizing the coculture model and for easy analysis of the connection of bile canaliculi and bile ducts. We fabricated a small PDMS culture device with two compartments, in which bile canaliculi or bile ducts were constructed.

Corresponding author's email: masayuki.s.205@keio.jp

There is a growing demand for transplantable bioengineered livers for patients with end-stage liver diseases due to a shortage of donor livers. Decellularized liver scaffolds are thought as a promising platform for constructing bioengineered livers because of their intact scaffold architecture, ECM composition, practical scale, and low immunogenicity. Although bioartificial liver surrogates have been developed using decellularization techniques, hemocompatibility of vascular networks in the liver surrogates is not enough, which is the main cause of the difficulty in long-term transplantation. Therefore, hemocompatibility improvement of liver surrogates is important, which can be achieved by re-endothelialization of vascular lumens. Here, we hypothesized that construction of sinusoid-scale microvessels in a decellularized liver could provide better hemocompatibility of liver surrogates. We recently established a method to construct vascular networks including sinusoid-scale microvessels in a decellularized liver1. In the present study, we tested hemocompatibility of the constructed vascular networks in a decellularized liver. Specifically, a re-endothelialized liver on day 2 was perfused with diluted rat blood. The number of platelets attached to the scaffold was counted to evaluate hemocompatibility of the re-endothelialized livers. The number of platelets in a decellularized liver with sinusoid-scale microvessels was five times smaller than that without sinusoid-scale microvessels and about ten times smaller than that in an acellular liver scaffold. These results could be attributed to both physical effect of covering vascular lumens with endothelial cells and endothelial biochemical antithrombic effect.

Substrate topography at the micro and nanoscale is emerging as a powerful tool to manipulate cell behaviour, but studies into these effects are hampered by a lack of access to topographies that can be readily incorporated with the standard biological techniques and methods of analysis. Current techniques to produce micro and nanopatterned substrates are often difficult to produce across a surface area large enough to perform biological analyses, require time consuming and tricky manipulation of substrates into standard cell culture plates and are typically not made of the same material (polystyrene), which further complicates any comparison with typical cell culture datasets.

We have developed a simple and scalable technology to produce precise micro- and nano-scale topographic patterns on the surface of standard cell cultureware. We show that the characteristics of the surface are maintained and that the process does not impede imaging. We further highlight the utility of this technology by performing a high-throughput screen to interrogate the effects of 12 surface topographies across 5 different cell types and are able to identify common and distinct cellular response to topographic features as well as image-based signatures to identify specific cell phenotypes. This technology could open up the potential of micro/nano-topographies in the culture and screening across an enormous range of biological applications.

As a treatment for type I diabetes, clinical islet transplantation in which donor islets of Langerhans are transplanted in the liver of the recipient has become a viable option for patients. However, the success of this procedure is limited by factors including ischemia, host immunological factors, and delayed vascularization of the hypoxia-sensitive islets. One solution would be to use a synthetic biomaterial scaffold as a carrier for the transplanted islets, as it would allow for their transplantation into a more favorable normoxic environment and protect the cells from host immune reactions. To realize this potential solution, it is important that the synthetic biomaterial implant not interfere with the functionality and survival of the islets. In order to determine which biomaterials best meet this essential condition, we examined the interactions of human islets from six donors cultured on four clinically-approved materials: polyetheretherketone (PEEK), polyvinylidene fluoride (PVDF), polyphenylsulfone (PPSU) and polysulfone (PSU). Human islet morphology, viability, insulin secretion, functionality and gene expression were investigated to assess the suitability of these biomaterials as a carrier for transplanted islets. We found three of the synthetic biomaterials (PEEK, PPSU and PVDF) showed promise based on their overall favorable assay results, while the functionality of islets cultured on PSU resulted in significantly reduced insulin secretion from five of six donors. Our findings demonstrate that certain synthetic biomaterials can influence islet function and an examination of any synthetic biomaterial on islet function would be beneficial before selecting that material for fabricating an islet implant device.

A major limitation to the integration and survival of large tissue engineered bone at the site of implantation is the lack of an intrinsic vascular network. In this work, a customized cell patterning approach was developed to create a vascularized bone construct, made from a bilayered scaffold of electrospun PLGA/nHA composite fibres interleaved with a PEG based-hydrogel displaying an osteogenic peptide (OP), patterned with human bone marrow-derived mesenchymal stem cells (hBMSCs) and human endothelial cells (hECs). Utilizing this novel co-culture approach, a bone osteon mimic, comprised of lumen structure seeded with hECs surrounded by multilayers of hBMSC-laden PLGA matrix, was produced. The co-cultured PLGA-nHA-PEG-OP implant produced significant improvements in bone formation and cell maturation (even in growth/maintenance only medium) compared to hBMSC-based monocultured implants, confirmed through gene expression and protein secretion. Importantly, the co-cultured scaffolds showed promising results in terms of maintaining hEC morphology and function, even after 21 days, with VE-cadherin staining confirming the formation of tube-like structures between regions populated with hBMSCs and hECs. Osteocyte-like cells with multi-dendritic morphology, communicating with neighboring osteocyte-like cells, were observed throughout the scaffold. These osteocyte-like cells expressed early osteocyte marker gene, including E11/gp38 (E11) as well as late marker expression, including dentin matrix acidic phosphoprotein 1 (DMP1). The outcomes of this study demonstrate that when seeded with cell types constituent of the bone marrow microenvironment, these novel multilayered composite scaffolds, in presenting native bone-mimicking biochemical and biophysical features, are able to create osteocytes within vascularised osteon-like structures, in vitro.

Parkinson's disease (PD) is a highly debilitating disorder of the nervous system that affects more than 1% of the population over the age of 60. Cell therapy has emerged as a promising strategy for modifying PD's progression [1]. However, early evidence suggests that a high percentage of implanted cells die, possibly due to mechanical stress during transplantation and the subsequent host immune and inflammatory responses. Encapsulating cells within a biomaterial could potentially confer protection and promote engraftment [2]. In this work, we propose a multidisciplinary approach to identify a suitable biomaterial and define the optimal seeding density, oxygen availability and spatial distribution of ventral midbrain dopaminergic progenitors differentiated from human pluripotent stem cells.

Initial experiments compared different biomaterials to identify those which protected the cells from mechanical stress during injection, with a blend of collagen and hyaluronic acid identified to be most appropriate. Additionally, the effects of cell seeding density and oxygen availability on cell survival were explored, revealing that these cells were able to tolerate hypoxic conditions associated with relatively high seeding densities and low levels of environmental oxygen in vitro.

Using an in-house mathematical framework, parameterized with the data acquired, the interactions between cell seeding density and relevant spatial and temporal distributions can be modelled and optimised in silico prior to in vivo testing [3]. This interdisciplinary approach combines experimental work with mathematical modelling to accelerate the clinical translation of new therapeutic strategies.

The efficacious repair of severe peripheral nerve injuries is currently an unmet clinical need. These injuries require surgical intervention and the gold standard of repair, transplanting nerve tissue from elsewhere in the body to bridge the gap, suffers from donor-site morbidity, limited supply and graft diameter mismatch. Polymeric electrospun nanofibrous nerve conduits potentially offer an artificial alternative to this technique by providing guidance for the regenerating nerve, in order to achieve target reinnervation and functional recovery. Generating these conduits with aligned fibres and encapsulated drugs, alongside the post-fabrication seeding of therapeutic cells, may further improve regenerative outcomes by mimicking the native nerve structure and cellular environment.

Here, two conduits were developed with a trilayered wall material formed from randomly-orientated drug-eluting fibre mats sandwiched between two aligned polymer-only fibre layers. The central drug-eluting layer contained either glial cell line-derived neurotrophic factor (GDNF), a potent neurotrophic factor, or tacrolimus, an immunosuppressant known to promote nerve regeneration. The encapsulation of GDNF into polycaprolactone (PCL) fibres was achieved using emulsion electrospinning, and GDNF-PCL fibres were optimised for uniform morphology and sustained release of bioactive protein. Coaxial electrospinning was used to fabricate PCL fibres containing tacrolimus and also yielded fibres with consistent morphology and controlled drug release. The ability of the axon-interfacing layer of the wall material, aligned PCL-only fibres, to guide neurons was also explored. These conduits show promise for nerve repair and may support regeneration across gaps in nerve tissue as an alternative to the current gold standard.

Hydrogel bioprinting holds potential for capturing the zonal architecture of native cartilage, enhancing tissue regeneration[1]. Yet, fixation of hydrogel constructs is a major challenge due to limited lateral integration and the risks of damage to the surrounding tissue upon crosslinking. The aim of this study was to develop a printable hydrogel with potential for in situ cartilage repair, based on a cell-laden gelatin methacryloyl hydrogel modified with tyramine moieties (gelMA-Tyr) bearing dual crosslinking capacity.

Photo-induced gelation of the reactive acryl- and tyramine groups was triggered in one step via visible-light irradiation using Ru/SPS. GelMA-Tyr and gelMA were loaded with articular cartilage progenitor cells and cultured in vitro. Both gelMA and gelMA-Tyr supported cell survival and chondrogenesis in terms of viability, glycosaminoglycans production and compressive modulus.

GelMA-Tyr exhibited shear-thinning behaviour and could be printed using an extrusion-based platform, while showing shape retention post-printing[2]. The tissue-binding capacity was studied using a push-out test upon casting in chondral explants. The visible-light tyramine-methacryloyl dual crosslinking showed 15-fold the adhesive strength to native cartilage compared to Irgacure-gelMA.

Moreover, the Ru/SPS visible-light crosslinking system resulted on average on 57% higher cell viability of surrounding native cartilage when compared to UV-Irgacure crosslinking. Ru/SPS crosslinkers did not show oxygen inhibition, facilitating the use of the gel in situ.

Overall, visible-light crosslinkable gelMA-Tyr hydrogels in combination with the dual crosslinking mechanism triggered by Ru/SPS demonstrated potential for direct delivery and integration into damaged cartilage. Its potential as a bioink enhances the possibilities for the repair of complex, patient-specific defects.

Peripheral nerve injury (PNI) affects 1M people in Europe and the USA p.a., and patients often experience debilitating symptoms [1] including loss of sensation and paralysis. The associated healthcare and societal costs amount to around 100 billion $/year in the USA alone [2].

The current gold-standard for large gaps injuries consists of connecting the two stumps through microsurgical autografts. However, this requires the extraction of healthy nerve from patients, resulting in donor site morbidity and often poor functional outcomes [2]. Researchers aim at replacing grafts by developing nerve repair conduits (NRC) that provide the required durotactic and chemotactic cues to promote neurite regeneration, however, none yet have surpassed the graft [3]. Here, an in silico model is integrated into the NRC design workflow, that allows for more sophisticated considerations of the distribution of cues within the device. Specifically, we focus on including both motor and sensory neurite populations, which have marked differences in terms of their growth rates and response to cues, and this could contribute significantly to the limitations of the current designs [4,5].

A discrete-continuous modelling framework was devised to consider the two neurite populations, where they differ by their response to cues and their growth rate. The model is parameterised using in vivo data on neurite counts at the proximal and distal stumps. It is then used to propose the optimal organisation of chemical and durotactic cues within novel NRC designs to maximise the rate of neurite population regrowth.

Nanocomponents are widely used as bioactive signals in the field of tissue engineering and regenerative medicine. Thus, the incorporation of magnetic nanoparticles (MNPs) and graphene oxide (GO) in the structure of biomaterials proved to have a positive impact on cellular behavior. Here, we analyzed a fibrous composite based on fish gelatin (G), loaded with MNPs (GM), GO (GG) or both (GMG) for its potential to support the neural differentiation of human adipose-derived stem cells (hASCs). After seeding of hASCs, cells were induced towards the neural lineage for 14 days. Detection of expression for specific neural markers (MAP2, Sox2, β-III tubulin and NeuN) was performed using Real-Time PCR and protein expression was detected by immunolabeling coupled with confocal microscopy. Our results showed that the expression levels found on GM and GG were significantly higher than those found on G control material. Interestingly, better results were obtained for GMG scaffold, implying that the presence of both MNPs and GO contributed to the formation of a proper microenvironment for the neural differentiation of hASCs. In conclusion, we demonstrated that the novel nanomaterials are suitable for applications in the field of nervous tissue engineering and further studies are required in order to elucidate the specific molecular mechanisms involved in the neural differentiation of hASCs facilitated by the presence of MNPs and GO.

Transplanting alginate-encapsulated pancreatic islets or beta cells is a promising strategy for the treatment of type 1 diabetes. However, islets used for encapsulation often show lower functionality due partially to islet dysfunction associated with the destruction of the extracellular matrix (ECM) interactions during the islet isolation process. Furthermore, factors produced by alpha and endothelial cells have a great impact on beta-cell insulin secretion. Therefore, mutual signaling between alpha, endothelial cells, and beta cells should be considered for the development of encapsulation systems to achieve high insulin secretion and maintain beta-cell viability. Here, we investigate whether coculture of beta with alpha and endothelial cells could improve beta-cell function within encapsulated aggregates of these cells.Rat insulinoma INS1E, Mouse insulinoma Alpha TC1-6 cells, and human umbilical endothelial cells were used for creating composite aggregates on agarose microwell platform. The composite aggregates were encapsulated within alginate beads with and without extracellular matrix components (collagen IV and laminin 111). Their functionality was assessed by glucose-induced insulin secretion test and compared to encapsulated and non-encapsulated free-floating beta-cell aggregates under hypoxic conditions.Upon glucose stimulation, their insulin secretion is improved in comparison to aggregates consisting of only beta-cells. Moreover, the composite aggregates encapsulated within alginate beads secrete more insulin than aggregates consisting of only beta-cells.Composite aggregates of beta, alpha, and human umbilical vein endothelial cells have improved insulin secretion in comparison to beta-cell aggregates alone showing that the interaction of beta, alpha, and endothelial cells is crucial for a functional encapsulation system.

BACKGROUND

The kidney tubuloids (KT), organoids from adult stem cells, are an interesting option for the development of bioartificial kidney (BAK) since they generate functional renal cells. Reproducing complete cell function remains a challenge. Extracellular vesicles (EVs) can regulate several cellular processes, including cell maturation. We aimed to investigate the use of renal EVs as an inducer of drug transporters, as OAT1, in KT and as supporter of tight monolayer formation.

METHODS

EVs from immortalized proximal tubule cells overexpressing OAT1 (ciPTEC-OAT1) were isolated and incubated with KT. As control, conditioned media (CM) of ciPTEC-OAT1, depleted or not of EVs, were used. Gene expression was determined by qPCR and Western blotting. For proximal tubule engineering, hollow fibers were seeded with KT exposed to EVs or CM. Monolayer integrity and cell polarity were analyzed by immunofluorescence.

RESULTS

EVs were capable of increasing the mRNA levels of OAT1 (2.6±0.4-fold, $p<0.04$), with respect to control. EVs contained OAT1 protein and mRNA as cargo, indicating a possible direct transfer to KT. Immunofluorescence showed that KT, seeded on hollow fibers and incubated with EVs, presented a 3D tubular structure with tight monolayer (ZO-1 expression) and cell polarity (apical cilia and Na+/K+-ATPase presence).

CONCLUSION

EVs from ciPTEC-OAT1 improved the expression of drug transporters like OAT1 and support tight monolayers formation on hollow fiber. Further research will explore functional characterization of bioengineered tubules for application in BAK.

EVALUATION OF KERATIN RICH ELECTROSPUN NANOFIBROUS SCAFFOLD FOR SKIN TISSUE ENGINEERING

Krishna Dixit$_P$[1], Ragavi Rajasekaran[1], Gayatri Mukherjee[1], Santanu Dhara[1]

[1] *IIT Kharagpur*

Corresponding author's email: krishnadixit021@gmail.com

The present study aims at the fabrication of a bioactive nanofibrous scaffold using keratin (Ker) and polycaprolactone (PCL) blended electrospun matrix with an attempt to have protein-rich composition. The homogenous blend of Ker and PCL was successfully prepared using about 60% Ker that was electrospun. The nanofibrous architecture of electrospun matrices was investigated by FESEM, which evidenced smooth nanofiber morphology with a diameter in the range of 150 nm to 300 nm. Further, the presence of a higher volume percent of Ker facilitated cellular affinity due to its innate property of native peptide cues in the protein molecules. FTIR study confirms the chemical interaction of Ker/PCL and the dispersion of natural protein within the PCL matrix. AFM was performed to evaluate the surface roughness with a value of 0.370µm. Contact angle measurement evidenced ~ 90º corresponding to moderate hydrophilicity owing to the presence of PCL in the blend composition. The swelling study revealed that water absorption of 90% in less than 22 h. In vitro evaluation using human dermal fibroblast (DHF) cells confirms enhanced bioactivity, cytocompatibility, and cell affinity on the matrices with enhanced proliferation and adhesion properties. Further, the Ker/PCL matrix was implanted subcutaneously in the mice model for the assessment of cutaneous wound healing efficacy. It was evidenced by wound closure in 19 days without any further treatment. This indicates the fact that Ker/PCL based nanofibrous matrix imbibe all the potency to serve as a substitute for dermal and support skin tissue engineering.

Osteoarthritis (OA) is one of the leading debilitating diseases within the adult population. The avascular nature of cartilage limits its capacity for endogenous repair, therefore, costly and invasive exogenous interventions such as microfracture are often required before total joint replacement. Thus there is an urgent need for new drugs and therapies which can delay disease progression.

Synthetic polymers are an attractive choice for tissue engineering applications, as their chemical and mechanical properties can be controlled and manipulated with relative ease. Poly(ethylene glycol) (PEG) is one such polymer, which has already been widely utilised in the medical field. We have developed the first fully synthetic fluid gel from a PEGDA precursor using a combination of UV curing and the application of shear force2. We have shown that these fluid gels are cytocompatible and, when functionalised with hyaluronic acid (HA), they promote increased expression of SOX9 in a human bone marrow stromal cell (BMSC)-derived cell line. These synthetic microgel suspensions (SyMgels) offer great potential for use as injectable cell therapies for joint repair.

In addition we have developed a 3D model of chondrogenesis using quiescent PEG hydrogels functionalised with chondro-inductive molecules such as HA. Progenitor cells are seeded on top a molecule such as Wnt3a (which induces proliferation, migration and asymmetrical division) and allowed to migrate into the hydrogel where they respond to chondroinductive cues. This model can easily be adapted to a 96/384-well format and used for high throughput screening of potential therapeutic molecules for joint repair.

Metallic implants replace hard tissues in orthopedic and dental applications. Many are anchored in the bone and extend through soft tissues, either temporarily or permanently, to aid in recovery from lesion or to replace native tissues.[1] However, a main reason causing their failure is the lack of integration of metallic surfaces with soft tissues. This allows bacteria entering the implantation site, form a biofilm and trigger a complicated inflammatory response.[2] We hypothesized that multifunctional surfaces with cell-instructive and antimicrobial properties could improve soft tissue integration while decreasing bacterial colonization. We created anisotropic nanopatterns based on the controlled deposition of cellulose nanocrystals (CNC) on metallic surfaces. Furthermore, we used CNC surface chemistry to sequester and present bioactive molecules from platelet lysate (PL). The ability of these surfaces to guide cell growth was tested using human gingival fibroblasts. The bioactivity of the nanocoatings was tested using macrophage polarization assay and bacteria live/dead assay. We produced anisotropic nanopatterns on titanium surfaces by spin coating CNC at high speed. Furthermore, CNC-coated surfaces sequestered and formed a coating of PL-derived biomolecules, as confirmed by proteomic analysis. The anisotropic nanopatterns guided fibroblasts growth and alignment for 14 days of culture. Moreover, the PL-derived proteins polarized macrophages towards M2-like phenotype. As well, the PL-coated surfaces showed antibacterial activity against Staphylococcus aureus. These results suggest that the developed multifunctional surfaces could promote soft tissue integration to metallic implants and, at the same time, prevent bacterial invasion, tissue inflammation, and failure of biomedical metallic implants.

Platelet Lysate (PL), containing platelet growth factors, is able to support isolation, expansion and proliferation of Mesenchymal Stem Cells derived from different tissues and cell lines. The PL effect on different types of cells and the molecular mechanisms involved in these processes remains poorly understood. We focused our attention on a family of highly conserved proteins involved in different cellular mechanisms such as cell growth, proliferation and apoptosis: C-MYC's family. The three isoforms of C-MYC are:C-MYC1, C-MYC2 and C-MYCS differently expressed during cell growth. MSCs obtained from Bone Marrow, Adipose tissue, Articular Chondrocyte, human Osteoblast, Amniotic Fluid Stem Cells and HeLa cell line, were cultivated in medium supplemented with 10% FBS or 5% PL for proliferation analysis, apoptosis and C-MYC protein expression.

All primary cell cultures treated with PL showed a high proliferation rate respect to cultures treated with FBS and expressed the C-MYC1 isoform, which was absent when cells were cultured in FBS. The same cells expressed the C-MYC2 isoforms independently from the culture conditions. For the cell line, the C-MYC1 isoforms was expressed also in FBS condition. Immunofluorescence analysis indicated that MSC cultures showing C-MYC1 protein expression were in a proliferative stage. All these experiments showed that PL was responsible for the induction or increasing of C-MYC1 isoform in primary cells culture and much more slightly in the cell line. These results pave the way to a deeper molecular study in order to understand peculiar differences of PL stimulation on various types of cells.

An in vitro bone model comprising all bone cells (osteocytes, osteoblasts and osteoclasts) arranged in a spatially defined manner was developed. Instead of using cell lines we isolated all cells for the model from primary human tissue. Based on previously developed co-culture systems of human primary osteocytes with osteoblasts (1) and osteoclasts (2) we extended the system to a triple culture of all bone cell species. Osteocytes were differentiated in collagen I gels, spatially separated by porous membranes from osteoblasts and osteoclasts. Silicon templates were used to seed osteoblasts and osteoclasts onto the membrane and to separate the cell species after cultivation for further analysis. All cell types developed their typical morphology, which is dendritic extrusions for osteocytes, multinucleated cells for osteoclasts and cobblestone-like morphology for osteoblasts. Furthermore, specific markers for the different cell species were detected both by gene expression analysis and by measurement of specific enzyme activities like alkaline phosphatase, tartrate resistant acid phosphatase, cathepsin K and carbonic anhydrase II.

Magnesium and its alloys are innovative resorbable biomaterials with potential for application as bone implant, since the mechanical properties are similar to bone. Furthermore, magnesium was shown to stimulate osteogenesis (3). Therefore, triple cultures were cultivated in the presence of degradation products of magnesium materials. We demonstrated changes of gene expression of marker genes for osteocytic and osteoblast differentiation.

In conclusion, the tested in vitro bone model comprised markers of all bone cells and is a useful tool to test bone graft materials, especially those releasing bioactive ions.

NOZZLE-FREE ACOUSTIC DROPLET EJECTION ENABLES MULTISCALE 3D BIOPRINTING

Bioprinting allows the manufacture of complex cell-laden hydrogel constructs that can mature into tissue replacements in a subsequent cell culture process. The nozzles used in currently available bioprinters are critical components because they limit the print resolution. In addition, at dimensions below 100 µm clogging is expected. The reduction of the nozzle diameter also increases shear stress during printing process. At a critical shear stress, mechanical damage to printed cells triggers cell death. To overcome these limitations, a novel 3D bioprinting method based on the principle of acoustic droplet ejection (ADE) is introduced here. The absence of a nozzle in this method minimizes critical shear stress, amplifying the options for bioprinting. A numerical simulation reveals that maximum shear stress during the ADE is 2.7 times lower than with a Ø150 µm microvalve nozzle. Average droplet diameters with a minimum size of 54 µm and a maximum of 183 µm were achieved. Printing of cell clusters contained in droplets at the millimeter length scale, as well as in droplets the size of a single cell is feasible. The precise 3D build-up of cell-laden structures is proven. Evidence is provided that the method has no negative effects on stem cell morphology, proliferation, or differentiation capacities. The multi-scale acoustic bioprinting technique thus holds promise for cell-preserving creation of complex and individualized cell-laden 3D hydrogel structures.

The use of ceramic biomaterials for dental bone regeneration is a reliable treatment option compared to the autologous bone which involves higher morbidity. Improving scaffold design for optimal osseointegration can be obtained by changes to the local geometry, surface roughness, material composition, etc. In this study, we report the development and use of a computational model describing neotissue formation in 3D scaffolds. After calibration with in vitro experiments, we use the model to design 3D structures that subsequently are tested in a calvarial model in rat.

The level-set method is used to simulate the neotissue growth. [1] For the in vivo study, 2 designs were selected: a lattice structure with square struts and a gyroid structure. BioOss, currently the standard biomaterial used in the clinic, was taken along as a control. The scaffolds were implanted under a CaP shell on the calvaria of rats. Scaffolds were explanted after 2 and 8 weeks, n=10 for per condition per time point, and evaluated using nanofocus Computed Tomography and histology.

The computational model developed in this study was used to design geometries for 3D printed CaP-based scaffolds. In vivo testing of these scaffolds showed a strong improvement of the amount of bone formation in the model-based design (gyroid) over the clinical standard (BioOss) or a classical 3D printed geometry (orthogonal lattice). This result, obtained without several in vivo iterations as normally would need to be performed, clearly shows the added value of in silico tools in the design of novel biomaterial structures.

Osteochondral tissue damage is common in the young, active population, remaining a major clinical challenge. 3D printing is an exciting method for development of novel scaffolds for tissue regeneration especially within personalised medicine. However, many 3D printing techniques rely on creating a lattice structure, which often demonstrates poor cell bridging between filaments to fill the gaps due to its large pore size; reducing regenerative capacity as host or seeded cells are unable to efficiently remodel the scaffold. This study aimed to tackle this issue by developing a novel silk reinforced 3D printed scaffold. Biphasic scaffolds consisted of 3D printed poly(ethylene glycol)-terephthalate-poly(butylene-terephthalate)(PEGT/PBT) lattice, infilled with a cast and freeze dried porous silk scaffold, along with a seamless silk top layer. Fluorescent microscopy showed biphasic scaffolds and silk scaffold controls can support human bone marrow stromal cell attachment and spreading after 24hours of seeding with no obvious difference. No clustering of cells was seen around the 3D printed lattice in the biphasic scaffold. Compression testing showed that scaffolds had a compressive modulus of 12.7±0.9Mpa and ultimate compressive strength of 1.56±0.1Mpa, theoretically allowing for the scaffold's survival during implantation and joint articulation without stress-shielding mechanosensitive cells. The silk material provides a secondary structure to the 3D printed scaffold enhancing cell attachment and bridging. The 3D printed scaffold provides a solid framework for the biphasic scaffold and increases its strength and versatility. These results indicate that the novel silk reinforced biphasic 3D printed scaffold is biocompatible and has suitable properties for osteochondral tissue regeneration.

DESIGN AND DEVELOPMENT OF ARTIFICIAL NERVE CONDUIT

Thanusha AV_P[1], Maurice N Collins[1]

[1] *STOKES LAB, BERNAL INSTITUTE, UNIVERSITY OF LIMERICK, IRELAND*

Corresponding author's email: Thanusha.av@ul.ie

Development of artificial nerve or nerve substitute from biopolymers will ease the requirements for donor nerve autograft and plays an effective role in the treatment of peripheral nerve injuries. The major disadvantage of commercially available nerve substitutes is lack of conductivity, failed to repair large nerve gap defects, limited availability and they are expensive to procure. The present research work is focussed on the fabrication of an artificial nerve conduit using the gelatin-based porous structure. Bioactive components such as glycosaminoglycans, curcumin were suffused in to the nerve conduit to enhance the native nerve action. Physicochemical characterization studies include morphology, swelling, degradation, tensile strength, conductivity test, Attenuated total reflection Fourier transform infrared analysis (ATR-FTIR), Differential Scanning Calorimetry (DSC) and Thermogravimetric analysis (TGA). Bio-based porous nano-carbon fibres were incorporated as a conducting material to the optimized nerve conduit to develop an electroconductive artificial nerve. In-vitro cytocompatibility studies include cell viability, cell proliferation assays and Immuno-fluorescence staining of protein markers on neural stem cells. The acquired result demonstrates that the artificial nerve has characteristic features like ease of scalability, cost-effective ,biodegradable, biocompatible and effective for the treatment of peripheral nerve injuries.

Silver nanoparticles (Ag-NP) have long been deployed for wound regeneration process owing to its high antibacterial efficacy however fabrication of an effective delivery matrix with enhanced efficacy is still an unresolved challenge. The study demonstrates a unique route to tailor a nanobiocomposite (EAZ) with effective loading of Ag–NPs wherein eggshell membrane (ESM) acted as a natural substrate and zinc oxide (ZnO) nanoparticles were deployed to attain a three dimensional spatial hierarchy for decoration of the Ag-NPs. A simple sonochemical guided approach was adopted to in-situ decorate ZnO nanoflakes and Ag-NPs on top of the microfibrous ESM in order to an attain sustain release profile. Microstructural analysis ratified hierarchically spatial arrangement of Ag–NPs on the three dimensional ZnO nanoflakes anchored on microfibrous eggshell membrane. XPS analysis confirms presence of Ag-NPs in its metallic state and also justify interaction between ZnO and the Ag–NPs. Further, ICP-MS studies substantiate excellent and sustainable release profile of Ag-NP from the nanobiocomposites at varying pH. The nanobiocomposites demonstrated exceptional bactericidal activity against Gram-negative, E. coli or P. aeruginosa and Gram-positive, S. aureus or B. subtilis bacterial cells. The nanobiocomposite exhibited excellent cytocompatibility when seeded with Human dermal fibroblast (HDF) cells. Furthermore, when grafted over a full thickness wound model, EAZ samples presented fast re-epithelization and collagen deposition thus leading to complete wound closure in 12 days. The architectural tribology along with exceptional wound regeneration kinetics of the nanobiocomposites manifests its application as an alternate platform in wound regeneration applications.

BACKGROUND & AIMS:

Osteoporosis is a major health burden. Current therapeutic treatments have disadvantages such as systemic side effect and low bioavailability. Bone-targeting drug delivery system are designed to improve the therapeutic effect of drugs and minimize the potential toxic side effects. We fabricated a novel drug nanocarrier for bone-targeting alendronate delivery using glycol chitosan (GC)-poly(lactide-co-glycolide) (PLGA) and PLGA-alendronate conjugates.

MATERIALS & METHODS:

Chitosan-based nanoparticles were prepared with GC-PLGA and PLGA-alendronate conjugate by nanoprecipitation. Alendronate sodium, a commonly used bisphosphonate drug for osteoporosis therapy, serves as both a bone-targeting ligand and a loading drug. The size of the nanoparticles was determined by dynamic light scattering (DLS) measurement. The morphology of the GC-PLGA/PLGA-alendronate nanoparticles was examined by scanning electron microscopy (SEM). Drug release profile, cytotoxicity and cellular uptake were evaluated in vitro. Bone-targeting potential was assessed by hydroxyapatite binding assay and an ex vivo porcine bone model.

RESULTS:

The conjugation of GC-PLGA and PLGA-alendronate was confirmed by Fourier-transform Infrared Spectroscopy (FTIR) and nuclear magnetic resonance (NMR) analysis. The prepared nanoparticles are highly aqueous dispersible with an average size range from 90 to 130 nm based on various polymer ratio. Morphological characterization (SEM) revealed that the nanoparticles are spherical in shape. In vitro tests demonstrated sustained drug release of alendronate, good biocompatibility and intracellular uptake of nanoparticles. Hydroxyapatite affinity test and ex vivo porcine bone model confirmed the bone-targeting potential.

CONCLUSION:

The bone-targeting GC-PLGA nanoparticles may be a drug delivery system for the treatment of osteoporosis. Further study of biodistribution is warranted.

Background: Oxidative stress is a major factor limiting encapsulated islet efficacy. Fucoidans (marine polysaccharide) possess strong anti-oxidant properties (1) but its effects on islet encapsulation is unknown. We assessed the feasibility of fucoidan hydrogels (Fucogel) for islet encapsulation to improve viability and function.

Methods: Fucogel prepared by blending fucoidan with alginate and fucoidan microcapsules made using a droplet generator. Total antioxidant capacity (TAC) and viscoelastic properties of Fucogel assessed. Ability of Fucogel to alleviate oxidative stress determined using transduced INS1E cells. Human, rat and neonatal pig islets encapsulated in Fucogel and viability, ATP and insulin secretion assessed. Fucogel potential to protect islets against cytokine and H2O2 induced oxidative damage assessed.

Results: The TAC of Fucogel was ~35-fold higher compared to alginate hydrogel. Both alginate and Fucogel had similar viscoelastic properties with no differences in their hydrogel mesh sizes. Fucogel significantly alleviated intracellular oxidative stress in transduced INS1E compared to alginate. Viability and ATP levels of human islets in Fucogel at days 1 and 5 were significantly higher compared to those in alginate. Human islets in Fucogel functioned better in response to high glucose with a ~ 2-fold higher stimulation index compared to alginate. Similar results were seen with rat and neonatal pig islets encapsulated in Fucogel. Exposure to proinflammatory cytokines or H2O2 dramatically rescued human islets in Fucogel with significantly higher viability, ATP and stimulation index compared to those encapsulated in alginate.

Conclusion: Fucoidan hydrogels possess strong antioxidant property, significantly alleviate oxidative stress and enhance encapsulated islet viability and function.

INFLUENCE OF STATINS ON CARTILAGE HOMEOSTASIS AFTER TRAUMATIC LOADING AND DURING CHONDROGENIC DIFFERENTIATION

Jana Riegger-Koch$_P$[1], Sai Pulasani[1], Rolf Brenner[1]

[1] *Division for Biochemistry of Joint and Connective Tissue Diseases, Department of Orthopedics, University of Ulm, Ulm, Germany*

Corresponding author's email: jana.riegger@uni-ulm.de

As inhibitors of HMG-CoA-reductase, statins are widely used as cholesterol-lowering drugs. Due to the anti-inflammatory effects, statin therapy has also been discussed for osteoarthritic disease. Therefore, we investigated the potential therapeutic effects of fluvastatin (hydrophile) and simvastatin (lipophile) after ex vivo cartilage trauma. Macroscopically intact human cartilage was obtained with consent of donors undergoing total knee joint replacement (n=11). Cartilage explants were subjected to a blunt trauma (0.59 J) using a well-established drop tower system and treated with simvastatin or fluvastatin (1 µM, 5 µM and 10 µM) for 7 d. Afterwards, cell viability (live/dead assay) as well as gene and protein expression of collagen type II (COL2) and catabolic enzymes (MMP-2, -13) were determined. Moreover, the influence of statins during chondrogenic re-differentiation of dedifferentiated chondrocytes was investigated (Saf-O staining; COL2 IHC). Statistics: one-way ANOVA.

Cell viability was decreased by 20.2 % after cartilage trauma. Both statins exhibited concentration-dependent cell protection and anti-catabolic effects as demonstrated by reduced expression of MMP-13 as well as attenuation of latent and active MMP-2. Chondroprotection was also reflected in decreased breakdown of COL2. While both statins suppressed the gene expression of COL2, only simvastatin had inhibitory effects on the biosynthesis. However, re-differentiation of dedifferentiated chondrocytes was impaired by both statins. Although, the tested statins exhibited cell and chondroprotective potential after ex vivo cartilage trauma, the therapeutics also suppressed chondroanabolic processes. Nevertheless, statin therapy might have beneficial effects during the acute phase after joint injury, reducing cell death and enzymatic cartilage destruction.

Keywords

statins; cartilage trauma; chondroprotection

Corresponding author's email: wendy.balestri2017@my.ntu.ac.uk

Regeneration and function of musculoskeletal tissues have been extensively investigated. Within that however, less focus has been placed on the interfaces between them. These transition zones may not regenerate after severe damage or deterioration, leading to incomplete patient recovery. The interfaces and composition are well known physiologically, but the knowledge on their development is limited1, especially for the tendon-muscle interface.

This research has developed a 3D in vitro model to investigate bone-tendon-muscle interface development. A mould was designed, and 3D printed in resin, containing different surface topographies; analogous to pores for bone and ridges mimicking fibres for tendon and muscle. Collagen-agarose composite gels were solidified in the mould. A gradient in stiffness was established by changing concentrations of collagen type I and agarose; and varying concentrations of hydroxyapatite. Human osteoblast-like cells (MG-63), human dermal fibroblast (HDF) and human skeletal muscle cells (Sket.4U) were co-cultured in the 3D model. Different cell seeding densities were tested (5,000, 50,000 and 100,000 cells/gel), to determine the optimum seeding densities for cells to reach homeostasis. To evaluate this point, cell metabolic activity, viability and proliferation were measured. The optimum cell seeding densities were 50,000 cells/gel for MG-63, as proliferation and metabolic activity were stable between day 7 and 14 ; and 100,000 cells/gel for Sket.4U and HDF, because, even though the DNA content decreased between day 7 and 14, the metabolic activity was stable (HDF) or increased over time (Sket.4U). Moreover, a unique 3D construct, consisting of different materials, mechanical properties and topographies was developed.

DEVELOPMENT OF SULFOBETAINE POLYMER CONJUGATES AS A DRUG DELIVERY SYSTEM TO CANCER CELLS AGGREGATES

Masaya Yamamoto$_P$[1], Nobuyuki Morimoto[1]

[1] *Tohoku University*

Corresponding author's email: masaya.yamamoto.b6@tohoku.ac.jp

Cell aggregates have attracted much attention in the research field of drug screening and regenerative medicine as a mimicry of in vivo microenvironments in culture. However, the poor permeability of substances, such as drugs and nutrients, is a big challenge in using cell aggregates. We developed a random copolymer composed of a sulfobetaine monomer, 3-dimethyl(methacryloyloxyethyl)ammonium propane sulfonate (DMAPS) and a macromonomer of poly(ethylene glycol) methacrylate (PEGMA), P(DMAPS-PEGMA), as a fast intracellular drug delivery. In this study, we investigated the permeation, growth suppression, and invasion inhibition of anticancer drugs-conjugated P(DMAPS-PEGMA) in tumor cell aggregates. Doxorubicin (Dox) and 17-AAG were selected as anticancer drugs and conjugated with P(DMAPS-PEGMA), (Mn = 17,000). Tumor cell aggregates of human glioblastoma A-172 cells or human hepatoma HepG2 cells were prepared from 1,500 cells/well in a low protein adhesion 96-well plate by 4-day cell culture. The fluorescence of Dox-P(DMAPS-PEGMA) was detected in the center of the tumor cell aggregates after 1-2 h incubation under confocal laser scanning microscope, while Dox alone could permeate through only 2 to 3 cell layers from the outside. Dox-P(DMAPS-PEGMA) significantly suppressed the growth of tumor cell aggregates. However, the growth suppression was a little bit lower than that of Dox alone. On the contrary, 17-AAG-P(DMAPS-PEGMA) exhibited more than ten times higher inhibition than that of 17-AAG alone in the A-172 cell invasion from the tumor cell aggregates in Matrigel. These results suggest that conjugation with sulfobetaine copolymers allows anticancer drugs to permeate throughout tumor cell aggregates, leading to enhance the drug efficacy.

A BIOPRINTED MODEL FOR METASTASIS OF TUMOUR CELLS INTO A HEALTHY BONE-LIKE REGION

Megan Cooke$_P$[1,2], Michael Weber[2], Derek Rosenzweig[2]

[1] *Department of Surgery, McGill University*

[2] *Division of Orthopaedics, McGill University*

Corresponding author's email: megan.cooke.research@gmail.com

A staggering 96% of oncology drugs fail to reach FDA approval and enter the market, one reason being the challenges of evaluating such drugs in physiologically relevant culture systems. This is exacerbated within bone metastasis, where spread of tumour cells to bone is often fatal. The complex bone tumour microenvironment is host to a range of biochemical and physical cues which cannot be replicated in 2D in vitro culture. In this study, bioprinting was used to produce a 3D model of tumour cell migration into a bone-like region. Two bioinks were prepared: 1) healthy primary human osteoblasts in an alginate-gelatin-hydroxyapatite blend was bioprinted into a ring shape before 2) MDA-MB-231 breast cancer cells were printed into the central cavity using an alginate-gelatin ink. Models were then cultured in the presence of doxorubicin, a common chemotherapeutic. The migration of tumour cells into the outer 'healthy' region of the model was quantified using light-sheet imaging, before quantifying the effect of tumour cell invasion and doxorubicin treatment on the ability of osteoblasts to form bone-like matrix. Results showed that without doxorubicin treatment mineralised bone-like matrix was formed in the outer 'healthy' region. Tumour cells were then shown to migrate through the alginate-gelatin matrix into the outer region over 28 days. Increasing the doxorubicin concentration reduced formation of multi-cellular tumour spheroids and thus, decreased migration of tumour cells into the healthy bone-like region. The bioprinted interface model therefore may be suitable for screening novel therapeutics against tumour growth and migration.

Biosensors are devices engineered to detect important biomarkers by generating analytical signals based on biological or chemical reactions. Here, we have engineered an optical biosensor based on localized surface plasmon resonance (LSPR) that can detect low concentrations of Glycated Albumin (GA). GA is an important biomarker for Diabetes that provides an indication of glucose level history over a roughly three week period in diabetes patients helping to track the overall effectiveness of Diabetes management strategies.. Gold nanoparticles were deposited on a quartz substrate by flame synthesis, a scalable, and low-cost synthetic route. These substrates were conjugated with a DNA aptamer capable of binding GA resulting in a plasmonic wavelength shift due to binding of GA to the DNA aptamer. This prototype biosensor was able to detect micromolar concentrations of GA. In the future, improvements to sensor architecture are expected to increase the sensitivity and selectivity.

Introduction Osteoarthritis (OA) is a debilitating disease of the entire joint characterized by degeneration of cartilage and altered bone remodeling with no available cure. The cause of OA remains unknown and the role of the subchondral bone is largely unstudied. Therefore, this study aims to identify OA subchondral bone factors that can induce phenotype changes in chondrocytes.

Methods Tibial plateaus were harvested from OA patients undergoing knee arthroplasty. Mass spectroscopy-based proteomics screening was performed on the conditioned medium (CM) of sclerotic and non-sclerotic OA bone, to identify factors secreted by the latter. Furthermore, chondrocytes isolated from intact and damaged OA cartilage regions were cultured for two weeks in a polyHEMA-coated 96 well plate. The resulting micro-cartilages were characterized biochemically, histologically, and by RT-PCR at the end of chondrogenic culture and after stimulation with sclerotic and non-sclerotic OA bone CM.

Results Proteomics revealed 108 significantly differentially expressed proteins between sclerotic and non-sclerotic OA bone CM, including POSTN, WIF1, and ALPL. Micro-cartilages generated with damaged OA chondrocytes expressed increased catabolic markers, including MMP13, ADAMTS4-5, and lower GAG amounts compared to those generated with intact OA chondrocytes. After stimulating the micro-cartilages with the OA CM, the expression of MMP13 increased compared to chondrogenic culture.

Conclusion The secretome of sclerotic and non-sclerotic OA bone is significantly distinct as determined by proteomics. The micro-cartilage model captures catabolic traits of OA chondrocytes from different degenerative states and will be used for experiments to study the influence of specific bone factors on chondrocyte alterations in OA.

To date, i-FACTOR™ Peptide Enhanced Bone Graft is the only osteobiologic to utilise the biological activity of a 15-amino acid peptide sequence (P-15) for stimulating the natural, self-regulating bone healing process, resulting in safe, predictable bone formation. P-15 is responsible for cell attraction, attachment, activation and initiation of the cascade of events leading to bone matrix formation. The combination of an osteoconductive anorganic bone mineral (ABM) scaffold and P-15 peptide provides a 3D biomimetic environment to support cellular attachment and early bone formation. The mechanism of action is attachment mediated, thereby reducing the risk of unwanted ectopic bone formation. Our results have found that P-15 promotes human bone marrow stromal cells (HBMSCs) and human dental pulp stromal cells (HDPSCs) adhesion and growth on the ABM scaffold and also increases the expression of alkaline phosphatase, the formation of Type I collagen matrix and calcium accumulation in vitro and leads to early bone matrix formation in vivo. The combination of HDPSCs with ABM-P-15 can improve bone regeneration speed and efficacy. Increased regulatory scrutiny needs for robust translational science and high-quality clinical evidence. The core ABM/P-15 technology has been used in dentistry in over 500,000 patients (PepGEN P-15, Dentsply Inc.) and in orthopaedic and spinal applications (i-FACTOR™) which have over 100,000 cases. In 2015 i-FACTOR™ became the first biologic bone graft to receive U.S. PMA approval for use in anterior cervical decompression/fusion (ACDF). The Level I randomised study concluded that i-FACTOR™ was significantly superior over the control, autograft bone.

Liver disease represents one of the fastest-growing diseases in the world, with an increasing Liver diseases represent one of the fastest-growing disease classes in the world, with an increasing mortality in the UK of 400% since the 1970s.1 Developing in vitro liver models to understand the underlying disease mechanisms is crucial for future treatments. Limited access to primary liver tissue, reduced survival time and the inability of primary hepatocytes to proliferate in culture had led researchers to look for an alternative cell source from which to secure a supply of mature, functional hepatocytes. 2 In severe liver injury, bipotential hepatocyte progenitor cells (HPC) located next to the bile duct are able to proliferate and subsequently differentiate into either hepatocytes or cholangiocytes. 3 In this study, we isolate human EPCAM positive HPC, expand them as organoids, and drive their differentiation and maturation on a 3D substrate. A 3D coaxial electrospun scaffold has been developed in order to mimic some of the biochemical features of the liver ECM environment and to deliver a combination of signalling molecules to aid in cell differentiation and maturation. The use of a synthetic electrospun scaffold in our model allows us to provide a more defined environment for cell expansion in comparison to 2D culture systems such as matrigel.

Spheroid-based bioprinting uses uniform spherical cell aggregates as building blocks to manufacture tissue constructs. Tissue maturation is more advanced in spheroids compared to isolated cells and a much higher concentration of cells can be precisely deposited. This offers the possibility of obtaining more complex and larger tissues, through controlled and reproducible ways. However, efficient spheroid-based bioprinting is still challenging, especially regarding construct stability during long periods of the maturation process. Assessing this approach to obtain mature cartilage tissue is of high interest, since it presents a low self-repair capability. Here, we optimized a set of parameters to improve the bioprinting process aiming at establishing a high throughput method to obtain stable spheroid-based constructs. First, we produced a high amount of uniform human mesenchymal stromal cells (hMSCs) spheroids using a micro-molded non-adhesive hydrogel. Spheroids encapsulated in a xanthan gum/alginate hydrogel were bioprinted and the structure ionically crosslinked. A high number of multilayered bioprinted hMSC spheroid-based constructs could be obtained. Thirty days post-bioprinting the constructs were still stable and cell viability in the spheroids high, with profuse extracellular matrix production. The cells in the construct were efficiently differentiated using chondrogenic media for 28 days, and expression of glycosaminoglycans and collagen II was clearly observed. Results on the quantification of specific chondrogenic markers will be also presented. Overall, we hypothesize that these results show the potential of an effective approach to obtain spheroids-based constructs to be applied in the biofabrication of cartilage tissue, as well as models of cartilage diseases studies.

Recent efforts in the field of Tissue Engineering have increasingly considered bottom-up approaches and the assembly of living and non-living building blocks into functional tissues. A particularly interesting aspect in this regard is remote control over the spatial organisation of cells or cell-spheroids within a carrier matrix by use of acoustic fields. This method takes advantage of acoustic waves and their generated hydrodynamic forces that act on cells to arrange them within a matrix. Importantly, however, viscosity and gelation kinetics of the precursor matrix, as well as mechanical integrity of the final hydrogel have only been addressed to a limited extent.

Here, we are exploiting the potential of acoustic manipulation at low frequencies (40 to 200 Hz) to pattern beads and subsequently cells in biomaterials of various origin, concentration, and viscosity. We experimentally investigate the relationship of the resistive force $F=3\pi\eta dv$ (where η is the viscosity of the matrix and v is the velocity of the cell) and compare the resulting patterns to a model of particle dynamics. This force, imposed by the hydrogel precursor, needs to be overcome by the hydrodynamic force induced by the applied frequency and amplitude in order to move cells within the matrix. Better insight into the biomaterials' rheological properties will allow fine-tuning of cell patterning and controlled spatial organisation. Our findings will contribute to a better understanding of the underlying effects of acoustic waves in various hydrogels and allow future researchers to tune the viscosity of their materials in order to achieve successful patterning.

Current tissue engineered skin fails to meet the need for skin replacement in full-thickness wounds. Bioprinting technology allows for organization of multiple cell types into biomimetic layers. In prior studies, we demonstrated that bioprinted skin integrates, vascularizes, and forms an epidermal barrier when implanted into mice. The purpose of this study is to assess the feasibility and efficacy of autologous and allogeneic bioprinted skin to treat full-thickness wounds in pigs. Porcine keratinocytes, fibroblasts, and pre-adipocytes were isolated from skin punch biopsies and endothelial cells from a carotid artery biopsy. Cells were expanded in vitro, suspended in bioink, and bioprinted to form a biomimetic tri-layer skin construct. 5x5cm excisional full-thickness wounds were made and treated with autologous bioprinted skin, allogeneic bioprinted skin, autograft, allograft, or left without treatment. Treatments sites were randomized, with blinded surgery and analysis. Digital photographs are taken twice per week during bandage changes for digital planimetry analysis, and serum proteins from bandages are used for proteomic analysis. The pigs are euthanized on day 28, and tissue samples are analyzed by histology, SEM, and omics analysis. We expect improved wound closure in autologous bioprinted skin treated wounds, improved epidermal maturity, and increased blood vessel density compared with the other treatments. Also, we expect normal collagen organization in wounds treated with autologous bioprinted skin. These results will suggest integration of the autologous bioprinted skin into the wound to support skin regeneration and healing. Ultimately, this technology could translate into a new treatment for full-thickness wounds in human patients.

Increasing evidence implicates intervertebral disc (IVD) degeneration as a significant contributor to low back pain. In this respect, tissue-specific progenitors may play a crucial role in tissue regeneration. Recently, a progenitor cell population (Tie2+) was described in the nucleus pulposus (NP) tissue of the IVD (1). Here, we studied the influence of the culture method and of the microenvironment on the human NP progenitor's proliferation and their differentiation potential in vitro.

The NP cells (NPCs) were obtained from trauma patients. Briefly, the NPCs were cultured in 2D (monolayer) or 3D (alginate beads) conditions. After one week, cells from 2D or 3D culture were expanded on fibronectin-coated flasks. Subsequently, expanded NPCs were then characterised by tri-lineage differentiation. Moreover, experiments using pure Tie2+ and Tie2- NPC populations were also performed, following the same study protocol.

In this study, we observed that only 3D culture of NPCs was able to maintain pluripotent gene expression. Moreover, only NPCs in 3D culture presented stromal cell surface markers. We were also able to maintain the expression of Tie2 marker in 3D culture overtime in our NPC populations.

The present study aims to demonstrate that 3D expansion of NP cells increases the differentiation potential compared to 2D culture. Our results highly suggest that the maintenance of pluripotent capacity is mainly but not exclusively due to the higher presence of Tie2+ cells. This project, by evaluating the influence of a two-step expansion protocol on the functionality of NP progenitors could also lead to an innovative clinical approach.

Three-dimensional spherical cellular aggregates can effectively mimic the natural microenvironment of tissues and organs, consisting of a feasible alternative for many different purposes. Recently, approaches involving sophisticated engineered strategies aiming to control spheroid diameter and shape, to reduce cell shear stress and to promote efficient mass transfer, are of high interest. The objective of this work was to evaluate the performance of an optimized device we have been developing over the years to obtain spheroids through controlled and reproducible ways. The methodology is based on the use of a micro-molded non-adhesive hydrogel. First, we designed a positive primary multiple well mold (Rhinoceros CAD) with previously defined well geometry, which was manufactured by 3D Printing (Polyjet Technology, Stratasys). The mold was used to cast a negative hydrogel structure in which human dental pulp stem cells (hDPSC) and fluorescent human embryonic stem cells (hESC) were cultured in alfaMEM and mTeSR™1 respectively, for 7 days to form the spheroids. Successful spheroid formation in large quantities was attained, around one-thousand spheroids in a single six well-plate. The spheroids showed appropriate shape and size distribution. Spheroids of hDPSC and hESC, starting from an inoculum 7,100 cells per spheroid, presented mean diameters around 250 and 500 micrometers, respectively. Fluorescence microscopy analysis showed presence of live cells in the whole 3D structure of hDPSC and hESC spheroids. Overall, these results show that 3D culturing stem cells with our improved method allows obtaining easily a large number of uniform and viable spheroids.

Minimally invasive techniques for valve replacement (MIAVR) are the common therapeutic approach that motivates the search for new valve materials[1]. In this study, a polymeric self-expandable tri-leaflet heart valve compatible with MIAVR procedure is designed, fabricated and characterized. The valve is composed by a polymeric stent to support the polymeric leaflets and an external metallic stent for anchoring on the aortic root.

The polymeric stent was fabricated by 3D printing technology using the CarboSil 55D, a thermoplastic silicone-polycarbonate urethane with good biocompatibility and hemocompatibility[2,3]. The valve leaflets were fabricated using dipping and custom spray-machine apparatus to spray a CarboSil 80A 2,5% solution in tetrahydrofuran/dioxane 1:1[4].

The external frame was made in nickel-titanium by laser cutting to obtain a self-expandable valve after the crimping process. The elements were assembled in the completed device using a surgical suture and characterized: i) assessing mechanical properties of the leaflets, ii) crimping test, iii) fatigue test and iv) evaluating hemodynamic parameters of the valve.

The employed technologies enable the fabrication of sprayed CarboSil leaflets with reproducible mechanical properties. The proposed design provides a self-expandable and crimpable device able to reduce its initial diameter up to 40% and to restore its initial dimension without shape changes. The fatigue test showed no leaflets macroscopic damages after 5x10^6 cycles and the hemodynamic performances were confirmed: the Effective Orifice Area and the total regurgitation fraction indexes showed values within the reported standard ranges for aortic valve (ISO5840-2).

Therefore, further in-vivo studies are required for assessing the long-term valve performance.

Stem cell-based bone tissue engineering has emerged as a promising approach for regenerating critical-size bone defects (1). Considering the repair of bone fracture a complex biological mechanism that requires the recruitment of stem cells from the bone marrow (BM), this microenvironment and its components become a powerful candidate to facilitate bone regeneration. This work used mesenchymal stem cells (MSC), hematopoietic stem cells (HSC), and human umbilical vein endothelial cells (HUVEC) to developed multifunctional BM in liquified capsules. Before the encapsulation, aggregates of MSC and surface-modified polycaprolactone microparticles (µPCL) were performed under osteogenic stimulation. Multilayered and liquified alginate capsules were produced as described (2,3). Tri-culture capsules (aggregates, HSC, and HUVEC) and co-culture (aggregates and HUVEC) were maintained in static and dynamic culture systems (spinning flasks). We observed an increase in cell viability and the expression of bone formation markers such as osteopontin, osteocalcin, and bone morphogenetic protein 2 (BMP-2) in both types of capsules cultured in the dynamic system compared to the static, but more significant in tri-culture capsules. The presence of vascular endothelial growth factor (VEGF) was also more prominent in the tri-culture capsules. Our results evidence the superior biological outcome resulting from the direct crosstalk between the BM cell components in the tri-culture capsules. The model supports cell viability, the secretion of osteo key-components, and vasculogenic potential. Our multifunctional liquified capsules mimicking the BM can provide an advanced platform of fundamental importance for new bone regeneration applications.

3D printing and bioprinting has witnessed a phenomenal rise in the fields of tissue engineering and regenerative medicine over the past few years. Due to the nascent nature of this field, there exists a broad knowledge base regarding various 3D printable material formulations and their unique printing conditions. This poses a challenge for researchers who wish to apply new or established 3D printing techniques and want a reliable source of information regarding 3D printing conditions. At the NIH/NIBIB Center for Engineering Complex Tissues (CECT), we have developed the world's first public repository/database of articles involving 3D printing in the field of tissue engineering and regenerative medicine that are easily searchable by a user. The database is free for use and can be found at https://cect.umd.edu/3d-printing-database. Key printing parameters are displayed, including bioink and cell composition, pressure, temperature, speed, and crosslinking methods. The database also allows us to draw insights into material printability and lays a foundation for machine learning approaches to further optimize multi-material 3D printing. We have created an open survey (https://umdsurvey.umd.edu/jfe/form/SV_ahIl2SK4amMiIIJ) that allows users to enter their published information regarding their 3D printing and bioprinting conditions, which is then added to this database. The ultimate aim is to make this database an active and reliable resource for the 3D printing and bioprinting community. While the current database is limited only to extrusion-based 3D printing, we hope to add other printing techniques such as stereolithography, inkjet printing and direct write electrospinning in order to reach a broader biofabrication audience.

FIBRIN-SPECIFIC SHORT LINEAR PEPTIDE MOTIF

Yoon Sung Nam[P1], Moon Young Nam[1], Jeong Heon Yu[1]

[1] KAIST

Corresponding author's email: yoonsung@kaist.ac.kr

The excess formation of fibrin networks, called hypercoagulation, is an important cardiovascular disease biomarker. However, it is technically very challenging to specifically diagnose hypercoagulation because fibrin is structurally very similar (~80 %) to its precursor, fibrinogen, which is abundant in the blood. Here we report a fibrin-targeting heptameric peptide specifically binding to the pocket space of fibrin generated during the fibrinogen-to-fibrin transformation. Fibrinogen is a 340 kDa plasma glycoprotein that facilitates blood clotting and has three submodules (alpha, beta, and gamma) in its soluble form. According to the crystal structure of the gamma module, pocket space is generated when P2 (γ381-390) in the beta-sheet structure is exposed outward and interact with adjacent P2. Computational docking simulations are used to design a heptameric peptide (IPLVVPM) that can bind to the pocket space where the P2 moiety is pulled out. The computational analysis indicates that the peptide including the PxxxP linear motif and amino acids with a hydrophobic and small side chain (e.g., isoleucine, valine, and leucine) can be inserted into the generated pocket space. For the experimental confirmation of the interaction between the peptide and the pocket space of the fibrin gamma module, two variations of recombinant proteins are generated: full gamma module and P2-truncated gamma module. The specific binding of the selected peptide to the pocket space is analyzed using recombinant variants of the gamma module by size exclusion chromatography and circular dichroism.

Oligonucleotides (e.g. siRNAs, microRNAs) and synthetic cyclic dinucleotides have enormous potential for the treatment of diseases (e.g. c ancer) and for tissue regeneration. However, they suffer from poor stability in physiological fluids and limited cell uptake [1]

In this work, "bioartificial" polymeric nanoparticles (NPs) for oligonucleotide encapsulation were prepared by nanoprecipitation from chitosan (CS) and poly(lactic-co-glycolic acid) (PLGA).

Nanocomplexes between positively charged CS and negatively charged oligonucleotides (microRNA mimic: miR-1) were initially formed. Then, PLGA was nanoprecipitated in the presence of CS/miR-1 nanocomplexes, to form "bioartificial" NPs, able to shield payload from degradation, enhance intracellular delivery and reduce cytotoxicity. "Bioartificial" PLGA/CS NPs were prepared with 140 nm hydrodynamic size and surface zeta potential increasing from -20 mV to +30 mV with increasing CS amount, efficiently encapsulating ~99% miR-1. NPs were stabilized against aggregation by adding Tween 80, a polyethylene glycol (PEG)-based emulsifier that helps in reducing protein corona formation, increasing NP stability overtime. Viability assay, performed using human umbilical vein endothelial cells after 24 and 48 h, demonstrated cytocompatibility of NPs at 0.25 - 0.5 mg/mL concentration.

Flow cytometry analysis of 293T cells treated with NPs encapsulating Fluorescein amidites (FAM)-labelled miRNA or CY3-labelled siRNA control revealed high level of transfection efficiency (80%), similar to Lipofectamine® (90%). Confocal imaging confirmed NPs internalization by cells. Overall, the work evidenced that PLGA/CS NPs represent promising candidates for the encapsulation and release of miRNAs and siRNAs, deserving further investigation using therapeutic payloads.

Activity was supported by MIT-POLITO grant (BIOMODE - Compagnia di San Paolo).

INJECTABLE, SELF-HEALING MESOPOROUS SILICA NANOCOMPOSITE HYDROGELS WITH IMPROVED MECHANICAL PROPERTIES

Aygul Zengin[P][1], João Pedro Olim Castro[1], Pamela Habibovic[1], Sabine van Rijt[1]
[1] *Instructive Biomaterials Engineering, Maastricht University-MERLN Institute, Maastricht, Netherlands*
Corresponding author's email: a.zengin@maastrichtuniversity.nl

Inspired by the autonomous healing process of natural tissues, self-healing hydrogels have received great attention to replacing the often brittle hydrogels currently investigated in clinical applications. However, despite the efforts in the design and development of injectable, self-healing hydrogels, the ongoing challenge is combining high material strength with rapid self-healing. Incorporation of nanoparticles within hydrogels to create nanocomposites is an attractive approach to create hydrogels with improved mechanical and/or biological performance. In particular, mesoporous silica nanoparticles (MSNs) are ideal building blocks within these constructs as they are bioactive, improve mechanical and biological properties of polymers, and can controllably release various types of cargo(1-4).
Here, we report injectable, self-healing, and stimuli-responsive nanocomposites for tissue regeneration using MSNs and hydrophilic linkers that self-assemble in a 3D matrix. In these constructs, the MSNs acted as dynamic covalent crosslinkers in the polymeric network, which resulted in a significant increase of mechanical properties compared to adding nanoparticles as fillers. In addition, their mechanical properties could be tuned by changing MSN weight %, where an up to a 25-fold increase in mechanical properties could be observed compared to the pure polymeric hydrogels. Moreover, these hydrogels degraded completely in a glutathione-containing environment for over six weeks. Additionally, their drug release behavior could be controlled by changing network stiffness. Actin/nuclei staining of encapsulated hMSCs inside the nanocomposites confirmed their biocompatibility. The proposed nanocomposite formulation is a promising strategy to overcome current constraints with the brittleness of self-healing hydrogels, widening their application in tissue engineering applications towards stiffer tissues.

Keywords
Nanocomposite hydrogels; Self-healing; Mesoporous Silica Nanoparticles

Space Tango is recognized as a leader in automated R&D and manufacturing systems for biomedical applications in low-Earth orbit (LEO). The unique domain of space provides a new frontier for discovery and innovation, and our vision is to inspire, innovate and create a better future for humanity, using the microgravity environment of the International Space Station (ISS). Space Tango's emphasis on automation is exemplified by the TangoLab, a fully autonomous system on the ISS since 2016, which allows multiple experiments to run simultaneously and independently on orbit. The recent addition of the Powered Ascent Utility Locker (PAUL) has enhanced Space Tango's on-orbit capacity for cell culture. The PAUL extends the capabilities for environmental control, media exchange, and data collection during the period of ascent and transport to the ISS. The foundational elements of Space Tango's autonomous research and manufacturing systems are compact, smart containers called CubeLabs™. The Cell Culture CubeLab was developed for the study of stem cells, 3-dimensional tissue models, and organoids in microgravity. Incubation and refrigeration subsystems maintain optimal conditions for biological specimens, while the fluid control subsystem provides precision delivery and exchange of media and reagents. The compact imaging system can support brightfield, phase contrast, and 3-channel fluorescence microscopy for high-resolution, live-cell imaging in real-time. Collectively, these integrated subsystems are controlled by the CubeLab flight computer to yield a compact microgravity research tool, toward the development of both capabilities and infrastructure for a new biomedical market sector in the expanding space economy.

Cartilage engineering approaches are being developed for evaluating the repair of articular cartilage lesions but few of them have reached the clinics. One limitation of current approaches is the lack of mechanical stimulus, which is one main factor regulating tissue homeostasis. We therefore aimed at better understanding the impact of mechanical stimulation on cartilage generation and extracellular matrix production. We relied on the use of a fluidic custom-made device for mechanical stimulation and characterization of mesenchymal stromal cells (MSCs)-derived cartilage micropellets. Human MSCs were differentiated into chondrocytes by culture in micropellets with a chondrogenic medium for 21 days. Six micropellets were placed into the conical wells of the chamber of the device and stimulated with different square signals of positive pressure (amplitude, frequency, duration). The sinking of each micropellet into the cone was recorded by a camera and its deformation was analyzed using a finite element model. 24 hours after stimulation, micropellets were harvested for chondrocyte marker quantification (SOX9, AGG and COL2B) by RT-qPCR and for histology. A single stimulation of 30 min with an amplitude of 3.5 kPa superimposed to a minimum pressure of 1.75 kPa, at 1 Hz for 30 min increased the expression of chondrocyte markers. The finite element analysis indicated moderate deformation of micropellets with compression, tension and shear that did not alter micropellet microstructure as shown by histological staining. Our data demonstrate the interest of fluidic-based compression for reproducible stimulation of cartilage micropellets and set the basis for further longitudinal studies on the long term.

The chicken eggshell membrane (ESM) is an exceptional biomaterial demonstrating unique biological characteristics and defined mechanical/physical properties. As such, the ESM has potential to be exploited as a novel membrane for regenerative therapy or as a biomimetic scaffold for advanced cell culture. In this study, a number of techniques were employed to extract (and enhance) the ESM. Thereafter, the membrane was characterized in terms of its physical, mechanical and biological properties.

ESM samples were prepared using either a manual, an optimised acid- and/or chelator-based extraction protocol and the physical/mechanical characteristics were assessed using DMA, SEM, WCA, FT-IR and THz sensing. Additional crosslinking of the ESM was introduced using EDC-NHS and an enzymatic technique. In vitro assessment was performed using standard biological assays for cell attachment/spreading, viability and mitochondrial activity with human (melanoma) fibroblast cell lines (Malme-3/Malme-3M), immortalised human corneal epithelial cells (ihCEC) and cornea mesenchymal (stromal) stem cells (cMSC). The chicken embryo chorioallantoic membrane (CAM) assay was also exploited to determine the effect of the ESM on angiogenesis.

Complete ESM samples were successfully isolated, modified and thereafter fully characterized. Cells cultured on the extracted ESM demonstrated high biocompatibility in terms of high cell attachment, spreading, viability and proliferation rates/characteristics and also allowed the promotion of new blood vessels (i.e. pro-angiogenic) in the CAM assay. As such, this work summarizes the development of an ESM-based material/scaffold- modulation of the characteristics of the membrane can be achieved via the isolation/extraction/preparation/enhancement techniques used and, therefore, be adapted to suit its final translational application.

Metal-organic-frameworks (MOF) are a rapidly growing class of nano-porous networks, with an extremely high (internal)-surface area. They find application in storage, separation and purification fields. Because of their tailorability, MOFs hold promises in the biomedical field as drug delivery agents, radioenhancers and application in theranostic and personalized medicine. For biomedical applications, the fate of these new materials is, next to efficacy, a major determinant of clinical success. Compared to their metal oxide counterparts, MOF typically exhibit higher instability and different degradation/biotransformation behaviours.

Zeolite-imidazole-framework-8 nanoparticle (ZIF-8) are one of the most extensively studied nanomedical MOFs.(1) Next to application as drug carrier with anti-inflammatory and anti-microbial properties(2) a ZIF-8-chitosan hydrogel composite for bone regeneration with angionesis and osteogenesis promoting properties was recently presented.(3) However, clinical translation is still challenging, amongst other reasons a tight control over nanomaterial chemistry during nanomedical life-cycle is needed. Stability and dissolution was excessively studied in the past but a detailed understanding of behaviour and chemical reaction in-vivo leading to phasetransformation and/or generation of secondary nanomaterial hampering efficacy, elimination and potential side effects is widely unexplored.

To overcome the gap between material engineering and medical application, and enable more rationalized safe-by-design material engineering, we investigate the environment-dependent biochemical-transformation of MOFs in physiologically relevant liquids and in-vitro systems. We present an example of MOF biotransformation where secondary particle formation with changes in elemental distribution and morphology suggesting nanomaterial formation from degradation products. Taken together, our nano-analytical characterization approach offers a route to follow the biological fate of MOF-based na-nomedicines.

The reduction of animal testing and the need to assess the health risk of new chemicals makes tissue engineering an essential tool in the development of in vitro models. In this work, we developed an inexpensive reconstructed human epidermis (RhE) by using electrospun scaffolds from synthetic polymers, like PET, PBT, and Nylon 6/6, and described in terms of its morphology. Epithelial tissues were constructed with and without dermis, followed by its histological characterization by H&E staining and immunohistochemistry, as well as Western Blot analysis. Finally, the epithelial constructions that demonstrated viable structures of RhE were submitted to an applicability model as a platform for skin irritation and corrosion testing, according to standards of OECD TG 431 and 439 [1]. The morphological and immunohistochemistry analyses revealed the presence of a stratified tissue, showing the presence of cytokeratin 14, cytokeratin 10, involucrin, and loricrin arranged in a stratification process, similar to human skin. To proceed with OECD protocols, acetic acid and lactic acid were used as corrosive substances, while SDS and KOH were tested as irritants. The relative viability values obtained for each chemical treatment fully compared with commercial models, as well as with the USP-RHE model [2], demonstrating its usability. These results showed that electrospun synthetic scaffolds are promising three-dimensional structures in the construction of epidermal equivalents.

ALIGNED POLYDROXYALKANOATE BLEND FIBRES FOR PERIPHERAL NERVE REPAIR

Caroline Sarah Taylor$_P$[1]

[1] *The University Of Sheffield*

Corresponding author's email: c.s.taylor@sheffield.ac.uk

INTRODUCTION: Nerve guide conduits (NGCs) are a favourable alternative to autograft use for nerve repair. However, as a hollow tube, they lack natural guidance cues for the regenerating axon. The addition of guidance scaffolds, in NGCs, has been shown to increase nerve regeneration distances1. Polyhydroxyalkanoates (PHAs) can be tailored to a specific application and exhibit excellent biological properties.

METHODS: P(3HB) and P(3HO) were produced by bacterial fermentation and characterised2. Aligned PHA and PCL fibres were fabricated by electrospinning, and fibre alignment and diameter quantified. NG108-15 neuronal cells, and primary Schwann cells, were seeded onto scaffolds, for 6 days, and labelled for β III tubulin and S100β. Whole rat Dorsal Root Ganglion (DRG) explants were placed onto fibres in a 3D ex vivo fibre model3. After 21 days, DRGs were labelled for β III tubulin, and S100β, and imaged to determine average neurite length and average Schwann cell migration distance.

RESULTS: Significantly longer neurite lengths were detected on 8µm P(3HB):P(3HO) 50:50 fibres (137.94 ± 17.35µm) compared to the other fibre conditions. However, significantly longer neurites grew from DRGs when cultured on the 5µm P(3HB):P(3HO) 50:50 fibres (1502.69 ±110.63µm). Average Schwann cell migration distance was also significantly higher on 5µm P(3HB):P(3HO) 50:50 fibres compared to 5µm PCL fibres.

DISCUSSION & CONCLUSIONS: Blends of PHAs can be fabricated into aligned fibre scaffolds using electrospinning, with known fibre diameters, for peripheral nerve applications. The use of PHAs eliminates concerns with the use of PCL, and has excellent properties to improve nerve regeneration.

Current corneal treatments mostly rely on transplantation of corneas from deceased donors. However, this procedure can only fulfil less than 2% of the global demand. On the one hand, tissue engineering strategies based on a pre-expansion of corneal cells in vitro would allow the treatment of millions of people whose corneas are damaged by trauma or disease. On the other hand, primary keratocytes and endothelial cells of the cornea are notoriously challenging to be maintained in culture or expanded without significantly alter their phenotype. Numerous attempts aim to overcome these issues. We hypothesized that also for corneal cells, physical and architectural cues provided by micro engineered cell culture substrates can be used together with media formulations to better tune cell growth, proliferation and differentiation.
In this study, we investigated the influence of topographically patterned films on the maintenance of native corneal cells phenotype in vitro. We compared several polymeric materials for the fabrication of thin textured films. In addition, we systematically screened synthetic 2 ½ D microtopographies by varying patterns shape, size and height to explore how these affect cell differentiation. We finally analyzed marker expression and cell morphology features to find significant correlations between substrates and cell phenotype. Our results show how a more comprehensive bioengineering approach can contribute to the development of better differentiation protocols for the expansion and differentiation of primary cell cultures in vitro.

Vascularization is a critical barrier to clinical application and scale of engineered tissues. The fate of engineered constructs after implantation highly relies on the rapid and sufficient vascularization, which guarantees long-term function and survival at the defect area. While some naturally-derived materials, e.g. Matrigel, show promising HUVECs organization these materials are limited by lot-to-lot variability and the inability to precisely tune material properties. In the search for suitable hydrogels to encourage vascularization, controllable and biomimetic systems are need to study the effect of materials properties on HUVECs organization.Here, we utilized a dynamic covalent hydrogel, which has controllable stiffness and stress relaxation, to investigate the response and organization of HUVECs to these mechanical properties, using oxidized alginate, modified with RGD, with different cross-linkers to obtain materials with different storage moduli (G', 13530.7 to 248.8 Pa) and time of relaxation(τ,134205 to 795 s). Rheological characterization revealed that the values of G' and τ of the soft dynamic hydrogels (248.8 Pa and 795 s) are in the same order than the values showed by Matrigel, 11.2 Pa and 755 s. All formulations showed good cytocompatibility. On the soft dynamic hydrogels, we observed cord-like HUVECs organization. Stiffer hydrogels did not show this organization. The HUVECs are being studied in order to determine cell-cell interactions and cell migration.This work contributes to the increasing interest in developing extracellular matrix-like hydrogels to study complex cell-cell and cell-matrix interactions. These soft and hydrogels remain one of the few synthetically controllable systems to show promising HUVECs organization.

STRETCH-GROWN GALSAFE® AXONAL TRACTS SERVE AS LIVING TISSUE ENGINEERED NERVE GRAFTS FOR PERIPHERAL NERVE REPAIR

Peripheral nerve injury (PNI) often results in protracted denervation of muscle, leading to loss of function. The current gold standard for nerve repair, the autologous nerve graft, not only requires sacrificing healthy nerve necessitating a second surgery with increased risk for donor site morbidity but frequently leads to inadequate functional recovery for large gap injuries. To address this, Axonova has developed tissue engineered nerve grafts (TENGs) by implementing the strategy of axon stretch growth that occurs during development. TENGs are living three-dimensional nerve constructs consisting of longitudinally aligned axon tracts spanning discrete neuronal populations. Based on preclinical data, TENGs target multiple neuroregenerative mechanisms, providing viable alternatives for current repair strategies. For clinical translation, a xenogeneic product strategy is being pursued through a partnership with Revivicor, Inc. Revivicor has developed a genetically engineered strain of pig that does not express a key antigen – galactose-α1,3-galactose (gal) – that would otherwise activate the complement system following transplant into humans, resulting in rapid rejection. Axonova's product development strategy is to build TENGs using neurons from Revivicor's GalSafe® pigs, presenting several advantages: (1) an off-the-shelf gal-free product; (2) cGMP manufacture from a qualified, FDA compliant starting biomass; (3) source of terminally differentiated motor and sensory neurons for modality-specific products. Pre-clinical studies have shown that GalSafe® TENGs promote host axon regeneration through the previously discovered mechanism of axon facilitated axon regeneration (AFAR). Successful biomanufacturing of TENGs is a critical first step in introducing this technology to the clinic as a revolutionary approach to major PNI.

The multipotent mesenchymal stromal cells (MSCs) may promote corneal regeneration through the paracrine action, reducing the inflammatory processes and providing trophic support for the host tissue. To ensure the fast availability of the safe cellular therapy for these applications, several aspects were considered in the study: a) the choice of the polymeric contact lenses able to act as cell carriers; b) the choice of minimal DMSO concentration ensuring sufficient cell viability during cryopreservation; c) the design of closed system, ensuring the seeding of cryopreserved cells onto the contact lenses in safe clinically-relevant environment.
Human Wharton's jelly MSCs were obtained according to ethical guidelines and expanded in the presence of 5% of platelet lysate (PL). The cryopreservation (-1°C/min) was prepared in PL, supplemented with 1-10% DMSO. The cell recovery was assessed by alamar blue assay. The commercially available contact lenses were tested as a carrier for MSCs. The closed system was designed and printed using 3D Creality Ender 3 printer, using PLA filaments.
We found that among the wide range of polymeric contact lenses, only a few types ensured attachment and growth of MSCs. The recovery of MSCs after cryopreservation in PL-based medium varied depending on the DMSO concentration and reached more than 80% at 5% DMSO. The designed closed system allowed to seed cryopreserved MSCs onto the contact lenses, minimizing additional manipulations and reducing the risks associated with contamination. Therefore, the presented approach can be applied for the preparation of therapeutic MSC-based grafts for clinical ophthalmology.

Fluorescence lifetime imaging microscopy (FLIM) is an imaging technology that allows the time resolution of fluorophores. This extra time-dimension transforms every single fluorophore into a microenvironment probe capable of reacting to changes in its surroundings. Coupled with multiphoton microscopy, FLIM enables the contact and marker free evaluation of cells due to the autofluorescence of endogenous free/bound reduced nicotinamide adenine dinucleotide (NADH). In this work, we employed FLIM NADH for the monitoring of cellular metabolism and death in 2-dimenttional human dermal fibroblast (hDFs) and 3-dimentional EndoC-ßH3 insulin-producing pseudo islets. Induced cell death in hDFs and hypoxia-induced damages for pseudo-islets resulted in an overall increment of fluorescent lifetimes of both bound and free NADH species. Moreover, as pseudo-islets are glucose responsive, fluorescence lifetime fluctuations throughout a glucose-stimulated insulin secretion (GSIS) assay revealed the metabolic integrity differences between normoxic and hypoxic pseudo islets. Here, we propose FLIM as a tool for the evaluation of cell integrity and functionality.

It is plausible that the functional improvements achieved by regenerative therapies for volumetric muscle loss (VML) to date are due, in part, to the induction of fibrotic bridge across the VML defect – a concept termed 'functional fibrosis'. However, to date, this concept has not been definitively experimentally proven. The purpose of this study was to evaluate the therapeutic potential of intentionally inducing functional fibrosis as a means to promote improved muscle function following VML. A rat tibialis anterior (TA) VML model was used with the following groups: 1) untreated (control), and 2) functional fibrosis, which was achieved by implanting a polypropylene mesh with a bolus of TGF-β — both of which are well known to induce fibrosis. At 4 and 8 weeks post-VML injury, in vivo functional analysis was performed and TA muscles were collected and analyzed for expression of Col1a1, Col3a1, and Acta2, among other analyses. As expected, functional fibrosis treatment of a VML injury resulted in increased Col1a1 and Acta2 expression relative to the untreated controls. Interestingly, at 8 weeks post injury, the functional fibrosis group had improved peak isometric force (61% increase) compared to untreated control. The findings presented herein support the concept of intentionally eliciting a super-physiologic fibrotic repair response as a means improving force transmission across a VML defect thereby improving the whole muscle functional capacity. As such, induction of functional fibrosis represents a plausible path forward for treating VML if the overall clinical goal of the treatment is focused on limb function.

Rheumatoid Arthritis (RA) is an autoimmune disease characterized by chronic inflammation and progressive destruction of synovial joints. Disease pathology is driven by an imbalance in the ratio of infiltrating pro-inflammatory vs. anti-inflammatory cell phenotypes, especially macrophages. Modulation of macrophage phenotype, specifically the M1-like to M2-like, pro- to anti-inflammatory transition, can be induced without immunosuppression by materials composed of extracellular matrix (ECM). This ECM-based immunomodulatory effect is thought to be mediated in part through recently identified matrix-bound nanovesicles (MBV) embedded within ECM that are released upon matrix degradation. MBV can modulate this M1-M2 transition. To examine the efficacy of MBV therapy for RA, MBV were delivered via intravenous (i.v.) or peri-articular (p.a.) routes to rats stimulated with pristane, an inducer of rat-RA. MBV therapy was compared to intra-peritoneal (i.p.) methotrexate (MTX), the standard of care. Relative to diseased animals, i.p. MTX, i.v. MBV, and p.a. MBV significantly reduced arthritis scores in both acute and chronic pristane-induced arthritis ($p<0.05$). There was no significant difference observed among i.p. MTX, i.v. MBV, and p.a. MBV in both phases ($p>0.05$). Post-mortem examination of joint tissue by histology and microCT at day 100 showed that both i.v. MBV and p.a. MBV reduced synovial inflammation, bone erosion, and the ratio of synovial M1:M2 macrophages compared to diseased animals ($p<0.05$). The results presented demonstrate that administration of MBV are equally efficacious to MTX for management of both acute and chronic pristane-induced arthritis and this effect is associated with immunomodulation of synovial macrophages, without immunosuppression.

The importance of 3D in vitro models has increased to replace animal studies, which are often not transferable to humans. However, even these models do not completely mimic the native tumour microenvironment: In previous multicellular 3D tumour models, which represent the interaction between tumour cells and non-malignant cells, different relevant cell types were chosen, but the tumour microenvironment was represented in a simplified way regarding to tumour cell migration and the surrounding vascular network.

In this study, we focussed on developing a vascularized 3D tumour model based on fibrin gel for in vitro testing of chemotherapeutic agents.

We co-cultured HUVECs and mesenchymal stem cells acting as pericytes in fibrin gel for 14 days at 37 °C and 5 % CO2. Lung tumour cells (A549) were subsequently injected into the gel by a punch-out method and maintained in culture for another 7-14 days under normoxic and hypoxic conditions. The tri-cultures were treated with a chemotherapeutic agent and analysed by 2-photon laser scanning microscopy. Cultivation of co- and tri-cultures under hypoxic conditions promoted vascularization as shown by significantly increased amounts of vascular structures and branching points as well as increased secretion of vascular endothelial growth factor compared to normoxic-cultivated controls.

The resulting functional tumour network was reduced by the addition of a tumour drug. Our data provide the first step towards patients individualised 3D tumour models and their application as an approach to effective therapeutic in vitro testing.

For the long-term success of percutaneous components like dental implants, a functional attachment of the soft tissue to the surface of the implant abutment is of decisive importance in order to prevent the penetration of bacteria into the implant-bone interface which can trigger peri-implant diseases. Here, we describe a surface modification approach, which includes the covalent immobilization of the extracellular matrix (ECM) proteins fibronectin and laminin via a crosslinker to silanized Ti6Al4V and Y-TZP surfaces. The surface properties were evaluated by static contact angle, X-ray photoelectron spectroscopy (XPS) and atomic force microscopy (AFM). Retained function of the ECM-proteins after surface coupling was shown in a centrifugation-assay. Here, human gingival fibroblasts (HGFs) seeded onto ECM protein modified surfaces exhibited significantly higher attachment in comparison to non-functionalized controls. Confocal microscopy revealed a much higher cell area and enhanced expression of pFAK-Y397 on ECM protein coated surfaces compared to those seeded on native surfaces. Moreover, HGFs cultivated on ECM protein coated surfaces showed a significantly higher proliferation rate and integrin expression. The presented approach holds great potential to enable a stronger binding between soft tissue and implant abutment surface, which could help to prevent the penetration of bacteria and thereby reduce the risk of peri-implant diseases.

INTRODUCTION:

Chronic obstructive pulmonary disease (COPD) is a worldwide health problem, where the tissue is gradually degraded, leading to emphysema and loss of tissue integrity [1]. Our goal is to improve regeneration of the damaged tissue by inserting a biomaterial with the ability to activate regeneration in the border zone between destroyed areas and remains of healthy tissue in COPD. Elastin-like Recombinamer (ELR) cryogel is a type of biomaterial that has proved to have excellent biocompatibility properties [2].

METHODS:

ELR is a two-part solution which are modified so that one part has an alkyne modification while the second part has an azide modification. When these two parts are mixed a covalent bond is formed resulting in a hydrogel. ELR cryogel was created by forming the hydrogel in subzero temperatures. A549 cells with GFP were seeded on top of the cryogel and grown for seven days, evaluated according to morphology and distribution in confocal microscopy.

RESULTS AND DISCUSSION:

The results show that the cells attach to the surface of the cryogel and per se to be able to migrate inward towards the center of the cryogel over time. The next step in this project is co-culturing the cryogel with primary human type 1 cells together with primary fibroblasts might lead to cells forming more alveolar like structures and the fibroblast adding native ECM to the gel.

CONCLUSION:

The data showed that an ELR-based cryogel is a promising synthetic scaffold for lung tissue engineering, mimicking the 3D environment of the extracellular matrix.

Introduction

Impaired wound healing is a health problem with limited treatment options. Autologous fat grafting may improve wound- and scar treatment. We hypothesized that adipose tissue-derived stromal cells' secretome and their profiency to bind to ECM underlies this regenerative effect. To test, we developed injectable ASC-secretome-loaded ECM-hydrogels to improve dermal wound healing in rats.

Methods

Decellularized pigskin (ECM) was finely powdered and mildly pepsin-digested to yield liquid pre-gels that gelated at 37°C. Human ASCs were from human lipoaspirates were used to prepare serumfree conditioned medium (ASCcme i.e. secretome). Full thickness dorsal skin flaps (3x10cm) were used to fill with ASCcme-loaded skin hydrogels. Gelation was within seconds Controls were gel or ASCcme alone or saline. At 1, 2 and 4 w, explanted wounds were assessed by H&E (general histology), Masson's Trichrome (matrix remodelling and fibrosis) and CD68 staining (macrophages).

Results

Decellularized ECM was free of cellular&DNA remains. Thin sections' (immune)histochemical analysis of excised wounds showed that during the course of wound healing, vascularization increased with angiogenesis scores highest after 2w. Collagen remodeling showed similar patterns in fiber length and angle, except for fiber width, which was significantly thinner in the ECM-hydrogel group. The presence of bare or ASCcme-loaded hydrogels did not influence wound healing nor did it cause adverse reactions at all times. Likely, the dose of ASCcme needs to be increased to accelerate wound dermal wound healing.

Conclusion

ECM-hydrogels are well-tolerated by rats in healing dermal wounds.

USING BIOPRINTING TO INTEGRATE HIGH CELL DENSITY HYDROGELS WITH METAL IMPLANTS FOR ENHANCED OSSEOINTEGRATION

Marcin Kotlarz$_P$[1], Ana Ferreira-Duarte[1], Piergiorgio Gentile[1], Kenny Dalgarno[1]

[1] *Newcastle University*

The surface of metallic implants serves as a powerful signalling cue for cells. Its properties play an important role in facilitating the early osseointegration by encouraging bone deposition on the surface and stabilising bone-implant interface. In this work, we demonstrated the application of a bioprinting process called Reactive Jet Impingement (ReJI) [1] to fabricate cell-laden coatings onto medical implants, with the ultimate aim of accelerating osseointegration through stimulating endogenous cells.

Natural hydrogel coatings consisting of collagen, alginate and fibrin [2] that delivered high cell densities (4 x 10^7 cells/ml) of human TERT immortalised bone marrow stromal cells were deposited onto the Ti6Al4V ELI titanium alloy implants. Three types of metal substrate with different surface roughness and morphology were used. The constructs were cultured over 21 days and assessed using Live/Dead, SEM, immunofluorescence and Alizarin Red.

Cell viability was not affected by the bioprinting process. Topographical and morphological features of the surface influenced cell organisation and cell-metal surface communication. All types of Ti6Al4V ELI implants supported the coating attachment. Cell migration and direct cell-metal implant interactions were visible from day 1. Significant calcium deposition in the area where the gel coating was printed was observed.

Morphologically robust and organised architectures were produced thanks to the drop-by-drop deposition and mixing of bio-inks at nano-litre scale using the ReJI process. High cell densities enhanced cell-biomaterial interactions at the hydrogel/metal surface interface and the coating supported the formation of a layer of functional bone-like tissue on the Ti6Al4V ELI implants.

Following a challenging history of viral gene delivery vectors, non-viral vectors have gained popularity in regenerative medicine. Our lab has pioneered gene-activated scaffolds for bone repair (1-3), most recently using the glycosaminoglycan-enhanced transduction (GET) peptide (4). A modified peptide (GET*) facilitates enhanced endosomal escape, thereby increasing transfection efficiency. The aim of this study was to optimise GET*pDNA nanoparticles for collagen-nanohydroxyapatite (coll-nHA) scaffold-based delivery (5) of a plasmid encoding stromal derived factor 1α plasmid (pSDF-1α), a chemokine which promotes bone repair by increasing angiogenesis (6). pSDF-1α plasmids were delivered to a co-culture system of mesenchymal stem cells (MSCs) and endothelial progenitor cells (EPCs), cell types which promote bone regeneration (7).

GET* nanoparticles were characterized at multiple N/P ratios by transfecting MSCs and EPCs with reporter plasmids in 2D and via two different scaffold compositions (coll-nHA 100% and 200% wt. scaffolds). pSDF-1α was then delivered to MSCs, EPCs, and co-cultures using the optimal GET* nanoparticles incorporated into coll-nHA scaffolds before quantifying the therapeutic effect.

GET* N/P 8 nanoparticles demonstrated the highest transfection efficiency in 2D monolayer and on both coll-nHA scaffold compositions. Delivery of pSDF-1α using this optimal gene-activated scaffold platform resulted in significantly higher calcium production in a co-culture of MSCs to EPCs compared to untransfected controls.

In conclusion, GET* N/P 8 nanoparticles demonstrated the highest transfection efficiency compared with other groups, in 2D monolayer and via coll-nHA scaffolds. pSDF-1α delivered to an MSC/EPC co-culture system using this platform showed promise in vitro, suggesting that the pSDF-1α is enhancing osteogenesis.

Despite 50 years of silicate bioactive glasses (SBG) research (with over 100 different SBGs formulations and in excess of 500 papers) there remains a lack of understanding of how soluble silica species (Si) released from the SBGs influences cellular responses. Using a systematic approach, this paper quantitatively compares the in-vitro responses of cells to BG dissolution products reported in literature (90 publications that quantify silicate ion concentrations [Si]). Both [Si] and changes to cellular behaviour (percentage difference relative to a control) were then collected from each paper.

The [Si] that most papers report desirable cellular responses (within 1-week culture) is between 1 & 40ppm. Si concentrations above 40ppm are almost 4 times more likely to cause unfavourable cellular responses. Cell-type and species specific differences in cellular responses were also found, where for example, an increase in proliferation is observed in response to [Si] in cells derived from human species ($P<0.001$), but not other species. There was, however, no statistical difference between the [Si] that caused altered expression of ALP, osteocalcin, collagen, VEGF or in vitro mineralisation in the reported literature, suggesting Si may not influence their expression or that insufficient evidence is available.

This review has, for the first time, quantitatively compared the cellular responses to SBGs from the literature . Whilst evidence is presented for the range of [Si] that cause positive cellular responses (<40ppm), this review demonstrates the need for greater standardisation of in-vitro methodological approaches.

Corneal disease is the fourth cause of blindness. To advance knowledge towards a tissue-engineering approach for corneal regeneration, information about biomaterials-tissue/cell interactions is needed. To develop such models, it is crucial to mimic the cornea in-vivo microenvironment.

The cornea is the outermost transparent part of the eye, and consists of five layers. Stroma is the thickest of the layers, composed of well-organized collagen fibrils and quiescent keratocytes. Keratocytes during in-vitro culture easily undifferentiate; however, most of these studies are conducted on 2D monolayers.1

To engineer a functional corneal in-vitro model, it is imperative to better understand the cornea structure and the effects of a variety of signals seen in-vivo, such as mechanical properties. 2

Here, we have formulated hydrogels based on UV-cross-linked alginate3 along with supramolecular or collagen based reinforcing networks. This has allowed us to control the processability, mechanical properties, and optical clarity of hydrogels to study keratocytes behavior in hydrogels with varying stiffness and shapes.

Hydrogels mechanical properties are tunable by varying the concentration, length, and structure of the cross-linkers, as well as the composition of the final gel.

The hydrogels obtained showed a transparency of ~97% and a refractive index of 1.333 (human cornea: 1.376).4 The effects of the hydrogel mechanical properties on the keratocytes is being studied by the expression of alpha-smooth muscle actin and aldehyde dehydrogenase-1A1.

Understanding the effects of the mechanical properties of the material on the keratocytes behavior is crucial to the development of a tissue-engineered cornea and biomaterial implants for the cornea.

Keywords

Hydrogels; Keratocytes

Osteoporosis is a bone pathology with a high economic and social burden, and an increasing incidence due to demographic ageing [1]. GIOTTO project aims to target specific osteoporotic fractures using smart, innovative and customized devices by leveraging advanced know-how in biofabrication technologies [2]. Blends of poly-L-lactic acid (PLLA), polycaprolactone (PCL) and poly(3-hydroxybutyrate-co-3-hydroxyvalerate) (PHBV) (90:5:5%wt), PLLA/PCL/PHBV + 5%wt of nano-hydroxyapatite (nHA) and PLLA/PCL/PHBV + 5%wt of strontium-substituted-nHA were fabricated into 1.75 mm diameter filaments. Degradation kinetics, mechanical and rheological properties were optimized. Rheological assessment showed a shear thinning behavior in the Fused Deposition Modelling (FDM) temperature range and confirmed the inorganic phases homogenous dispersion. The filaments were processed using a FDM-printer. Preliminary extrusion and printing tests were performed to optimize the process parameters, which were thus employed to produce cylindrical scaffolds for biological testing. The scaffolds were cultured in contact with pre-osteoblastic and bone marrow-derived mesenchymal stem cells. Cytotoxicity and morphology were evaluated by a colorimetric viability assay and scanning electron microscopy, respectively. The osteogenic potential was screened using alkaline phosphatase (ALP) activity measurement, alizarin red staining and sirius red staining. All materials demonstrated high cell viability, excellent adhesion and morphology. The addition of both inorganic phases indicated a significantly higher ALP activity and calcium mineralization when compared to the control. Finally, all blends showed an increasing collagen secretion. These results indicate the high osteogenic potential of the developed materials.

This project has received funding from the European Union's Horizon 2020 research and innovation program under grant agreement No 814410.

Bone morphogenetic protein-2 (BMP-2) is the most potent, clinically-approved, osteogenic cytokine. Yet, it has limited approved use, requires supraphysiological doses, and side effects are a concern. Gene transfer has been suggested to improve and prolong its delivery. Ex vivo gene transfer holds advantages as a therapy1, but the use of autologous cells is limited by the high-cost associated with harvesting and/or tissue culture expansion prior to re-implantation. This project aimed to overcome this limitation by generating a non-osteogenic, stably transduced, immortalized cell line that would serve as an off-the-shelf allogeneic product for bone healing.

HEK293 cells were lentivirally transduced to express BMP-2 constitutively. Clones were selected, expanded, characterized and frozen at 1x106 cells/vial. BMP-2 production was measured by ELISA. Individual vials were thawed and cells encapsulated in fibrin prior to surgical implantation in a rat, 5-mm, femoral, bone defect model. Defect bridging was monitored via weekly radiographs. Empty defects in this model fail to bridge the defect. FK506 was used to prevent xenograft rejection.

Clone CL1K was selected and BMP-2 expression confirmed for 50 passages. After 6 weeks, 5 rats presented with bicortical bridging, 2 with unicortical and 3 without bridging.

The ability of the BMP-2 expressing CL1K cells to bridge large bone defects while lacking intrinsic osteogenic potential is a novel approach to bone healing by gene transfer. The prospect of an off-the-shelf cell line for bone healing is a promising clinical solution. Future work is needed to optimize the conditions needed for this approach to be reliably successful.

Objective: Cartilage injuries can lead to osteoarthritis (OA) that cause cartilage loss, bone remodelling and osteophyte development and remain a therapeutic challenge. Medical engineering by 3D bioprinting with cells and therapeutic ink has potential to reconstruct patient-specific features that for example match an articular joint lesion.

Design: Here a human osteoarthritic (OA) tibial plateau with a cartilage defect was retrieved after total knee arthroplasty and scanned using following clinical imaging techniques; (I) computed tomography (CT), (II) magnetic resonance imaging (MRI) or (III) a three-dimensional (3D) scanner. Ink for 3D bioprinting with nano-carriers with a potential OA protective capacity was developed.

Results: Highest resolution was obtained using the 3D scanner and only the 3D scanner was able to detect the actual OA defect area. Human chondrocytes or micro cartilage tissue, generated from induced pluripotent stem cells (iPSCs), included in 3D bioprinted constructs produced extracellular matrix (ECM) and formed cartilage tissue fragments after two weeks of differentiation. High levels of a mature splice version of collagen type II (Col IIA type B), characteristic of native articular cartilage, and aggrecan (ACAN) were detected. 3D bioprinted micro tissue embedded with nanomaterials with enhanced cartilage repair or capable of mitigating illicit biological responses were safe in mice immune deficiency model.

Conclusion: Our results establish that articular cartilage similar to its native form can be made in shape of patient-specific 3D lesion. Further, nanomaterials loaded with OA combating molecules can have direct implications in personalised medicine and provides an attractive strategy for future treatments of OA.

The recent application of microfluidic technologies in bioengineering has driven considerable progress in the design of 3D micro-tissues on chips, which offer the possibility to improve preclinical experimentation respect to 2D culture systems, in agreement with the 3Rs principle. Commonly referred to as microphysiological systems, such biomimetic in vitro models replicate the in vivo tissue-specific microenvironments making use of human induced pluripotent stem cells (iPS) or primary cells embedded in extracellular matrix (ECM)-like hydrogels. Here, we designed three biologically-inspired 3D microphysiological models of multicellular-vascular interactions in microfluidic devices: human Blood-Brain barrier (BBB)[1], KRAS/LKB1 lung tumor and ALK-positive Anaplastic Large Cell Lymphoma (ALCL) model. These models have in common advanced perfusable microvasculature, obtained through self-assembled vasculogenesis or 3D macrovessel culture and supported by cell-cell dynamic contact interactions and continuous secretion of signaling factors. The BBB model, based on iPS-derived cells, showed increased maturation toward BBB-like structures with vascular permeability lower than conventional in vitro systems, and it was used to test transport of innovative carriers, such as polymer nanoparticles[2]. The lung tumor-microvascular model was critical to understand the biology of immune cell recruitment and exclusion in immunotherapy-resistant lung tumor microenvironment. The ALCL model was exploited to unveil a molecular mechanism of tumor drug resistance. These advanced and physiologically-relevant models have the potential to accelerate drug discovery by reliable prediction of therapeutic vulnerabilities and biotransport studies of drugs across barriers, thereby improving the understanding of several currently incurable diseases.

Activity was supported by MIT-POLITO grant (BIOMODE - Compagnia di San Paolo).

In recent years, decellularized tissues have been used as biomaterials for transplantation. Although many decellularized tissues that have been clinically applied are prepared using a surfactant, we then have developed a novel decellularization method using subcritical dimethyl ether (DME) instead of the surfactant. Perfusing the subcritical DME are usually used for lipid extraction. Therefore perfusing the subcritical DME would be able to destroy and remove the cell membrane composed of phospholipids. Since DME vaporized at room temperature and pressure, it is expected that it would not remain in the decellularized tissues. We have here prepared decellularized dermis by the subcritical DME perfusion and investigated the amount of residual DNA and the maintenance of tissue structure. The dermis was prepared by removing the epidermis and the fat layer from the porcine skin and trimmed into a disk shape with a diameter of 8 mm. The samples were placed in the extraction container, and perfused in a fixed direction for 5 hours with liquefied DME by applying a pressure of 0.7 MPa. The samples were then shaken in DNase solution to decompose DNA and remove cellular components. Quantitative DNA evaluation and histological evaluation were performed. It was revealed that our method using subcritical DME perfusion and DNA enzymatic degradation could prepare the decellularized dermis as same as the method using surfactant. It was suggested that the possibility of developing a novel decellularization method using subcritical DME.

For a long time, the ribosome has been regarded as a static machine and all ribosomes within a cell were assumed to be identical. This simplified view has been challenged in recent years, when the existence of heterogeneous ribosome populations was reported. Heterogeneous ribosomes may differ in rRNA, ribosomal protein composition or differential modifications of ribosomal proteins or rRNA. However, the functional consequences of these structural specializations are still poorly understood.

Presence of senescent cells in vivo is associated with several age-related changes. Using human dermal fibroblasts (HDFs) as a model, we found increased global protein synthesis and nucleolar size in senescent cells. As the underlying mechanisms of these effects are still unknown, we explored if specific methylations of the ribose backbone contribute to the senescent phenotype.

We quantified methylation levels across all positions of rRNA. Thereby, we identified several differentially methylated sites in senescent compared to proliferating and quiescent cells. We identified several positions to be hypo- or hyper-methylated in quiescent and senescent cells in comparison to proliferating cells. Methylation levels were highly correlated with expression of snoRNAs mediating these modifications. Currently we are testing functional consequences of depletion of these differently regulated snoRNA on cellular physiology and ribosome function.

Taken together, our data suggest that even subtle modifications of the ribosomal RNA might have profound and very specific effects on cellular physiology and contribute to the specialization of ribosomes.

Introduction

Acute kidney injury is affecting about 20% of surgically treated patients.1,2,3

Placental mesenchymal stem cells (PSCs) have been shown to possess anti-inflammatory and immunomodulatory properties.4

Methods

After the removal of maternal decidua basalis, placental amniotic and chorionic cells have been isolated, cultivated for four weeks and characterized by yield, viability, flow cytometry and potency in vitro.

Wistar rats underwent kidneys ischemia-reperfusion injury. Index group received 3x105 PSCs and Control group – vehicle in the corticomedullar region of each kidney.

Survival was analyzed. Urine and blood serum samples were collected on days 0, 3 and 7. Histological kidney analysis – days 3 and 7.

Results

PSCs had a consistent yield, viability, MSCs markers expression and suppressed proliferation of T cells in a numerical fashion. Survival rate improved – 100% (Index) vs. 80% (Control).

Creatinine clearance in Index group was comparable to healthy control on day 7. Normal serum creatinine, urea and Na+ was retained in Index group up to day 7.

Extensive acute tubular necrosis (ATN) with broad coagulative tubular epithelial necrosis was evident after 3 days in the Control. A clear tendency for a lower ATN area, loss of brush border and tubular dilatation and ATN without significant coagulative necrosis was evident in Index group up to day 7.

Conclusion

PSCs have the potential to prevent initial kidney fibrosis cascade through ameliorating initial kidney damage. A superior 100% survival rate of treated animal group exhibits the potential of characterized PSCs to be used in a larger scale preclinical study.

Neural interfaces in bionic devices are dominated by the foreign body response upon implantation. Tissue engineering of the neural interface by addition of cell-laden hydrogel coatings to bionic devices has the potential to improve device-tissue integration and device efficacy. A significant challenge in this space is the development of a suitable material platform able to support neuronal viability and function. This study evaluates the incorporation of different percentages of gelatin in poly(vinyl alcohol) - norbornene (PVA-NB-Gel) hydrogels to create a construct capable of providing topographical and biochemical guidance cues to encapsulated neural cultures. The mass loss and the Young's moduli of the PVA-NB-Gel hydrogels showed degradation of the material over a period of time of 28 days, with the Young's moduli ranging from 30 to 0.5 kPa and the rate of degradation being dependent on gelatin content. Cytocompatibility of PVA-NB-Gel hydrogels was tested by encapsulating primary rat embryonic ventral mesencephalic cells. The growth and migration of astrocytes, cells responsible for neural development in a mixed cell population, were confirmed assessing the YAP expression and MMP-2 production. The study of these cellular factors, coupled with standard morphological immunostaining, provided essential insights towards the understanding of cell-material interaction in complex 3D cultures. While additional topographical cues are necessary to create fully functional 3D neuronal networks, this work demonstrated the importance of studying cell behaviour at the molecular level to tailor both the degradation profile and the biological components of a biosynthetic hydrogel for living bionic devices.

Xerostomia, or dry mouth, affects >8 million people in the U.S and occurs as a result of salivary dysfunction due to autoimmune disease, medications, smoking, aging and radiation therapy for head and neck cancer. Absence of saliva severely compromises the oral health and quality of life of patients. There are no viable long-term treatments for salivary dysfunction, driving a need for new, translatable solutions. We have devised a promising new therapy for improving salivary gland function that is based on stem cell-mediated regeneration via local delivery of an acetylcholine mimetic, cevimeline, encapsulated in an injectable alginate hydrogel. Using a combination of in vitro and in vivo assays, along with a novel mass spectrometric quantification method, we have defined the chemistry of a biodegradable oxidized alginate that enables linear distribution across the salivary gland and local release of the drug. We show that local in vivo delivery of the cevimeline-alginate hydrogel to murine salivary glands is efficacious in promoting stem cell proliferation and long-term restoration of saliva production. This study provides the first in vivo evidence that stem cells can be stimulated to re-enter the cell cycle after radiation-induced damage. In effort to move these small animal findings closer to human studies, we have developed a novel canine survival model to test safety and efficacy of our bioactive hydrogel. Together, these studies represent the first use of an injectable hydrogel for alleviating xerostomia and suggest this neurogenic-alginate hydrogel could translate to a novel system for restoring salivary function after radiation-induced damage.

Bioprinting represents an innovative approach for the production of cellularized constructs with controlled and physiologically relevant properties. For cardiovascular regenerative medicine, microextrusion-based bioprinting is the prevalent choice. The formulation of application-specific bioinks represents a significant challenge in this field. Extrudability, shape retention and biocompatibility are essential bioink requirements, combined to adequate mechanical and rheological properties. Collagen is recognized as the gold standard, thanks to its excellent biological support for cardiovascular cells (1). However, its use as bioink is hampered by low mechanical properties and long gelation time. To overcome these limitations, in this study, collagen type I was combined with enzymatically crosslinked hyaluronic acid (HA) to formulate a bioink with tunable mechanical strength and gelation time (2) for engineering vascular constructs. Although HA use as bioink has already been proven to be suitable for tissue engineering, the co-formulation with collagen is innovative and still to be investigated.

The feasibility of this strategy has been investigated through rheological and biological characterizations, by varying horseradish peroxidase (HRP) and hydrogen peroxide (H2O2) content as mediators of HA enzymatic crosslinking. Amplitude sweep test showed the direct correlation between the HRP and H2O2 concentrations and the storage and loss moduli of the hydrogel. Preliminary viability tests were performed on vascular cell types, all showing similar trends, where the presence of collagen increases cell attachment and viability compared to bare HA.

The formulation here introduced is a promising bioink for biofabrication of collagen-based cardiovascular constructs in microextrusion bioprinting. Further optimization and printability characterization are ongoing.

The intestinal epithelium is formed by villi and crypts. Intestinal stem cells (ISCs) located at the crypt base divide giving rise to proliferative cells that migrate up along the villi while differentiating, ultimately dying at the tips of the villi. This homeostasis is tightly controlled by biomolecular gradients of EGF, Wnt and BMP signaling pathways along the crypt-villus axis1. Intestinal organoids, despite including many physiologically relevant features, are not valid cultures when access to the lumen is required. Here we present a culture platform that overcomes this limitation while comprising all key features of the intestinal epithelium: 3D architecture, proliferative and differentiated cell domains, and gradients of ISCs niche biomolecules.

Employing a simple photolithographic technique2, we fabricated poly(ethylene) glycol diacrylate (PEGDA) 3D villus-like scaffolds. We developed in silico models to simulate gradients of ISCs niche biomolecules, we created them through the hydrogels by free diffusion and we characterized them by Light-sheet fluorescence microscopy.

Organoid-derived intestinal epithelial cells covered the whole scaffold surface. The gradients profile and composition, constant over time, impacted on cell behavior by modifying the proportion and positioning of the different intestinal epithelial cell types along the vertical axis of our scaffold, faithfully recreating in vivo cell compartmentalization.

We have developed an apically accessible and 3D in vitro intestinal epithelial model, which bears biomolecular ISC niche gradients and all relevant epithelial cell types. Therefore, we believe our model can be employed in many applications, particularly in the study of intestinal epithelium biology in physiological and pathological conditions.

Hydrogels due to their favourable properties are attractive materials for bioprinting application [1]. However, as soft materials, they often lack sufficient mechanical properties [2]. This work aimed to investigate the feasibility of the Reactive Jet Impingement bioprinting system (ReJI) as a method to integrate a hydrogel with a fibrous mesh substrate in order to improve mechanical properties and handleability of the scaffold for wound healing applications.

The ReJI system allowed for mid-air processing of low viscosity bio-inks that upon the meet, react to form a hydrogel3. The simultaneous, drop by drop bio-ink deposition brought an opportunity to print onto different surface types. Dry-laid needle-punched fibrous mesh was used as an exemplar substrate. Cell-laden hydrogel/mesh constructs were assessed using Live/Dead assay, immunofluorescence, SEM and histological analysis.

Two cell densities of neonatal human dermal fibroblasts were embedded in collagen-alginate-fibrin hydrogels and bioprinted using the ReJI system onto calcium alginate meshes maintaining high cell viability. Hydrogels supported interactions with the mesh by infiltrating into the substrate. Fibroblasts quickly migrated outside hydrogels, organising around mesh fibres and producing ECM. It was shown that the application of ReJI is an effective method for the integration of high cell density hydrogel with a fibrous substrate that could serve as a construct for wound healing applications.

Pharmacological treatments for osteoarthritis (OA) are based on painkillers, and none can stop OA progression because mechanisms that control pathophysiology are not well understood[1]. However, overstimulation of catabolic events of cartilage chondrocytes (CC) compared to the biosynthetic activity is common[2]. To enable mechanistic explorations of key molecular players, we propose a network-based-model that incorporates the action of cytokines at chondrocyte level. The interactome consisted in a set of nodes, related to itself through a specific topology of activating and inhibiting links. It was mathematically translated into a semi-quantitative model through a system of differential equations that converges to steady stable states[3]. The model was calibrated against experimental data by minimizing the mean absolute difference (MAD) between predicted and measured molecules through a genetic algorithm. Independent validation showed that the optimized model reduced MAD to 2.4%, against 34.4% for the non-optimized. Qualitative evaluation against literature knowledge revealed that the optimized network could reproduce OA reported molecular outcomes with 87% of accuracy. Our model could switch between a healthy and an OA state given the appropriate perturbations by local cytokines. Besides, an OA treatment based on anti-inflammatory cytokines was reproduced. Results were consistent with the reported study[4]: matrix degradation and pain mediators were reduced, but cartilage matrix was not restored, highlighting the challenge to reverse OA. Therefore, a high-level CC regulatory network that maps measurable cytokines was successfully developed. Guided network enrichment and topology optimization define a viable strategy to achieve a predictive cell regulation models, to explore mechanistically anti-degenerative therapies.Acknowledgments:HOLOA-DPI2016-80283-C2-1/2-R,RYC-2015-18888)+CatalanGovernment-FI.

Over the last decades, most of the strategies to improve the vascularization of biomaterials based on calcium phosphates (CaPs) are based on the incorporation of well-known proangiogenic agents, such as growth factors, despite their high cost and the complexity of delivering safe and effective doses [1]. A promising alternative is the use of inorganic elements that naturally occur within the body, namely metallic ions [2]. It has been shown that dissolution products of CaPs are able to induce vascularization [3,4], although the particular mechanism by which calcium stimulates this process is not very well understood, mainly due to the lack of suitable in vitro and in vivo models.

In this work, we present a microphysiological system (MPS) to study the role of calcium in neovascularization. The bone-healing microenvironment was mimicked by 3D-culturing bone marrow rat mesenchymal stem cells (BM-rMSC) and rat endothelial progenitor cells (rEPC) either in mono or co-culture conditions. Migration assays were performed in our proposed system, showing that calcium-enriched media (10 mM) is only able to elicit a strong migratory response on endothelial progenitor cells when they are in co-culture conditions. We also show that calcium exerts a potent chemotactic effect on BM-rMSC and induces an increase in the osteopontin (OPN) secretion, a protein involved in chemotaxis and immune regulation [5]. Therefore, we propose a novel mechanism by which calcium can stimulate endothelial progenitor cell recruitment and subsequent vascularization and open up new possibilities to test calcium-releasing biomaterials using MPS.

Background

Peripheral nerve injuries can lead to paralysis and chronic pain1. Tissue-engineered solutions use cells and biomaterials to improve peripheral nerve regeneration (PNR) without the drawbacks of the 'gold-standard' autograft 1–3. Aligned cellular collagen hydrogels using a range of cell types 4–7 support PNR. This may be improved by using Schwann cells (SCs) as they are key in the regeneration process8,9. Human iPSCs (hiPSCs) have been differentiated to SCs10 as human SCs are difficult to obtain and culture11,12. The aim of this project is to characterise and compare hiPSC-derived Schwann cells (SCs) with hiPSC-derived Schwann cell precursors (SCPs) in their ability to support peripheral nerve regeneration.

Methods

hiPSCs were expanded and differentiated into SCPs and SCs. RT-qPCR and immunocytochemistry (ICC) were used to characterise differentiated cells, with hiPSCs used as the control line. Viability and contraction assays of the cells in hydrogels were carried out.

Results

Oct4 gene expression significantly decreased between hiPSCs and SCPs, alongside Sox-10 significantly increasing. hiPSCs at high seeding density differentiated into SCPs expressing low levels of S100B. SCPs plated at low density differentiated further to SCs expressing high levels of S100B. These differentiated cells were positive for expression of SC markers Sox10 and P75. The differentiated cells had 80% viability in collagen hydrogels but limited ability to contract hydrogels.

Conclusions

Over 75% of differentiated hiPSCs expressed SC markers (mRNA and protein) and survived in collagen hydrogels. Neurite outgrowth assays and neurotrophic factor release will be compared to determine their ability to support peripheral nerve regeneration.

Macrophages contribute to the elimination of pathogens, and also serve other roles in wound healing, angiogenesis, and organ regeneration [1]. According to recent studies, macrophages are responsible for modulating fibrosis and scarring during wound healing [2-4]. The present study aims to compare the effects of different macrophages activation states on the regenerative behavior of vocal fold fibroblasts. To this end, THP-1 monocytes were differentiated into inactivated macrophages (M0) through exposure to 200 nm phorbol 12-myristate 13-acetate. Macrophages were polarized by treatment with 20 ng/ml interferon-gamma and 100 ng/ml lipopolysaccharide for inflammatory macrophages (M1), 20 ng/ml Interleukin-4 and 20 ng/ml Interleukin-13 or 20 ng/ml Interleukin-10 for two subtypes of anti-inflammatory macrophages (M2a and M2c). A 3D co-culture system using two well silicon inserts allowed the encapsulation of fibroblast and macrophages separately in gelatin-based hydrogels. After 21 days, most of the fibroblasts co-cultured with M1 fibroblasts adopted a rounded morphology and produced a very low level of collagen type I (col-I) and collagen type III (col-III). The M2a group possessed aligned fibroblasts with significantly higher α-smooth muscle actin and col-I production compared to the other groups. The observations confirmed the contribution of M2a to wound healing via fibrosis. The fibroblasts affected by M2c showed an elongated spindle-like morphology similar to the M0 group. They also showed increased production of col-III, which is characteristic of scar-free wound healing. The results illustrate the potential benefits of immunomodulation for promoting tissue regeneration.

Complex tissues are comprised of spatially arranged building blocks, which facilitate their collective behavior, enabling the existence of emergent properties that characterize the function of native tissues. In recent years, novel technological solutions have been sought to incorporate spatial complexity into engineered tissues. However, straightforward, scalable, and translatable solutions have remained wanted, to incorporate modularity in complex engineered living matter, especially those that are of clinically relevant size. Here, we propose engineered regulated single cell microgels as micro building blocks that can act as individually tuned voxels within a three-dimensional bulk system. Specifically, we exploited droplet microfluidics to encapsulate individual cells in biotinylated dextran-based microgels that could be further functionalized with moieties of interest via a cytocompatible and orthogonal crosslinking route. In bulk, these functionalizable single cell microgels formed a granular medium that could be processed via standard additive manufacturing approaches, thereby acting as tunable, printable, and living voxels. This approach effectively uncoupled the micro- and macro environment, which allowed the design space in which emergent properties can be created. Moreover, by selecting a biomaterial that allows on-demand biochemical and mechanical tunings, the substrate stiffness and composition of the microencapsulated cells could be controlled temporally. We demonstrated that this engineering strategy was compatible with additive manufacturing technologies such as bioprinting, which jointly offers novel and unique opportunities to engineer hierarchical structures that exhibit the collective behavior that drives the existence of emergent properties.

Biomanufacturing functional human tissues and organs derived from patient-specific cells is a grand challenge. Specifically, the cellular density and organ-specific microarchitecture within these engineered constructs must be replicated to ensure functional outputs akin to their native counterparts. An embedded network of perfusable vessels is also needed to efficiently supply oxygen and nutrients needed to sustain bulk tissues. Building upon recent advances in patterning vascular networks [1–4] and generating multicellular aggregates [5–7], we recently reported a new biomanufacturing method, known as sacrificial writing into functional tissue (SWIFT) [8], which enables the rapid fabrication of densely cellular (>100 M cells/mL), vascularized cardiac tissues. To create the desired multiscale vasculature, we complemented this method by promoting the bottom-up assembly of microvascular features. While this talk will focus on engineered cardiac tissue, our integrated biomanufacturing platform can be broadly applied to creating functional organ-specific tissues at therapeutic scales.

Craniomaxillofacial (CMF) defects remain a significant health concern. Current restoration of large CMF bone and tooth defects requires a two-staged surgical approach – bone repair followed by dental implant placement. The long-term goal of our research is to develop effective therapies for coordinated regeneration and functional repair of CMF defects that reduce surgical costs and patient recovery times. To achieve our goals, we tested a well-characterized tyrosine-derived polycarbonate scaffold, E1001(1K)-bTCP, for CMF repair in a critical sized rabbit mandible defect model. Our published results showed abundant jawbone formation using E1001(1K)-bTCP scaffolds seeded with human dental pulp cells (hDPCs), the ideal cell type for craniofacial bone and tooth regeneration. Here we further improved this approach using a modified E1001(1K)/dicalcium phosphate dihydrate (DCPD) scaffold supporting a dental implant. First, DCPD scaffolds with or without seeded hDPCs and HUVECs were cultured in osteogenic media for one week. A titanium (Ti) implant was screwed into each 10mm diameter x 6mm DCPD scaffold immediately before implantation. For each of 2 time points (1 and 3 months), 3 hDPC/HUVEC seeded and 2 acellular constructs were placed in full width, 10mm diameter mandibular defects, one per rabbit. MicroCT analysis was performed immediately after harvest, followed by histological and IHC analyses. Although ongoing, our preliminary analyses showed significant new bone formation in cell-seeded constructs, indicating the potential utility of hDPC/HUVEC seeded E1001(1K)-DCPD scaffolds for coordinated CMF bone and tooth regeneration.
These studies were supported by AFIRM2CF-04 W81-XWH-14-2-0004 (PCY) and NIH/NIDCR/NIBIB R01DE026731 (PCY).

Introduction: Osteochondral defects cause pain and disability in the human body. It is important to create a scaffold that mimics the cartilage and the subchondral bone as an alternative to reduce the risk of conventional treatment such as device failure, donor site morbidity, and host rejection to allografts. 3D printing is a method to fabricate a bilayer scaffold with an intricate structure that corresponds to the properties of each osteochondral layer. This study aims to develop a 3D printed bilayer scaffold to meet the requirement for osteochondral regeneration by using CSMA-2 for the bone layer and hydrogels as the candidate for the cartilage layer.

Methods: CSMA-2 scaffolds with gyroid design were printed by using Digital Light Processing (DLP) 3D printing method. MC3T3-E1 cells were seeded on the scaffold to evaluate its biocompatibility. In vitro metabolic activity, live cell visualisation, cell attachment, and spreading were analysed using Alamar blue assay, LIVE/DEAD assay, and SEM.

Results: The results showed that the gyroid structure with 400 µm pore size diameter was successfully printed by using CSMA-2 with the DLP 3D printing method. MC3T3-E1 cells remained viable after 14 days of incubation. The cells were found to attach and spread on the 3D printed scaffolds. The distribution of the cells also followed the gyroid architecture of the scaffold.

Discussion and Conclusions: CSMA-2 can be developed as bone layer material for the bilayer scaffold. This work will allow further development of the 3D printed biocompatible and functional scaffold with mechanical integrity, particularly under load-bearing conditions.

Context: The functionality of engineered corneal endothelium (ECE) is linked to the ability of the corneal endothelial cells (CECs) to form intercellular junctions. The purpose of this study is to assess the influence of intraocular pressure on the formation of intercellular junctions of CECs.Materials and methods: Cultured CECs were seeded on devitalized corneas and culture for 7 days to form ECE (n = 6 pairs). One of the ECEs was placed 7 days in a corneal bioreactor in the presence of a pressure of 16 mmHg, while the mate cornea was cultured without IOP. Morphology was assessed using cell circularity. The RNA was harvested, and gene expression of proteins associated with intercellular junctions was quantified by PCR. Results: IOP increased gene expression by 1.72 ± 0.31, 1.58 ± 0.41, 6.18 ± 1.03, 1.80 ± 0.71, 1.77 ± 0.55, 2.42 ± 0.71 for intercellular junctions related proteins gene GJA1, CDH2, TJP1, ITGAV, ITGB5 and CTNND1. CECs population circularity (0.66 ± 0.15, 0.77 ± 0.1, 0.62 ± 0.17, 0.82 ± 0.09, 0.74 ± 0.13 and 0.77 ± 0.12) correlated with the increase of mRNA transcription fold-change of TJP1and CTNND1, with r = 0,8305 for TJP1 and r = 0,5776 for CTNND1.Conclusion: These results indicate that the intraocular pressure increases the transcription of intercellular junctions-associated proteins. A better understanding of the genesis of CECs intercellular junctions can help to improve ECE functionality thus better tissue engineered corneas.

ECM-derived biomaterials are biologically advantageous for wound healing, tissue remodeling, and regeneration, due to the presence of many inherent biologic molecules. Despite these benefits, they lack sufficient compliance (inverse of stiffness, or the ability to stretch under minimal applied force) required to reconstruct a mechanically functional compliant-tissue. Moreover, due to the lack of a urine-resistive mechanism in these scaffolds, the surrounding tissues are prone to urine toxicity, especially during the initial days of tissue remodeling. Here, we present a transient crosslinking-based biomaterial strategy that leads to the development of bladder-like compliance without the covalent crosslinking, simultaneously reducing the urine leakage into the surrounding peritoneal cavity. The resulting biomaterials displayed superior stability towards enzymatic degradation and mimicked native tissue compliance more closely. Additionally, the developed biomaterials exhibit a pro-regenerative in-vitro and in-vivo immune signature without any significant fibrotic response. This is significant as chemical modification, such as covalent crosslinking, commonly used to alter mechanical properties of ECM-based scaffolds, can cause biomaterial immunogenicity. Bladder augmentation in rats indicates that the regenerated tissue support regeneration of all the bladder wall components with a significant reduction in susceptibility towards the urine-stone formation. Here we will also present our recent data on the mechanical functionality of the regenerated bladder tissue in terms of contractility and its relationship to the single-cell transcriptomics of the bladder tissue regeneration process.

Regenerative medicine (RM) represents a new area of knowledge in biomedical sciences. The interaction of RM and tissue engineering (TE), currently referred by the acronym TERM, has allowed to optimize the development of biomaterials for insertion of cells or different types of molecules. Propolis is one of the most well-known antibacterial and anti-inflammatory agents used by humans since ancient times. Recently, studies have evaluated the effectiveness of propolis associated with biomaterials for wound healing. Therefore, the aim of this study was to conduct a scientometric analysis of the published studies about the use of propolis for wound healing. The data was obtained from the sites SCOPUS and Web of Science by searching the terms “Propolis and wound healing” in title, abstracts and keywords. We found 275 documents and, after filtering, 113 articles were evaluated. The results show that researches involving the use of propolis for wound healing has grown in recent years and about 70% of the studies have been developed in the last decade. Brazil is the main country in research about this subject and medicine, pharmacology and biochemistry were the most related subject areas. Moreover, we observed a recent trend to the association of propolis with biomaterials, mainly films and hydrogels, resulting in a better efficiency in wound healing. In conclusion, the analysis evidenced that the use of propolis is a promising therapeutic alternative for wound healing, since the vast majority of studies have shown that treatment with propolis is significantly more effective than control.

Extracellular vesicles (EVs) are cell- derived lipid membrane nanoparticles that serve as messengers of intercellular communication, transferring bioactive molecules such as DNA, RNA, proteins and lipids to recipient cells. EVs have a natural therapeutic potential with high flexibility and biosafety for employing natural and synthetic biomolecules as therapeutic delivery vehicles. To get insights into the tissue-specific cargo in vivo for complete exploitation of EVs as therapeutic, biomarker and diagnostic tools, EV purification methods are critical. The aim of the study was brought about to develop an efficient EV purification method both in vitro and in vivo and to further investigate EVs as therapeutic targets in cellular senescence.

Firstly, to isolate tissue- specific EVs we developed Snorkel-tag based Extracellular Vesicle Affinity Chromatography (StEVAC). We systematically evaluated the purification of EVs harboring snorkel-tag by employing different methodologies. Our findings suggest that EVs harboring snorkel-tag indeed can be purified at high purity without altering EV characteristics and uptake. Furthermore, we expressed CD81-snorkel-tag under p16ink4a promoter and were able to purify EVs derived from senescent fibroblasts in vitro.

Finally, we are developing an in vivo model with recombinant CD81-snorkel-tag under p16ink4a promoter. This will provide us detail insights into the senescent cell derived EV cargo, allowing us to develop potential biomarker and therapeutic tools.

Summarized, we have here developed novel tool for studying content and function of EVs in the context of aging and disease. This will now pave the way for studying the molecular mechanisms underlying these EV functions in vivo.

In the human body several different flow conditions could be identified in the vascular tree, depending on the vessel type, vessel size and that to be supplied tissue. Current microfluidic systems often use ranges of those fluid flow forces which are not mimicking accurately those conditions or only include a small range of forces known in vivo. To understand which fluid flow forces could potentially benefit the formation of a vascular network in engineered tissues it is necessary to analyze with high accuracy the combinatoric effect of different wall shear stress and the interstitial fluid velocities. In the present study, authors have developed a microfluidic system to study the combinatoric effect of five different wall shear stress simultaneously with a uniform constant interstitial flow velocity through the used fibrin hydrogel to mimic the flow conditions in vivo. For studying the effect of mechanical signals and the angiogenic growth factor (VEGF165) on vascular network formation, human umbilical vein endothelial cells (HUVECs) and mesenchymal stem cells (MSCs) were encapsulated within the hydrogel. The results obtained from initial COMSOL modelling and experiments confirmed a high control about different combinations of wall shear stress and transmural flow. Furthermore, the formation of vascular networks could be observed promoted by the interstitial fluid and differences in their structures were analyzed by image processing.

DECELLULARIZED MAN-MADE HYALINE CARTILAGE GRAFT FOR CARTILAGE TISSUE ENGINEERING

Dongan Wang$_P$[1,2]

[1] *City University of Hong Kong*

[2] *Karolinska Institute Ming Wai Lau Centre for Reparative Medicine*

Corresponding author's email: dwang229@cityu.edu.hk

Introduction: The key challenge of lower-limb-joint osteochondral regeneration lies in restoration of the avascular articular cartilage. Articular cartilage repair has been a significant challenge due to the limited self-regenerative capability of cartilage tissue. A quality articular cartilage engraftment is validated by the graft's hyaline cartilaginous phenotype and genuine microstructural architecture. Current treatments are frequently reported to result in regeneration of mechanically inferior fibrocartilage.

Experimental methods: In this study, we have developed a continuous methodology to directly set up a scaffold-free macro-scaled three-dimensional living hyaline cartilage graft (LhCG) with the aid of a biomaterial-based interim scaffolding system. The practical performance of allogeneic decellularized LhCG (dLhCG) is evaluated in the knees of pig models with full-thickness chondral defects beyond critical sizes for 6 months.

Results and discussions: Sound regeneration of articular hyaline cartilage via allogeneic dLhCG engraftment in 6 months after implantation has been shown, including the recoveries in form and function with correct composition, structure, phenotype and mechanical property.

Conclusions: The successful regeneration of articular cartilage defects in large animal models suggests the readiness of allogeneic dLhCG for clinical trials and applications.

DISEASE MODIFYING TREATMENT OF SPINAL CORD INJURY WITH DIRECTLY REPROGRAMMED NEURAL PRECURSOR CELLS IN NON-HUMAN PRIMATES

Vladimir P. Baklaushev[P][1], Vladimir A Kalsin[1], Gaukhar M Yusubalieva[1]

[1] *Federal Clinical and Research Center, FMBA of Russia*

Corresponding author's email: serpoff@gmail.com

We have previously described the development of a model of evoked potentials guided complete SCI on NHP (Macaca mulatta) that we used in the current study with the goal of investigating the safety and efficacy of intraspinal transplantation of directly reprogrammed neural precursor cells (drNPCs). Seven NHPs with verified complete thoracic SCI were divided into two groups: drNPC group (n=4) was subjected to intraspinal transplantation of 5 million drNPCs rostral and caudal to the lesion site two weeks post injury, and lesion control (LC, n=3) was injected identically with the equivalent volume of vehicle. Follow-up for 12 weeks revealed that animals in the drNPC group demonstrated a significant recovery of the paralyzed hindlimb as well as recovery of SSEP and MEP of injured pathways. MRI data confirmed the intraspinal transplantation of drNPCs did not adversely affect the morphology of the CNS or cerebrospinal fluid circulation. Subsequent immunohistochemical analysis showed that drNPCs maintained Sox2 expression characteristic of multipotency in the transplanted spinal cord for at least 12 weeks, migrating to areas of axon growth cones. Our data demonstrated that drNPCs transplantation was safe and contributed to improvement of spinal cord function after acute complete SCI, based on neurological status assessment and neurophysiological recovery within 12 weeks after transplantation. The functional improvement described was not associated with neuronal differentiation of the allogeneic drNPCs. Instead, directed drNPCs migration to the areas of active growth cone formation may provide exosome and paracrine trophic support, thereby further supporting the regeneration processes.

Advancement in bone scaffolds that support mineralized tissue formation relies on biologically relevant animal studies. However, animal studies are cost-intensive and hardly scalable. Here, we present an in vitro bioreactor approach to monitor bone formation and mineralization in scaffolds under dynamic compression. Biomaterial processing of a resorbable polymer using a high-volume content of ultrasonically treated hydroxyapatite (HA) nanoparticles and a mixture with barium titanate (BT) was used to engineer mechanically competent bone scaffolds. The piezoelectric property of BT is attractive for tissue engineering due to its ability to deliver additional electrical stimulation under mechanical loading1. However, the high linear absorption property of BT requires advanced imaging protocols for comparison with other scaffold materials.The engineered scaffolds exhibited compressive moduli exceeding values of previous reports twofold, while maintaining their high porosity. After seeding with human bone marrow stromal cells, time-lapsed micro-CT imaging allowed longitudinal monitoring of scaffold mineral density (SMD), mineral volume and formation rates to assess the effect of cyclic loading on mineral maturation. After week 7, mineral volume in HA scaffolds under cyclic loading was 50% higher than under static conditions. Local bone formation rates corresponded to cell distributions. Longitudinal analysis of the SMD based on a single threshold showed a significantly higher maturation rate for scaffolds containing BT and HA under cyclic loading compared to static and to pure HA under dynamic or static conditions. This observation was corroborated by collagen and mineral stainings, suggesting scaffolds containing BT and HA as promising candidates for bone tissue engineering applications.

CONDUCTIVE ELASTOMERS FOR APPLICATIONS IN FLEXIBLE BIOELECTRONIC DEVICES

Estelle A. Cuttaz$_P$[1], Christopher A.R. Chapman[1], Josef A. Goding[1], Rylie A. Green[1]

[1] *Imperial College London*

Corresponding author's email: estelle.cuttaz18@imperial.ac.uk

Bioelectronic devices aim to stimulate and record neural activity to provide a therapeutic effect in neurological disorders [1],[2]. Conventional technologies utilise metals as electrode materials for interfacing with the nervous system. Metallic electrodes present serious limitations such as low charge injection limits [3] and high stiffness resulting in chronic inflammatory responses and scar tissue encapsulation. This ultimately hinders long-term device stability and performance. Soft, flexible fully polymeric bioelectronics have been proposed for addressing these limitations. This work explores the fabrication of soft and flexible polymer-based electrode arrays based on conductive elastomers (CEs). CEs are composites of poly(3,4-ethylenedioxythiophene) (PEDOT) and polyurethane elastomer. Flexible sheets of CEs with thicknesses ranging from 30 to 200 µm were produced by solvent casting dispersion of PEDOT particles within polyurethane, across varying PEDOT loadings. Electrochemical properties of the CE sheets were improved by increasing PEDOT content, resulting in lower impedance and increased charge storage capacities. Conductivities of CEs also improved with higher PEDOT amount, reaching up to 155.56 S.cm-1. In vitro cytocompatibility was assessed by cell growth inhibition assays. Bioelectronic device fabrication was done by laser micromachining the CE sheets and insulating with polydimethylsiloxane to produce flexible bipolar nerve cuff arrays. CE cuffs were able to stimulate ex vivo rat sciatic nerves and showed improved electrochemical performance over commercial metal-based cuffs. Overall, CEs resulted in a machinable and flexible conductive material. The fabrication of functional bioelectronic devices suggests that CEs are a promising alternative to metal-based bioelectronics with the potential for better chronic functionality.

Autologous blood-derived products are known to be involved in musculoskeletal regeneration by promoting cell proliferation and modulating inflammation (1-3). By altering the cell-hostile microenvironment we are pursuing to stop or even reverse the degenerative process in the joints of osteoarthritic patients. Hyperacute serum is a blood-derived product that retains the regenerative potential of platelet-rich plasma (PRP) overcoming its variability disadvantages (4,5). Hyperacute serum is obtained by squeezing a fibrin clot; its composition has been compared to PRP showing that it better resembles cellular and molecular concentrations of in vitro and in vivo samples (6). To expand the potential therapeutic use, a new formulation method was established. The stable, sterile, antibody-deprived freeze-dried format enables allogenic therapy with a highly regenerative and standardized blood product. Our aim is to test its regenerative capacities in the context of osteoarthritis alone and in combination with hyaluronic acid (HA). Two-dimensional cultures of primary chondrocytes were used for XTT viability analysis showing that hyperacute serum or its combination with HA supports cell growth comparable to the gold standard fetal calf serum. Moreover, gene expression of genes involved in extracellular matrix maintenance (aggrecan, collagen type II, metalloproteinases 3 and 13), together with inflammatory and chondrogenic markers are quantified. Confocal microscopy of 3D chondrogenic cultures are used together with histology to better understand the regenerative potential of hyperacute serum. We conclude the combination product retains the regenerative potential of both components, ie. the blood derivative and hyaluronan, and serves a potential new therapeutic modality for degenerative joint disesases.

Bone's inherent piezoelectricity is a key factor in guiding mesenchymal stem cells (MSCs) differentiation towards the osteogenic lineage. Piezoelectric polymers, such as poly(vinylidene fluoride) (PVDF), combined with magnetostrictive nanoparticles (MNPs) provide a suitable approach for MSCs electro-mechanical stimulation. When applying an external magnetic field, MNPs deform, deforming the polymer and varying the surface charge due to the piezoelectric effect. Our approach is based on a 3D cell culture platform consisting of a gelatin hydrogel with embedded MSC and PVDF microspheres, with and without cobalt ferrite oxide (CFO) nanoparticles.Microspheres were produced by electrospray technique, favouring the presence of around 85 % of beta-phase, the most electroactive one, and a crystallinity degree around 60%, in both PVDF and PVDF-CFO microspheres. PVDF-CFO microspheres presented a 9% (w/w) content of MNPs.Absence of cytotoxicity of the 3D construct was studied by means of a live-dead assay after 24 hours. No significant differences in viability were observed, using a gelatin hydrogel as control. MSCs proliferation, in static and dynamic conditions, was studied by means of MTS assay up to 7 days. MSCs were able to proliferate in the 3D constructs in both situations and the presence of the magnetic field enhanced proliferation in the environments containing microspheres.These findings lead the way for future approaches in bone tissue engineering using a 3D piezoelectric environment to induce the osteogenic differentiation of MSCs.Acknowledgements: Spanish State Research Agency (AEI) (including Feder funds) PID2019-106099RB-C41 and -C43 / AEI / 10.13039/501100011033 projects and BES-2017-080398 FPI grant are acknowledged.

Viruses are recognized as the most efficient transfection vectors available for gene therapy. However, they are immunogenic and cytotoxic. As alternatives, several types of non-viral vectors have been developed. Among them, dendrimers are an attractive choice that promises high transfection efficiency, low toxicity, and fast body elimination. The aim of this work was to investigate different generations polyamidoamine (PAMAM) dendrimers for gene delivery to human cells. We prepared different dendriplexes formulations using generations from G4 to G7 of PAMAM dendrimers and eGFP and metridia luciferase (MetLuc) DNA plasmids. Variables such as charge ratio (N/P), complexation time, the solvent used for complexation, and incubation time were optimized. HEK 293 and NIH 3T3 cells were successfully transfected with obtained dendriplexes and the transfection efficiencies and cytotoxicity were assessed. The maximum level of expression was achieved at 48 hours post transfection for all tested dendriplexes. PAMAM G4 and G5 and high N/P ratios (1:25 and 1:50) yielded the highest transfection efficiency. LDH assay revealed good biocompatibility of all tested dendriplexes, with values of cell viability higher than 94% at 72 hours post-transfection.
Our results illustrate the potential of G4 and G5 PAMAM dendrimers as non-viral vectors for gene transfer into human cells.

Several studies are aimed at developing systems based on natural and biocompatible polymers for bone tissue engineering. Here, we emphasized how the bio-activation of chitosan (CS)-based scaffolds by organic and inorganic signals is able to promote osteogenesis, angiogenesis and to modulate the inflammation response by using in vitro models to mimic bone fracture microenvironment. CS scaffolds by using two different approaches based on inorganic and organic compounds, were bio-activated respectively1. The expression of inflammatory mediators was investigated (TGF-β and IL-6). Additionally, to assess the effect of CS scaffold on angiogenesis, CD31 expression, cell adhesion, proliferation, migration and tube formation by HUVECs were detected. The results highlighted that inorganic and organic signals promote cell proliferation and differentiation without significant differences between the material groups. In particular, scaffolds bio-activated by using inorganic signals (hydroxyapatite nanoparticles) inhibit pro-inflammatory mediator's production (IL-1β and IL-6), induce anti-inflammatory cytokine generation (IL-10) and reduce nitric monoxide metabolites (nitrites). Conversely, scaffolds bio-activated by using organic signals (BMP-2 mimicking peptide) were able to decrease pro-inflammatory markers without any effect on anti-inflammatory cytokines levels and on nitrites. Furthermore, scaffolds promote angiogenesis by increasing cell proliferation, migration and tube formation with best results obtained for BMP based-scaffolds. Our results support the concept that CS biomaterials may be novel multi-target devices to treat bone related inflammation stimulating neo-vascularization of tissue-engineered constructs.

INTRODUCTION: Brachytherapy is the most advanced radiotherapy strategy for the local treatment of prostate cancer and it consists in the placing of radioactive sources closed to the tumour side thus killing cancer cells. However, brachytherapy causes the same adverse effects of external-beam radiotherapy [1]. Therefore, alternative treatment approaches are claimed for enhancing radiotherapy effectiveness and reducing side effects. Nanostructured exfoliated black phosphorus (2D BP) represents a novel strategy for local cancer therapy because of its ability to induce singlet oxygen production and act as photosensitizer [2]. Hence, we evaluated 2D BP in vitro effect on healthy and cancer prostate cell behavior.
METHODS: 2D BP was obtained through liquid exfoliation. 2D BP effect on healthy and cancer prostate cell behaviors was analyzed by investigating cell viability, oxidative stress and inflammatory marker expression.
RESULTS: 2D BP inhibited prostate cancer cell proliferation, meanwhile promoted healthy prostate cell survival in vitro by modulating oxidative stress and immune response with and without near-infrared light (NIR)-irradiation.
CONCLUSIONS: Nanostructured 2D BP is able to inhibit in vitro prostate cancer cell survival and preserve healthy prostate cell vitality by controlling oxidative stress and immune response.

Microorganisms can often adhere to biomaterials forming biofilms on foreign bodies. The incorporation of IL in biomaterials (i.e. synthetic or natural polymers1) allows to obtain innovative biocompatible materials able to inhibit biofilm formation. In the present work, the effect of IL incorporated in polymer materials on cell response (cell adhesion, proliferation and inflammation reaction) was investigated.

Biocomposites based on polymers and IL [CnMIm]Cl were prepared at different compositions. The polymers (i.e. chitosan, PLA, HDPE) were dissolved in appropriate solvent and the IL [CnMIm]Cl solution with different chain-lengths at different concentrations (0.125, 0.250, 0.500 and 2.00 wt%) was added. The films obtained were characterized to evaluate the biological properties by using murine fibroblast cell line (L929) and human Mesenchymal Stem Cells (hMSC). The cell–material interaction in terms of cell biocompatibility and inflammation reaction was analyzed.

Results on cytotoxicity demonstrated that composites could be used as polymers for biomedical applications. The effect of the polymer-based biomaterials with different contents of ILs on hMSC behavior has confirmed a good biocompatibility. The study suggested that ILs incorporated in polymers provides access to biomaterials promising for the development of medical devices.

INTRODUCTION: Actually, osteoporosis standard therapy consists in the systemic administration of biphosphonates and anti-inflammatory drugs, which cause several side effects [1]. In this scenario, the development of injectable materials loaded with therapeutically active agents could represent an effective strategy for locally treating bone loss and inflammation related to musculoskeletal diseases [2]. Here, we developed three different compositions of injectable Calcium Phosphates (CaP) as new carrier materials of therapeutic compounds such as bisphosphonates (i.e. Alendronate), anti-inflammatory drugs (i.e. Diclofenac) and natural molecules (i.e. Harpagoside), for the local bone disease treatment.
METHODS: Biological quantitative analyses were performed for screening osteoinductive and anti-inflammatory properties of injectable drug-loaded systems. Meanwhile, cell morphological features were analyzed through SEM and confocal investigations.
RESULTS: The results exhibited that the three systems (Alendronate-loaded CaP, Diclofenac-loaded CaP and HR-loaded CaP) exerted osteoinductive effect during later phases of osteogenesis. Simultaneously, all compositions showed an anti-inflammatory activity on inflammation in vitro models.

CONCLUSIONS: In conclusion, the three systems displayed beneficial osteogenic and anti-inflammatory properties in vitro, thus representing a multi-target strategy for the local therapy of inflammation and bone loss determined by osteoporosis.

The rapid establishment of antibiotic resistance in bacteria demands new therapies for the treatment of wound infections. A promising option is the combination of light with a photoreactive substance termed antimicrobial photodynamic therapy (aPDT). In this study the effectiveness of aPDT was tested as a treatment option for polymicrobially infected wounds in a new developed infection model.

A new pre-clinical wound healing model was established in immunocompromised BALB/c mice based on fecal bacteria. PDT was applied twice within 24h using 100 µM methylene blue (generally regarded safe for topical application on human skin) and 24 J/cm2 pulsed red LED light (Repuls). The effects of aPDT were analyzed by selected quantitative methods for wound analysis like wound area, wound score, microbiological analysis and imaging techniques.

Polymicrobial infection significantly delayed wound healing leading to larger and slower closing wounds. A newly established wound score, assessing the severity of wounds and the establishment of infection based on clinical monitoring, confirmed the infection-induced delay in wound healing. Wound healing of infected wounds was drastically enhanced by aPDT treatment with methylene blue.

Wound infections are challenging for patients and nursing staff, but also for medical research, especially with the increasing incidence of multidrug-resistant bacteria. The new model presented in this study with appropriate analysis tools provides the means to investigate complex microbiological interactions and new therapy approaches. Our data suggest that aPDT has the potential to significantly improve wound healing also in complicated polymicrobially infected wound situations.

Human pluripotent Stem Cells (hPSC) have an enormous potential as a source for cell replacement therapies, tissue engineering, and in vitro toxicology applications. The lack of standardized and robust bioprocesses for their expansion and analytical tools for their characterization has hindered the application of PSC in clinical settings and as alternative cell sources for in vitro cell models used in pre-clinical research [1]. Bioengineering approaches exploiting the potential of 3D cell culture models and scalable perfusion bioreactor technology for the production of hPSC will be discussed together with the application of -omic tools for characterization of the cell-based products [2,3]. A focus will be given to integrative approaches that allow the identification of metabolic hallmarks to support bioprocess developmentResults concerning the establishment and refinement of culture systems for efficient stem cell differentiation and maturation into cardiac, neural and hepatic cells, as well as their applicability for long-term toxicity testing will be presented.

The combination of controlled growth factor delivery and physical support for cell growth onto biodegradable three-dimensional scaffolds (3D) established a notable change in the tissue engineering field. The objective of this work was to develop an electrospun 3D scaffold with the capability of controlled release of recombinant human bone morphogenetic protein-7 (rhBMP-7) for enhancement of bone tissue regeneration. Here, the rhBMP-7 protein was loaded to the surface of 3D PCL scaffold coated by the Layer-by-Layer (LbL) technique, with heparin and chitosan as the polyelectrolyte pair [1]. The physicochemical properties, such as surface morphology, functional group, thermal properties, and wettability of these protein reservoirs, were examined using different techniques, such as SEM, FTIR, TGA, contact angle measurement, and immunofluorescence. No changes in morphology and porosity of the fiber mat were observed upon LbL growth. The hydrophobic PCL surface was rendered hydrophilic upon the addition of polyelectrolytes, with protein coating over the surface. PCL coating with 50 ug/mL rhBMP-7, along with polyelectrolytes, was confirmed by immunofluorescence. The in vitro release profile of rhBMP-7 indicated an initial burst release, followed by a controlled release, measured by ELISA. Pre-osteoblastic C2C12 cells were cultured on scaffolds constructed with rhBMP7 reservoirs to assess cell attachment, proliferation, and differentiation under in vitro conditions. In vivo, rhBMP-7 delivered from electrospun scaffolds induced significant new bone formation. Therefore, this study presents a new approach to control both the loading and unloading of signaling proteins from biodegradable implants at infected tissue sites.

In tissue engineering, miniature Electrical Impedance Tomography (mEIT) is an emerging tomographic modality that contributes to non-destructive and label-free imaging and monitoring of 3D cellular dynamics [1]. It visualises the cross-section conductivity distribution within the Region of Interest (ROI) by measuring differential voltages on the boundary. The main challenge of mEIT comes from the nonlinear and ill-posed image reconstruction problem, leading to the increased sensitivity to imperfect measurement signals [2]. Physical model-based image reconstruction methods [3-7] have been successfully applied to conventional setup, but are less satisfying for the mEIT setup in terms of image quality, conductivity retrieval and computational efficiency. Learning-based methods are a new frontier of EIT image reconstruction, which have been investigated on single-level conductivity variation between the homogeneous background and imaging objects [8,9]. However, in practice, continuous, multi-level conductivity variations have wider presence in 3D cell culture imaging. In this paper, we propose a deep learning and physical model based hybrid image reconstruction framework to enable high-quality cell culture imaging with mEIT. We validate our approach by imaging 3D cancer cell spheroids (MCF-7). Our method can be readily translated to spheroids, organoids culture and cell culture in biomaterials scaffolds. As the measured conductivity is a proxy for cell viability, mEIT has a great potential to enable non-invasive, real-time, long-term monitoring of 3D cell growth, opening new avenues in regenerative medicine and drug testing.

For the correction of congenital defects, the removal of oral tumours and the reconstruction of the head and neck region, the surgeon is usually limited with devices available to restore both function and appearance for the patient. With the ever-increasing demand for low-priced efficient facial implants, there is an urgent need to advance new manufacturing approaches and implants with a higher osteointegration performance. Three-dimensional (3D) printing has the ability to enhance the production of on-demand fabrication of patient-specific devices as well as anatomically fitting implants with high complexity in a cost-effective manner. In recent years, the use of additive systems that employ vat photopolymerization such as stereolithography (SLA) and digital light projection (DLP) have been used widely in the field of biomedical science and engineering. However, additive manufacturing methods can be limited by the types of materials that can be used. In this study, we present an isosorbide-based formulation for a polymer yielding a range of elastic moduli between 1.7-3 GN/mm2 dependent on the photoinitiator system used as well as the amount of calcium phosphate filler added. The monomer was prepared and enhanced for 3D-printing using an SLA technique that delivered stable and optimized 3D- printed models. The resin discussed could potentially be used following major surgery in replacement of current materials and techniques used.

VARIABILITY OF EXTRACELLULAR VESICLES DERIVED FROM MESENCHYMAL STROMAL CELL CLONAL SUBPOPULATIONS: IMPLICATIONS FOR CLINICAL USE

Savvas Ioannou[1], Andrew Stone[1], David Kuntin[1], Chris MacDonald[1], Paul G. Genever[1]

The use of extracellular vesicles (EVs) as acellular alternatives to cell-based therapies demands a defined EV population with a consistent bioactive cargo. Mesenchymal stem/stromal cells (MSCs) are an attractive source for therapeutic EVs, but they are highly heterogeneous which questions the quality and reproducibility of the EVs they produce. We have identified a biomarker (CD317) that discriminates human MSC subpopulations with regenerative properties (CD317-) from differentiation-incompetent/pro-inflammatory MSCs (CD317+). We investigated the morphological features, protein/miRNA content and functional activity of EVs isolated from CD317- and CD317+ clonal MSCs to help define appropriate therapeutic routes.
EVs isolated from CD317- and CD317+ MSCs by ultracentrifugation (100K fraction) had broadly similar peak average sizes (nanoparticle tracking analysis) and morphological characteristics (diameter, perimeter, area, roundness; TEM image analysis). However, using LC-MS/MS we identified a significantly enhanced EVome in CD317- compared to CD317+ MSCs (68 versus 2 upregulated proteins, $p<0.01$), and NanoString miRNA quantification identified 9 significantly upregulated ($q<0.05$) miRNAs in CD317- MSCs versus 2 in CD317+ MSCs. Bioinformatic analysis of proteomic and miRNA target data demonstrated functional links to cell migration/matrix interactions in the CD317- population, with a specific enrichment for PI3K-Akt signaling compared to CD317+ MSCs. We showed by fluorescent tracking that CFSE-labelled EVs from CD317- regenerative MSCs were taken up by primary MSCs and stimulated cell numbers (1.4-1.8 fold change compared to controls, n=3 biological replicates) determined by alamarBlue quantification.
These findings demonstrate the need to develop acellular regenerative therapies using defined EV populations and cell sources to optimise clinical outcome.

INTRODUCTION: Myocardial infarction (MI) is an ischemic and inflammatory event majorly orchestrated by macrophages from infiltrating monocytes (1). These macrophages play a critical role in deciding the fate of the heart post-MI (2). However, there is no cardiac disease model in existence that incorporates an appropriate inflammatory environment. Hence, the aim of this project is to develop a humanised model of MI, using induced pluripotent stem cell (iPSC) derived cardiomyocytes together with inflammatory cytokine stimulation, to model the disease environment. The first objective of this project is to obtain immune cell-conditioned media for stimulating cardiomyocytes, followed by developing a hydrogel platform to model MI.

METHODS: In order to achieve the first objective, iPSCs were expanded and cultured on different platforms such as ultra-low attachment plates (ULA), agarose microwell plate (AP) and Aggrewell plate (AW) to identify optimal conditions for differentiating them into immune cell lineages.

RESULTS: ULA, AP and AW plates successfully facilitated embryoid body (EB) formation. The sizes of EBs were more uniform in AP and AW as opposed to ULA.

DISCUSSION & CONCLUSIONS: Comprehensively, according to the preliminary data, ULA, AP and AW facilitate EB formation and differentiation into immune cell lineages. In order to determine the ideal hydrogel candidate for modelling MI, collagen-matrigel and collagen-fibrin hydrogels are being studied.

ACKNOWLEDGEMENTS: The authors acknowledge SFI for the funding (18/EPSRC - CDT/3583) and lifETIME CDT.

Preclinical models are often unable to faithfully recapitulate human physiology. Organ-on-a-chip platforms that are being developed to overcome these shortcomings remain limited by their dependence on materials that are highly absorbent to drugs. We report the design and utilization of a novel, integrated, open setting, drug-binding free, tumor-heart tissue platform that allows for simultaneous assessment of the efficacy and cardiotoxicity of anti-cancer drugs. Previously, we established bioengineered human tissue models of Ewing sarcoma (ES) and cardiac muscle: the former recapitulated critical tumor microenvironmental phenotypes, while the latter emulated aspects of adult-like cardiac physiology and function. The two bioengineered tissues were studied in isolation and in the integrated platform following administration of linsitinib, a chemotherapeutic recently evaluated in clinical trials, according to the 3 week-long clinical regimen. Only the engineered tumor tissues, and not monolayers, recapitulated the clinically-relevant differences in drug responses between non-metastatic and metastatic ES tumors. More importantly, the responses of non-metastatic ES tissues and heart muscle to linsitinib were much closer to those observed in the clinical trial for tissues cultured in the integrated platform than those in isolation. Specifically, drug treatment of isolated tissues showed decreases in tumor viability and increases in both proarrhythmic events and beat frequency not seen in patients. Meanwhile, drug treatment via circulation in the platform showed poor tumor response and significantly milder cardiotoxicity, which matched the results of the clinical trial. Overall, the integration of the tissues in the platform improved predictive accuracy for both the direct and off-target effects of linsitinib.

Ischemia/reperfusion (I/R) injury, caused by acute kidney damage, causes histopathological alterations, tubule cell apoptosis, inflammation, oxidation, and loss of renal function. We evaluated the protective effects against IR injury of beluga lentil pretreatment. Mice were divided into four groups: normal, untreated, low- and high-dose beluga lentil treatment groups. Beluga lentil was orally administered for 2 weeks, followed by bilateral renal ischemia for 20 min and reperfusion for 30 min. Blood and kidneys were collected and analyzed to investigate renal function, histopathology, epithelial and endothelial cell damage, apoptosis, oxidative stress, and inflammatory responses. The pretreated groups maintained renal function, with significantly lower blood urea nitrogen (BUN) and creatinine levels, compared with the other groups. The histopathological analysis showed reduced proximal tubule injury and decreased injury-related molecule (KIM-1 and NGAL) secretion in the pretreated groups compared with the other groups. TUNEL-positive cells and the secretion of apoptosis-related molecules (Fas and caspase-3) was significantly reduced in the pretreated groups compared with the other groups. The pretreated groups showed positive microvessel-associated gene (CD31) expression and negative adhesion molecule (ICAM-1) expression. An antioxidant effect was observed in the pretreatment groups, with reduced malonaldehyde (MDA) expression and increased antioxidant enzyme (SOD, CAT, GSH, and GPx) secretion. In the pretreated groups, F4/80+ macrophages and CD4+ T cell infiltration were inhibited and pro-inflammatory cytokine (IL-1β, IL-6, and TNF-α) levels decreased; however, the levels of anti-inflammatory cytokines (TGF-β, IL-10, and IL-22 increased. Beluga lentil pretreatment demonstrated protective effects against IR induced renal damage, via anti-apoptotic, anti-inflammatory, and antioxidant activities.

Tissue transitions like tendon bone junctions (enthesis) consist of a variety of features including gradients of properties with specific characteristics e.g. in structure as well as in composition and mechanical characteristics. At present there are limitations of implants with respect to such notably inhomogenous materials. Electrospun poly (ε-caprolactone) (PCL) fiber mats may be considered as a promising material for this kind of tissue engineering. They can be hydrophilized for cyto- and biocompatibility, e.g. by modification with a chitosan graft with PCL. This allows further modifications by nanoparticular drug-delivery systems. In order to achieve a controlled delivery of bioactive factors such as drugs or proteins to a specific region in vivo, nanoparticles are a promising option. Here we used chitosan/tripolyphosphate nanoparticles loaded with recombinant (E. coli) human TGF-β3. The transforming growth factor superfamily, including TGF-βs and BMPs, is involved in various cellular processes such as proliferation, differentiation and development. The release of TGF-β3 from the nanoparticle-coated fiber mats induced chondrogenesis in human bone marrow-derived mesenchymal stromal cells (MSCs). These findings make modified fiber mats in combination with the release of relevant factors a promising candidate for implants bridging complex tissue transitions.

Dexamethasone is commonly used to induce osteogenic differentiation of bone marrow mesenchymal stromal cells (BMSCs). However, the rationale for its use is not clear considering that dexamethasone is also employed for chondrogenic and adipogenic differentiation, it is known to have a strong adipogenic effect, and its use both in vitro and in vivo is associated to reduced mineralization and maturation of osteoblasts. This work aimed then to clarify the role of dexamethasone during in vitro osteogenesis.

Human BMSCs were induced to osteogenic differentiation using a combination of concentrations of dexamethasone and time points of exposure. Biochemical characterization and gene expression analysis showed that the presence of dexamethasone on one side repressed SOX9 expression (hence improving osteogenic differentiation), but also increased PPARG expression with consequent development of pre-adipocyte-like cells within mineralizing cultures. RUNX2 expression was unaffected by dexamethasone, contrarily to previous reports.

Based on these results, we have introduced dexamethasone in a computational model describing the interaction between RUNX2, SOX9, and PPARG [1]. Thus, we used approximate Bayesian computation (ABC) simulations to estimate the parameters of the theoretical model that best fit the experimental measure of the activity of the three transcription factors. The simulations successfully reproduced the trends that were observed experimentally. However, the simulations also predicted a lower RUNX2 activity compared to experimental gene expression data, indicating that further signalling components are necessary for a better convergence of the model to the experimental observations.

LOW-DENSITY LIPOPROTEIN RECEPTOR-RELATED PROTEIN 1 PLAYS A KEY ROLE IN CHONDROCYTE DIFFERENTIATION AND PROLIFERATION

Wenjin Yan[P][1]

Low-density lipoprotein receptor-related protein 1 (LRP1) is expressed at a high level in articular chondrocytes, and the articular chondrocytes and synoviocytes in osteoarthritis have decreased amounts of LRP1 [1-3]. However, the underlying mechanisms and functional consequences for disease development remain poorly understood.

We identify extensive rare LRP1 variants in 126 severe developmental dysplasia of the hip (DDH) patients. By combining a WES high-throughput analysis with a comprehensive DNA screening, we targeting 16 rare LRP1 variants. By establishing a mouse line with Lrp1 gene knock-out mice via CRISPR-Cas9 System and blocking Lrp1 by using shRNA treatment in ATDC5, we discover an unexpected critical role for Lrp1 influencing chondrocyte differentiation and proliferation.

We evaluated the expression of chondrogenic differentiation markers by using real-time PCR and western-blot in ATDC5 on day 7, 14, 21. Sox9, Runx2 and Col2a1 was significantly decreased in Lrp1 knock down group. And after the day 28, proliferation of chondrocytes was also significant decreased. Lrp1 gene knock-out mice tends to grow with smaller acetabular volume and the “Y” cartilage closes earlier. The change of acetabular morphology will caused the decrease of acetabular volume which will lead to the increase of local stress on the articular surface and increase the instability of the hip joint.

Taken together, our results suggest that LRP1 plays a key role in chondrocyte differentiation and proliferation.

During Clinical Islet Transplantation (CIT) donor islets are transplanted via the portal vein and transfused into the hepatic vasculature. Although the liver is still considered the best-case scenario, the efficiency of this procedure is low because of allo- and autoimmune reactions, and risky due to the use of systemic immunosuppressive therapy. We report on the development of an immunoprotective macroencapsulation device for islets to omit the use of immunosuppressive drugs.

Thin and porous membranes were produced by a customized automated solvent-non solvent casting method from polyvinylidene fluoride (PVDF) in dimethyl-acetamide (DMA) and optionally supplemented with a water-soluble factor, polyvinylpyrrolidone (PVP). Encapsulation devices are made by fixating two membrane sheets. The membrane characteristics were determined by analyzing diffusion kinetics of different relevant molecules such as glucose. Immunoprotective properties were confirmed in both membranes with a macrophage migration assay. Human islets were cultured for 7 days inside the devices. The islet viability remained high over time in all conditions with viability over 90%. Islet function was assessed with a glucose-stimulated insulin secretion assay. Inside the devices, islets responded to changing glucose levels by releasing insulin, quantified by the stimulation index being larger than 2. PVDF/PVP devices had a higher stimulation index compared to PVDF devices.

We conclude that PVDF/PVP devices outperform PVDF devices with respect diffusion and the islet stimulation index. The immunoprotective PVDF/PVP device has the potential to improve the efficiency of current CIT.

To meet the growing demand for engineering relevant materials with a functional vasculature, the cliché of a multidisciplinary field was never so required as today. Inspired by biology, chemistry and engineering approaches, we herein propose the development of a magnetoenzymatic carrier system to sculpt a topographical patterning that resembles the native vasculature within laminarin hydrogels. For that, magnetic nanoparticles were prepared and entrapped into a poly-L-lactic acid (PLLA) shell for the development of the magnetic microcarrier system.[1][2] The enzyme laminarinase, which is able to degrade laminarin, was further immobilized in the PLLA shell via aminolysis and glutaraldehyde coupling reactions, respectively.[3] Physicochemical characterization of magnetite PLLA microparticles (m-PLLA) revealed a spherical particle shape and a size ranging from 15-40μm, which is consistent with the physiological size of small vessels. Additionally, XRD diffractograms confirmed the successful entrapment of the magnetite in the PLLA shell, and its magnetic properties demonstrated a superparamagnetic behaviour with a value of saturation magnetization of 3.7emu/g. The efficacy of enzyme-functionalized m-PLLA was assessed using the Bradford assay and its enzymatic activity by the 3,5-dinitrosalicylic acid (DNS) method. Regarding the sculpture process, the effect of magnetoenzymatic degradation on triggering channel-like topographies was assessed through confocal imaging. In the future, stem and endothelial cells will be seeded on the exposed construct, aiming to expedite a new therapeutic strategy towards bone repair. We acknowledge the FCT project “PROMENADE”-PTDC/BTM-MAT/29830/2017, the doctoral grant SFRH/BD/146740/2019 and the project CICECO-Aveiro Institute of Materials, POCI-01-0145-FEDER-007679 (UID /CTM /50011/2013).

Multipotent mesenchymal stromal cells (MSCs) are promising in adipose tissue engineering. However, little is known about the efficiency of adipogenic differentiation depending on the cell source. The clinical application of MSCs for adipose tissue engineering requires the use of xeno-free supplements, but their effect on adipogenic differentiation is not fully revealed. Here, we describe the comparative analysis of the efficiency of adipogenic differentiation of MSCs from human adipose tissue (AT) and Wharton's jelly (WJ) in media containing human derived supplements – human platelet lysate (PL), human serum albumin (HSA) or human serum (HS).
Human WJ and AT-MSCs were obtained according to ethical guidelines and expanded in the presence of 5% PL. Cells were differentiated in adipogenic lineage, using conventional inducers, different concentration of glucose (5 and 25 mM) and either FBS, PL or HSA as supplements (5%). The efficiency of adipogenic differentiation was assessed by Nile Red staining and quantification using Tecan Infinite 200 Pro reader.
The efficiency of adipogenic differentiation was remarkably higher in AT-MSCs compared to WJ-MSCs, in all studied conditions. The absence of medium supplement minimized the adipogenic differentiation of AT- and WJ-MSCs. The supplementation of differentiation medium by PL significantly lowered the efficiency of adipogenic differentiation of MSCs from both sources. However, the use of HSA or HS can be used as a xeno-free supplement, providing efficient adipogenic differentiation of MSCs for clinical applications. The MSC adipogenesis in xeno-free conditions was further confirmed in 3D collagen based scaffolds.

Corresponding author's email: c.chapman@imperial.ac.uk

Non-resectable glioblastoma multiforme is an untreatable brain cancer with treatment options limited to radiotherapy and systemic chemotherapy. Treatment with localised delivery of chemotherapy has seen limited clinical use due to diffusion limitations and increased intracranial pressure[1]. Ionic drug delivery has the potential to mitigate these challenges by delivering chemotherapy without the use of a liquid carrier[2]. This mode of delivery causes no increase in the volume to the surrounding tissue and therefore can improve bioavailability of chemotherapeutic drugs at the tumour.

Conductive elastomers (CE) consisting of a dispersion of a doped conducting polymer poly(3,4-ethylenedioxythiophene) (PEDOT) in polyurethane[3] demonstrate promise as a unique platform for ionic drug delivery. To evaluate the efficacy of a CE-based platform, release profiles of both positively and negatively charged drug analogues were investigated. The voltage-driven release of the small molecule drug analogues methylene blue (MB) and fluorescein (FITC) were investigated over a range of applied voltages. Maximum increases in release were found to be a 5.4-fold increase at +0.5 V for MB and a 3-fold increase at -3 V for FITC.

Using these voltages, the release of charged chemotherapeutic molecules doxorubicin and cisplatin was quantified. Clinically relevant concentrations of both drugs ranging from 1 – 100 µM were achievable through voltage application. Experiments are underway to confirm the active anti-cancer effect of the device in vitro. This technology constitutes a significant step forward in bioelectronics-based cancer treatments and shows promise for ease of translation into clinical use to improve the outcome of patients with non-resectable GBM.

Magnetic cell targeting represents a promising approach in medicine for several applications (e.g. cell therapy, tissue engineering). The goal is to guide the cells, in a precise way, in a 3D environment to achieve a better and most rapid organ/scaffold colonization, and/or loss less cells. Considering the importance of vascular network in reproducing predictive in vitro models such as thyroid organ, we focused our research in the design and the optimization of a protocol to obtain magnetic endothelial cells that can be finely guided and localized by an external magnetic field during the 3D printing process. For this aim we designed novel iron-doped hydroxyapatite nanoparticles (FeHA NPs), fully biocompatible and bioreasorbable nanoparticles, and we verified their behavior once internalized by the cells. In details human umbilical vascular endothelial cells (HUVECs) were culture with 100 µg/ml FeHA NPs, and commercial magnetic particles (SPIONs) were used as control. We successfully defined a magnetic labelling protocol. This protocol permits to obtain magnetic cells that can be moved by a static magnetic field application (450 mT). Magnetic HUVECs could be used to enhance the vascular network formation, in order to obtain an advanced 3D scaffold where thyroids cells could be seeded. In this way we could achieve a predictive thyroid model for the final screening of the endocrine disruptors.

The incidence of osteoarthritis (OA) is higher in women than in men. Sex as a variable is rarely considered in animal studies and in vitro experiments of OA[1-3]. There is a need to incorporate both male and female subjects in the development of cell-based, therapeutic strategies. We investigated the intrinsic differences of de novo extracellular matrix quality between engineered cartilage derived from male and female chondrocytes.

Articular cartilage was harvested from skeletally mature canine humeral heads. Cells were encapsulated in clinically-relevant agarose constructs and cultured in chondrogenic medium. Constructs were assessed for equilibrium modulus (EY) and biochemical content. Data were analyzed with mixed-effects analysis followed by Sidak's multiple comparisons test ($\alpha < 0.05$).

The sex of the animal did not statistically influence the day 42 EY values, glycosaminoglycan and collagen content of the engineered constructs. Both male and female constructs approached native EY and glycosaminoglycan levels, indicating that the culture procedure, which excluded sex hormones, could grow functional tissue irrespective of donor sex. Our findings may have implications on clinical translation, where the same culture regimen can be used to fabricate cartilage derived from male or female chondrocytes. Sex hormone supplementation to culture will be evaluated in the future and may reveal sex-specific differences in tissue development. Moreover, the impact of matching engineered cartilage with recipient sex on graft clinical performance remains to be elucidated with in vivo studies. Defining the importance of sex-based differences in cartilage growth may better direct the development of cell-based therapeutics for OA treatment.

ENGINEERING IN PRECISION MEDICINE

Ali Khademhosseini[P][1]

[1] *Terasaki Institute*

Corresponding author's email: khademh@terasaki.org

Engineered materials that integrate advances in polymer chemistry, nanotechnology, and biological sciences have the potential to create powerful medical therapies. Dr. Khademhosseini's group is interested in developing 'personalized' solutions that utilize micro- and nanoscale technolgoies to enable a range of therapies for organ failure, cardiovascular disease and cancer.In enabling this vision he works closely with clinicians (including interventional radiologists, cardiologists and surgeons). For example, he has developed numerous techniques in controlling the behavior of patient-derived cells to engineer artificial tissues and cell-based therapies. His group also aims to engineer tissue regenerative therapeutics using water-containing polymer networks called hydrogels that can regulate cell behavior. Specifically, he has developed photo-crosslinkable hybrid hydrogels that combine natural biomolecules with nanoparticles to regulate the chemical, biological, mechanical and electrical properties of gels. These functional scaffolds induce the differentiation of stem cells to desired cell types and direct the formation of vascularized heart or bone tissues. Since tissue function is highly dependent on architecture, he has also used microfabrication methods, such as microfluidics, photolithography, bioprinting, and molding, to regulate the architecture of these materials. He has employed these strategies to generate miniaturized tissues. To create tissue complexity, he has also developed directed assembly techniques to compile small tissue modules into larger constructs. It is anticipated that such approaches will lead to the development of next-generation regenerative therapeutics and biomedical devices.

Cardiovascular diseases (CVDs) are the leading cause of death worldwide and therefore pose a huge burden on healthcare systems. Myocardial infarction (MI) is one of the most fatal results of CVDs, as it can cause ultimate heart failure. Current available treatments, including coronary angiography, coronary angioplasty, or blood-thinning medication, are able to mitigate the MI symptoms but do not repair the damaged tissue. A final option is a heart transplant, however lack of organ donors and the subsequent lifelong reliance on immune-suppressant drugs reduces the popularity of this option. A potential solution to this issue is the use of a tissue engineered patch to deliver healthy cells to repopulate the area of infarct.

In this work we have developed a cardiac patch to replace the scar tissue developed post MI, using a family of bioresorbable and biocompatible polymers called Polyhydroxyalkanoates (PHAs)(1-4). Poly(3-hydroxyoctanoate-co-3-hydroxydecanoate), P(3HO-co-3HD), a medium chain length PHA, has been produced using a Pseudomonas species and thoroughly characterised. P(3HO-co-3HD) exhibited highly elastomeric properties, ideal for cardiac tissue engineering applications and a low melting temperature, ideal for 3D printing. Multimaterial 3D printed patches have been produced using P(3HO-co-3HD) including induced pluripotent stem cell (iPSC)-derived cardiomyocytes (iPSC-CMs) encapsulated in a natural alginate hydrogel as an infill. In vitro cytotoxicity assays and imaging has been carried out on the complete patch.

Context: Rheumatoid arthritis (RA) is the most prevalent autoimmune disease, in which CCL2 and CCL5 are critically involved.

Aims: The objective was to evaluate the therapeutic effects of bone marrow-derived mesenchymal stem cells (MSCs) on the foregoing chemokines in RA patients.

Settings and Design: Thirteen RA patients were evaluated in terms of clinical manifestations, paraclinical factors, gene expression, and plasma levels of CCL2 and CCL5 prior to treatment and 1 and 6 months after intervention.

Subjects and Methods: Real-time-polymerase chain reaction and enzyme-linked immunosorbent assay were employed to assess the gene expression and plasma levels of CCL2 and CCL5 at different time points after MSC therapy. Statistical analysis was performed by SPSS 16 and Prism 7.

Results: The CCL2 gene expression had statistically significantly increased ($P = 0.034$), and its plasma level had insignificantly reduced after 1 month. Furthermore, the gene expression and plasma level of CCL5 had statistically significantly decreased ($P = 0.032$, $P < 0.001$). The CCL5 gene expression had statistically significantly increased after 6 months ($P = 0.001$) and its plasma level had insignificantly reduced.

Conclusions: The most significant inhibitory effects of MSC therapy on the gene expression and plasma level of CCL5 were observed at the end of 1 month. The differences between the gene expression and protein levels during the treatment might be related to microRNA effects or the insufficient number of MSC injection.

ASSESSING THE ELASTIC PROPERTIES AND CYTOCOMPATIBILITY OF DECELLULARISED ECM-DERIVED HYDROGELS FROM PORCINE LIVER

The extracellular matrix (ECM) comprises a number of large macromolecules that play an important role in cellular activities such as motility, differentiation and adhesion. The reproduction of a scaffold with comparable composition to the ECM is therefore highly desirable as it can provide a 3D environment which can replicate the liver architecture and biochemical complexity. One of the main challenges of producing such a scaffold is to find suitable replacement biomaterials that best mimic, not only the extra cellular matrix but also the biological organisation of the tissue. Hydrogels have been explored due to their biocompatibility, degradability and having similar mechanical properties to ECM. Adult progenitor liver cells have been identified as bipotent cells capable of differentiating to hepatocytes and cholangiocytes. Given the right cues and three-dimensional environment, progenitor liver cells can be differentiated into functional hepatocyte-like cells.

In this study, porcine livers were decellularised using an enzymatic and detergent washing process. Decellularised livers were digested and solubilised to form hydrogels. DNA and glycosaminoglycan content were assessed, and hydrogel mechanical properties characterised.

Human progenitor liver cells were encapsulated in porcine ECM-derived hydrogels to create in-vitro liver scaffolds. The cells remained viable for at least 10 days and showed increased proliferation when encapsulated in lower concentrations of ECM. Efficiency of organoids formation was comparable with the commercial matrix BME2.

This novel approach can be utilised to produce a 3D environment that closely resemble the liver niche to culture progenitor liver cells and differentiate them into functional hepatocyte-like cells.

Tissue engineering is a promising approach for the treatment of damaged blood vessels. The aim of this study was to develop a small-diameter tissue engineered arterial equivalent by mimicking layers of arterial wall. The scaffold was composed of porous tubular film prepared by dip coating, circumferentially aligned electrospun fibers collected over the film layer, and random electrospun fibrous mat which was wrapped over the aligned fibrous layer. The lumen of tubular scaffold was seeded with human umbilical vein endothelial cells (HUVECs), while human Wharton's Jelly mesenchymal stem cells (WJ MSCs) were seeded onto the circumferentially aligned fibrous mat. Proliferation and organization of the cells on the scaffold were investigated with MTS and Phalloidin-DAPI, respectively. WJ MSCs were differentiated into smooth muscle cells (SMCs) on the scaffold. The expression of specific markers by HUVECs and SMCs was investigated by immunocytochemistry. The tubular scaffold having ca. 3 mm inner lumen diameter was obtained successfully. HUVECs were evenly distributed on inner side of the porous film, while WJ MSCs were oriented on the circumferentially aligned fibers along the fiber axis. It was observed that WJ MSC-derived SMCs and HUVECs preserved their cell morphology and cell specific protein expression on the scaffolds. The results indicate that the tissue engineered vascular substitute developed would be a potential therapeutic approach in regenerative medicine for the treatment of arterial diseases.

The aim of this work was to develop a 3D microenvironment for glioblastoma brain tumor engineering based on alginate hydrogels as a matrix for cell immobilization followed by cultivation in a biomimetic perfusion bioreactor. Alginate microfibers with immobilized cells were obtained by a simple extrusion technique. We have examined the influence of the needle diameter (22G - 28G), cell density in alginate solution (1 x 106 - 8 x 106 cells/ml) and different cancer cell lines (rat C6 and human U251 and U87) on cell immobilization efficiency and viability. The best alginate microfibers (500 µm in diameter) with all immobilized cells were obtained by applying a 25G needle with a minimal cell density of 4 x 106 cells/ml. The obtained microfibers with immobilized cells (C6 and U87) were cultivated in a perfusion bioreactor at the continuous medium flowrate in the range 0.05-0.30 ml/min over short- and long-term cultivation periods. The results have shown that the flowrate of 0.30 ml/min, corresponding to the superficial velocity of 100 µm/s, in combination with the C6 cell density of 8 x 106 cells/ml in short-term studies yielded higher cell viabilities and proliferation as compared to the control static culture. In addition, U87 cells immobilized in alginate microfibers at the density of 4 x 106 cells/ml after long-term cultivation at the medium flowrate of 0.05 ml/min (superficial velocity of 15 µm/s) stayed viable.

The overall results have shown potentials of the applied approach for tumor engineering provided optimization of cultivation conditions for each cell type.

CLIMBING THE VASCULAR TREE IN TISSUE ENGINEERING

Debby Gawlitta[P][1,2]

[1] *University Medical Center Utrecht*

[2] *Regenerative Medicine Center Utrecht*

Corresponding author's email: d.gawlitta@umcutrecht.nl

Nowadays, de novo vasculogenesis and subsequent angiogenesis in small engineered tissues is common practice. Also, channeling the shape of the vascular tree into bioinks and decorating them with endothelial cells appears a well-trodden path. As a consequence, the engineering of interconnected vascular structures that can be readily perfused and implanted seems not too far away from reality.

Contrarily, when taking a closer look at current achievements and how to transform them to clinically implantable and perfusable cm-scale tissues, there are still numerous challenges to be met. These include functional interconnection of multi-scale vasculature, creating and sustaining the surrounding target tissue, and implantation in and anastomosis to a recipient.

Complex in vitro models are presented that show interconnection of capillary-like networks in hydrogels with endothelialized channels.(1) The presence of another viable tissue, in which the vasculature is embedded, requires finetuning of culture regimes to accommodate multilineage cell differentiation and maintenance. The hydrogel-based models cannot be sutured to the existing vasculature of a recipient. An alternative is to recapitulate the intricate multilayer structure of small diameter blood vessels by electrospinning bilayered vascular grafts that are suturable in a small animal model. The heterotypic culture of endothelial cells and smooth muscle cells on such a graft requires multifaceted culture regimes.(2) Next steps require ingenuity of the TERMIS community to provide suitable biomaterials for biofabrication of tissues accommodating a vascular tree, increased control of capillary-to-vessel connection, intricate culture regimes, and animal models that enable evaluation of vascularized specialized tissues in their natural niche.

NANOFIBROUS NETWORKS WITHIN LIQUEFIED-CORE SYSTEMS FOR TISSUE ENGINEERING APPLICATIONS

Miguel Simões[P][1,2]

[1] *University of Aveiro*

[2] *Aveiro Institute of Materials- CICECO*

Corresponding author's email: miguelgsimoes@ua.pt

As the field of tissue engineering and regenerative medicine (TERM) evolved, new tissue repair technologies have emerged. An alternative to conventional hydrogels with fixed geometries, consists of Liquefied Multi-layered Capsules (LMC)[1]. Comprised of a layer-by-layer membrane, a liquefied alginate core containing cells and poly(L-lactic)acid (PLLA) nanofibers, LMC allow free movement of cells across the 3D construct, while maximizing the diffusion of essential molecules. Nanofibers are of utmost interest given its function as an anchoring and assembly 3D system, mimicking the fibrous microenvironment of the extracellular matrix found in vivo. Considering their higher surface area and aspect ratio, compared to microparticles, nanofibers may represent superior cell carrier systems, and aid in cell orientation. To test this hypothesis, PLLA nanofibers were co-encapsulated with stromal cells, under dynamic conditions, and compared with LMC containing only cells (control).

Results show that, after fragmentation of electrospun mats, nanofibers ranged between 5 and 50µm and 1 and 2µm, in length and diameter respectively. Upon encapsulation, the inclusion of nanofibers promoted the formation of cell agglomerates within the LMC, containing biomimetic fibrous networks. Cells shown to remain viable, throughout 14 days of culture, but also metabolically active, in both conditions. Together with dynamic stimulus, a closer representation of in vivo conditions is accomplished, thereby possibly serving as hybrid devices implantable by minimally invasive procedures for TERM applications.

DEVELOPMENT OF SCAFFOLD BASED PLATFORMS FOR LIVER AND KIDNEY RELATED DISEASES

Anthony Callanan[P][1]

[1] *Institute for Bioengineering, School of Engineering, University of Edinburgh*

Corresponding author's email: anthony.callanan@ed.ac.uk

Chronic kidney and liver disease are major global health problems, with drastic shortages in organs available for clinical transplant limiting patient treatment options. Tissue engineering is a rapidly accelerating field; recent advances using induced human pluripotent stem cells to create functional organoid structures for human organs hold great promise for patients (1, 2). To further advance these and address their limitations, our research is focussing on optimising the cellular microenvironment.

We have developed polymer-based scaffolds alongside 3D printed bioreactors as conditioning tools for cells and organoids, providing a highly controlled and customizable microenvironments within which to influence cell differentiation, survival and function. These bioreactors were optimised using an in silico approach in their design allowing control over the applied stimulus. Our results highlight the complexity of the cellular microenvironment shear stress and strain stimuli, while demonstrating how scaffold design has inherent functions in controlling biological response.

The findings highlight the need for further consideration into understanding and controlling niche cellular microenvironments. Advanced platforms such as ours are emergent innovative tools which will play a major role into treatment optimisation strategies in chronic diseases.

SPONTANEOUS 3D-MICROPATTERNING OF BMP-2 IN SELF-ASSEMBLING NANOCLAY GELS FOR BONE TISSUE REGENERATION

Roxanna Ramnarine Sanchez$_P$[1], Nicholas Evans[1], Richard Oreffo[1], Jonathan Dawson[1]

[1] *University of Southampton*

INTRODUCTION: Emulating the three-dimensional (3D) organization of biochemical cues present in cellular-microenvironments is likely to be key in developing biomaterials able to promote regeneration. However achieving stable structures incorporating 3D-micropatterning of biochemical cues that combine high cell-level resolution at clinical scale is challenging1. Nanoclay-gels have established potential in TE owing their capacity to sequester proteins for sustained/localised bioactivity2. The current study reports a method to self-assemble nanoclay-gels with spontaneous 3D-protein micropatterning to deliver localized/stable niches for bone regeneration.

METHODS: Clay suspensions (Laponite®) were added to solutions containing biomolecules present in blood plasma to initiate a diffusion-reaction mediated self-assembly process. Assembled structures were tested for their ability to pattern various fluorescently-labelled proteins and to localize the bioactivity of bone morphogenetic protein (BMP-2). The structures were analysed using fluorescent, polarized-light and electron microscopy, and functionality assessed through a 28-day murine subcutaneous bone induction assay.

RESULTS: Assembled structures provided a template for 3D-protein micropatterning, and spatial localization could be controlled down to a resolution of ~20µm by changing the assembly parameters, including concentration, ionic strength, incubation time and temperature. Furthermore, assembly of structures at scale with a range of dimensions (0.2-1mm) and shapes (droplets, cylinders, strings) was possible. Finally, the in vivo study indicated that localized BMP-2 was able to precisely template bone formation within the gel structure.

DISCUSSION & CONCLUSIONS: This study reveals the potential to harness interactions between clay-nanoparticles and biomolecules to design scaffolds with biochemical gradients, dimensions and shapes for bone with clinical relevance.

EXTRACELLULAR MATRIX ENGINEERED FROM HIPSCS ENHANCES THE BONE REGENERATION POTENTIAL OF AGED HUMAN BONE MARROW STROMAL CELLS

Corresponding author's email: dominik.hanetseder@trauma.lbg.ac.at

Background and aim: Regeneration of bone defects in elderly patients is limited due to the decreased function of bone-forming cells and compromised tissue physiology. The aim of our project was to investigate whether extracellular matrix (ECM) engineered from human induced pluripotent stem cells (hiPSCs) can enhance the bone regeneration potential of aged human bone marrow stromal cells (hBMSCs).
Methods: ECM was engineered from hiPSC-derived mesenchymal-like progenitors (hiPSC-MPs), as well as young (<30 years) and aged (>70 years) hBMSCs. ECM structure and composition were characterized before and after decellularization using immunofluorescent stains and biochemical assays. Three hBMSC strains of different ages were cultured on engineered ECMs, and their growth and differentiation responses were compared to tissue culture plastic, as well as to collagen- and fibronectin-coated plates.
Results: Decellularized ECMs contained collagens type I and IV, fibronectin, laminin and < 5% residual DNA. Cultivation of young and aged hBMSCs on the hiPSC-ECM in osteogenic medium significantly increased hBMSC growth and osteogenic differentiation compared to tissue culture plastic controls and single protein substrates. In aged BMSCs, matrix mineralization was only detected in ECM cultures in osteogenic medium. ECMs engineered from hiPSC-MPs and hBMSCs of different ages exhibited similar structure, composition and potential to enhance osteogenic responses in aged BMSCs.
Conclusions: Our studies suggest that aged BMSC regenerative capacity can be enhanced by culture on hiPSC-engineered ECM. In particular, we showed that engineered ECM outperforms single-protein substrates. Tissue engineering strategies employing engineered ECM materials could thus potentially enhance bone regeneration in elderly patients.

FIBRILLAR MESH HYDROGELS FOR LIVING BIONIC DEVICES

Catalina Vallejo-Giraldo[P][1], Martina Genta[1], Roberto Portillo-Lara[1], Josef Goding[1], Rylie Green[1]

[1] Imperial College London

Corresponding author's email: cata.vallejo@gmail.com

The use of cell laden hydrogel matrices as soft tissue interfaces has led to the concept of "living electrodes", which refers to bionic devices with a functional neural cell component1. The "living" layer is proposed to actively drive the integration of the device into the endogenous tissue1. To achieve this, a cell supportive network with optimal structural stability and microarchitecture must be formed to support cell viability and guide function. The aim of this study was to investigate the use of a biological polymer, collagen, for providing topographical cues within a synthetic poly(vinyl alcohol)-tyramine (PVA-Tyr) hydrogel. Collagen type I was hypothesized to promote cellular migration and infiltration to encapsulated neuroprogenitor cells, facilitating the development of 3D neural networks. PVA-Tyr-Col hydrogels were synthesized using different mass ratios of collagen to PVA-Tyr (1:1 to 1.5:1) and the physical and mechanical properties of the resulting scaffolds were evaluated using AFM. Hydrogel cytocompatibility was tested in vitro using 3D primary neuron culture. Immunological staining was carried out using monoclonal anti-β-tubulin and anti-GFAP antibodies, to evaluate the growth of neurons and astrocytes, respectively. In addition, the formation of functional neural networks was assessed via calcium imaging and Piezo1 expression. PVA-Tyr-Col hydrogels were found to support the growth of both neuronal and astrocytic cell populations with improved viability, compared to PVA-Tyr-gelatin hydrogels which contain similar bioactive peptide sequences but lack the topographical cues imparted by the whole protein. PVA-Tyr Col hydrogels provide a promising platform for the development of living interfaces for stimulating bioelectronic devices.

The application of extracorporeal shock wave therapy (ESWT) on tissues results in well establish therapeutic and regenerative benefits to the patients. Through mechanotransduction of the incoming pressure pulse, a cascade of biochemical responses is triggered within the cells. Simultaneously, there is a non-linear response in the physical bulk properties of the targeted structures. Either one of those processes may be both beneficial or detrimental for the treatment outcome. We present findings on the efficacy of treating lung tissue using low energy shockwaves which is normally considered a counter-indication for the therapy. Potential attenuated proinflammatory cytokine expression and regenerative benefits have to be seen in the light of potentially destructive tensile forces imparted on the lungs resulting in pulmonary capillary hemorrhages. Based on water bath reference measurements, computational simulations, and in-vivo experiments we provide a comprehensive overview of competing considerations in moving towards a clinical use of ESWT in the potential treatment of a wide range of new indications.

Introduction: Hydrogels have been widely used in tissue engineering to accommodate the culture of cells. A novel class of catechol-functionalized polymers could lead to hydrogels with improved mechanical properties by designing reversible crosslinkings using metallic coordination. This reversible coordination is depending on pH and promoted at slightly basic pH(1), as long as the oxidation of the catechol group be avoided(2). On other hand, supramolecular entities namely polyrotaxanes (PR) could form hydrogels with similar mechanical properties of cartilage, with the possibility of promote the differentiation of pluripotential stem cells due to the capacity of the cyclodextrin to slide trough the PEG chain and be loaded with active agents(3). However, PR functionalized with catechol residues is not explored yet.

Methods and Results: PRs were functionalized by EDC/NHS coupling reaction(4) with a novel nitrocatechol synthetized in our lab, following a modified methodology described to avoid the quickly oxidation of entities containing catechol(5). Functionalization was confirmed by H1NMR. Functionalized supramolecular entities were then dispersed in aqueous media, and hydrogels were prepared(2).The elastic and the viscous moduli and the self-healing ability of formed hydrogels were evaluated. Cytocompatibility of hydrogels was ensured with SAOS-2.

Conclusions: A biocompatible cutting-edge reversible crosslinked hydrogel was developed, taking advantage of a functionalized sliding ring polyrotaxanes with nitrocatechol, able to avoid the issues of oxidation. This completely novel combination results in hydrogels with capacity to distribute the typical stresses that suffer the biomaterials, for example in cartilage substitution, along the entire volume of the hydrogel, trough reversible free movements of cyclodextrins.

During a myocardial infarction or a heart attack, cardiomyocytes (CM) are deprived from oxygen, leading to death with almost no regeneration. Tissue engineering holds promise towards developing solutions to produce more efficient diagnostic and drug discovery platforms, patient-specific organ transfer, and models for basic science research. Embryonic stem cells and induced pluripotent stem (iPS) cells can differentiate into all cell types, making them a valuable cell source for applications in tissue engineering. Moreover, because iPS cells can be made patient-specific, their derivatives could also eliminate the need for immunosuppressive therapies. In order to direct the cell fate of human iPS to CM cell lineage, mechanical forces have been shown to play an important role such as mechanical strain, topography-guidance, and substrate stiffness. Our goal for these studies was to culture iPS-derived CM on wrinkled microchips and examined alignment on various surfaces. We used a cost-effective shrink-based fabrication method to create the wrinkle topography for guiding cell alignment on physiological stiffness. The results show that the pattern can be retained in PDMS as well as lower stiffness polyacrylamide (PA) hydrogels, but the CM preferentially adhered to the flat glass rather than the wrinkled PA. Future work plans to optimize the cell seeding density, extracellular matrix proteins and the linker's concentration in order to increase the adhesion of CM on PA.

TOUGH ANTIBACTERIAL HYDROGELS AS TISSUE ADHESIVES FOR WOUND HEALING

Yumin Yang$_P$[1], Jue Ling[1]

[1] *Key Laboratory of Neuroregeneration, Nantong University*

Corresponding author's email: jl2016@ntu.edu.cn

INTRODUCTION: Current shortcoming in tissue adhesives commonly used in clinical practice was based on their poor tissue compatibility and/or weak tissue adhesion.1,2

METHODS: Evaluation of tissue adhesion of the hydrogels, in vitro and in vivo cytocompatibility and in vivo wound healing.

RESULTS: Our biocompatible hydrogels comprising sodium alginate, chitosan, and polyacrylamide exhibited good cytocompatibility, antibacterial activity, and excellent tissue adhesion.

DISCUSSION & CONCLUSIONS: We developed biocompatible hydrogels comprising sodium alginate, chitosan, and polyacrylamide and exhibiting good cytocompatibility, antibacterial activity, and excellent tissue adhesion. The hydrogels exhibited significantly enhanced mechanical properties following the addition of polyacrylamide, which synergistically promoted their enhanced adhesion. Moreover, results showed that the hydrogels exhibited good biocompatibility and antibacterial activity and promoted wound recovery during use as wound dressings.

FREESTANDING SELF-HEALING COATING TOWARDS TISSUE REPAIR

Jue Ling$_P$[1]

[1] *Key Laboratory of Neuroregeneration, Nantong University*

Corresponding author's email: jl2016@ntu.edu.cn

INTRODUCTION:Self-healing materials have received intense attention because of their excellent ability of restoring their properties and shapes after automatically repairing their damaging sites without additional adhesives, whose ultimate aim is to improve the resilience of safety-critical components.[1]

METHODS:SF-βCD or HA-AD were alternately deposited on a glass surface to fabricate the self-healing (SF-βCD/HA-AD)*n coatings. Cytocompatibility evaluation of the coating by MTT.

RESULTS:The freestanding and self-healing (SF-βCD/HA-AD)*n coating based on host-guest interactions by layer-by-layer (LbL) self-assembly. This coating could easily and repeatedly heal external mechanical damage and be pulled of the glass substrate. Antibacterial and cytocompatibility evaluation illuminate that the coatings have an admirable antibacterial activity and cellular bioactivity.

DISCUSSION & CONCLUSIONS:Based on host-guest interaction, a freestanding self-healing coating with excellent biocompatibility and promising antibacterial activity was prepared by LbL assembly and we believe that the (HAD/SCD)n coatings will have great potential in tissue engineering.

Electrical stimulation (ES) is a noninvasive potent tissue engineering tool whose mechanisms are yet to be fully understood. Despite promising experimental results, it is still difficult to optimize stimulation protocols due to the translational limitations between in vitro and in vivo. Stimulation devices as well as cellular microenvironment differ significantly between the two layouts. To bridge this gap, we used in silico finite element method (FEM) models to investigate the cell detectable signals, such as charge and current density, present in the microenvironment. Two types of scaffolds were modelled; either artificial, i.e. Poly(3,4-ethylenedioxythiophene) poly(styrenesulfonate) (PEDOT:PSS) coated silk fibers, or natural extracellular matrix (ECM) made of collagen fibers and interstitial fluid. Furthermore, our simulations show how fiber alignment to the electric field (EF) determines electrical microenvironment in nanofibrous electroconductive scaffolds. This observation can be explored to investigate cellular mechanisms of response to EF and design of scaffolds with complex fibrous networks for functional tissue engineering.

Chitosan-based artificial nerve scaffolds have been identified as suitable products for peripheral nerve defects in clinical trials. In our previous study, chitosan degradation products, chitooligosaccharides (COS), could facilitate peripheral nerve regeneration by constructing macrophage-constructed microenvironments.

Fibroblast (Fbs) and Schwan cells (SCs) are main components of peripheral nerves. Exosomes carry functional miRNA and protein to operate their biological properties. In the present study, we observed that COS enhances exosome secretion from Fbs, which markedly promotes neurite outgrowth and nerve regeneration.

By using iTRAQ, protein profiles in the proximal nerves treated with COS were analyzed. COS promotes secretion of exosomes from Fbs and sequencing data revealed that miR-132-5p was decreased. Exosomes were prepared from Fbs with a commercial kit. RNA expression profiles in exosomes were analyzed by RNA sequencing. COS-induced exosomes remarkably stimulated axon growth in cultured DRG explants and injured sciatic nerves. Neurite outgrowth was evaluated by neurite length in cultured DRG explants. Nerve regeneration in vivo was assayed by behavioral performances, electrophysiological tests and morphological analysis. Inhibition of miR-132-5p also induced similar results in axon growth. Camkk1 is a target of miR-132-5p for transducing its promotion effect on axon growth.

Our present study further revealed a new aspect of COS in nerve regeneration, i.e. COS-induced exosomes from Fbs accelerate axon growth and the axis of miR132-5p/Cammk1 is responsible for this beneficial effect. Overall, our present data, together with our previous work, provide a strong theoretical basis for application of chitosan based biomaterials in peripheral nerve regeneration.

[1] *Department of Biomedicine, University Hospital Basel, University of Basel, Switzerland*

Corresponding author's email: laura.doenges@usb.ch

Osteoarthritis (OA) is the most common degenerative joint disease worldwide and treatment options are limited to palliative care or, at the end stage of the disease, to total joint-replacement therapy. During OA progression, articular chondrocytes acquire hypertrophic traits followed by full remodelling of the cartilage into bone. Recent cartilage developmental biology studies showed that endogenous inhibition of bone morphogenetic protein (BMP) plays a central role in insulating articular stable cartilage from transient cartilage, which will be vascularized and undergo endochondral ossification. We hypothesize that by applying developmental biology concepts in vitro, BMP signalling inhibition can be applied to counteract hypertrophic differentiation of OA chondrocytes. To test this, human bone-marrow derived mesenchymal stromal cells were differentiated in vitro towards the chondrogenic lineage using a 3D high-throughput micro-aggregate culture system. After the chondrogenic phase, the generated micro-aggregates were exposed to inflammatory factors highly present in an OA joint (IL1, IL6 and TNF). At the end of such OA inducing phase, we showed a significant decrease of the expression of hyaline cartilage genes (COL-II and ACAN) and a significant increase of expression of the hypertrophic (MMP-13 and BMP2) and pro-inflammatory (IL6 and IL8) genes. Moreover, glycosaminoglycan content decreased in response to inflammation, whereas interleukin-8 and BMP2 secretion increased. We thus demonstrated that our model well recapitulates key features of OA cartilage. We are now using this model to investigate whether treatment by BMP type I receptor kinase inhibitors counteracts the evolution of such OA features as well as modulate angiogenic properties.

HIGHLY BRANCHED POLY(B-AMINO ESTER)S AS A NEW GENERATION OF NON-RIVAL GENE DELIVERY VECTOR

Dezhong Zhou[P][1], Chenfei Wang[1]

[1] *Xi'an Jiaotong University*

Corresponding author's email: dezhong.zhou@xjtu.edu.cn

Since the first development of poly(β-amino ester)s in 2000, more than 2350 poly(β-amino ester)s have been synthesized and screened for gene transfection, and the most efficient candidate can even rival adenovirus in stem cells. However, until 2015, all the poly(β-amino ester)s developed had been linear structured. Herein, we have developed a highly controllable and flexible "A2+B3+C2" Michael addition strategy to synthesize highly branched poly(β-amino ester)s. The "A2+B3+C2" strategy not only effectively delays the gelation but also endows the synthesized polymers with a 3D topology with multiple terminal groups. In vitro gene transfection studies over 12 different cell types including stem cells and primary cells show that the gene transfection efficiency of highly branched poly(β-amino ester)s is up to 8521-fold higher than their corresponding linear counterparts. Highly branched poly(β-amino ester)s can also effectively deliver nerve growth factor (NGF) encoding DNA to PC12 cells to promote the outgrowth of neurites. In vivo, highly branched poly(β-amino ester)s can effectively deliver collagen VII encoding gene COL7A1 to fibroblasts and keratinocytes to restore the expression of collagen VII, which accelerates the wound healing of recessive dystrophic epidermolysis bullosa. Cytotoxicity studies further show that highly branched poly(β-amino ester)s can preserve high cell viability in diverse cell types and induce negligible inflammation in vivo. All these results highlight the great potential of highly branched poly(β-amino ester)s in non-viral gene therapy, in terms of high transfection efficiency and low cytotoxicity.

PREPARATION OF POLY (Ɛ-CAPROLACTONE-RAN-LACTIDE) SCAFFOLD USING LOW TEMPERATURE 3D PRINTING AND ITS PRINTABILITY TEST

Joon Yeong Park[1], Moon Suk Kim[1]
[1] *Ajou University*
Corresponding author's email: pjy16@ajou.ac.kr

3D printing has a method of manufacturing a complex and elaborate structure by dividing it into a certain thickness and stacking it layer by layer. Compared to other manufacturing methods, it has the advantage of being able to easily manufacture complex shapes. In the case of most 3D printing inks used a material that melts at a high temperature of 180 ℃ or higher is used, which has a disadvantage in that it is not possible to apply a temperature sensitive bioactive material. In this work, poly(ε-caprolactone-co-lactide) 3D printing ink was prepared by controlling the ratio of caprolactone and lactide monomer. The ratio of lactide to caprolactone was gradually increased to have a melting temperature of 40 to 60 ℃. We manufactured 3D printing scaffold at 110 ℃. We measured line width and porosity using Scanning electron microscope and stereomicroscope images and confirmed by comparing the modeled theoretical results. Under the same conditions, we confirmed that the higher the melting point, the more stable the shape was maintained. In the same material, the printing speed, temperature, and pressure were controlled to confirm appropriate printability. In conclusion, we manufactured 3D printing inks capable of printing at low temperatures compared to the existing printing methods and verified optimal printability. Also, we developed a 3D printing inks have potential using with thermal-sensitive materials.

PREPARATION AND EVALUATION OF ADAPALENE EMULSION CONTAINING POLYCAPROLACTONE HAVING FUNCTIONAL GROUPS FOR IMPROVED TREATMENT OF SKIN DISEASES

Yun Bae Ji[P][1], Hye Yun Lee[1], Gi Ru Shin[1], Moon Suk Kim[1]

[1] *Ajou university*

Corresponding author's email: jyb26267@ajou.ac.kr

Polycaprolactone has the advantage of having adequate biocompatibility and biodegradability. However, it is difficult to impart additional functions for efficient disease treatment due to the absence of functional groups and strong hydrophobicity. In this study, an emulsion formulation containing polycaprolactone with an amine group (MCL-NH2) was developed to improve skin permeability through electrostatic interactions and applied together with adapalene (AD) to evaluate the effect of treating skin diseases. First, we manufactured polycaprolactone with a benzyloxy group (MCL-OBn) were by ring opening polymerization. After that, MCL-NH2 and AD-emulsion prepared through additional reactions. We confirmed through the dynamic light scattering (DLS) measurement that the larger the number of amine groups of MCL-NH2, the smaller the size of the emulsion particles due to electrostatic interaction with AD. Through stability evaluation, it was confirmed that the emulsion formulation was maintained for a time during which the drug in the emulsion could be sufficiently absorbed into the skin. Based on the above experimental results, we conducted in vitro and in vivo experiments, and proved that the anti-inflammatory and acne treatment effects are more effectively improved by the electrostatic interaction of the AD-emulsion with MCL-NH2. As a result, we confirmed that by manufacturing a polycaprolactone having a functional group, it is possible to impart the function of skin permeability improvement and drug-controlled release. In addition, it is expected to be a promising material that can further increase the treatment efficiency of various diseases and can be useful in tissue engineering and biomedical fields.

PREPARATION OF ANTICANCER DRUG-CONTAINING INTRATUMORALLY INJECTABLE HYALURONIC ACID HYDROGEL

Hyeon Jin Ju[P][1], Min Ju Kim[1], Gi Ru Shin[1], Moon Suk Kim[1]

[1] *Ajou University*

Corresponding author's email: tssos@ajou.ac.kr

The first method used to treat cancer is a surgical method in which the cancer tissue is directly incised and removed. In addition, a drug treatment method is used to remove cancer tissues that have not been completely removed after dissecting the cancer tissues, or to prevent cancer metastasis by remaining cancer cells and cancer tissues. Doxorubicin (Dox) which is used as an anticancer agent has excellent anticancer effects, but it is very toxic and has a short half-life in the human body, so the concentration and release of the drug must be well controlled. We have prepared a click-cross linkable hyaluronic acid hydrogel that can be directly injected into cancer to improve the efficacy of anticancer drugs and reduce toxicity by drugs. We individually introduced trans cyclooctene and tetrazine into hyaluronic acid (HA) so that the trans cyclooctene modified HA and tetrazine modified HA immediately formed Dox-containing hydrogel after being injected inside the tumor and the drug could be sustainably released. Cross-linked HA hydrogel consistently inhibited tumor growth, whereas non-crosslinked HA loaded with Dox and Dox solution increased the amount of Dox in the tumor and showed low anticancer activity. In conclusion, we successfully prepared a hydrogel capable of forming a drug depot within tumor and the anticancer effect of Dox loaded hydrogel could be increased.

ENZYMATICALLY CROSSLINKED SILK FIBROIN HYDROGEL MICROFLUIDIC PLATFORM

Mariana Carvalho$_P$[1,2], Cristiana Carvalho[1,2], Raquel Maia[1,2], David Caballero[1,2], Subhas Kundu[1,2], Rui Reis[1,2], Joaquim Oliveira[1,2]

[1] *3B's Research Group, I3Bs – Research Institute on Biomaterials, Biodegradables and Biomimetics, University of Minho*

[2] *ICVS/3B's - PT Government Associate Laboratory, Braga/Guimarães, Portugal*

Corresponding author's email: mariana.carvalho@i3bs.uminho.pt

Microfluidic fabrication typically involves non-degradable materials including silicon and PDMS. However, these devices are generally not implantable, mainly because they are non-degradable and can induce inflammation and trigger foreign body reaction. Strategies for developing more natural implantable systems comprise the use of agarose, gelatin, collagen and alginate [1]. We have developed and patented a transparent enzymatically crosslinked silk fibroin hydrogel-based microfluidic device based on microfabrication techniques. It may be used ex vivo and in vivo, in tissue engineering applications, organ or tissue disease models, tissue-, organ- and body-on-a-chip, drug discovery, drug screening, tissue implant, tissue regeneration, and implantable microdevices. The new formulation is based on rapidly responsive silk fibroin hydrogels formed by a horseradish peroxidase (HRP) crosslinking reaction at physiological conditions, with potential use as an artificial biomimetic 3D ECM [2].

Preliminary results show the obtained hydrogel presents flexibility and elasticity, being organically adapted to any organ or structure in vivo. It is fully transparent until day 7, when its amorphous structure changes to β-sheet. The microfluidic serpentine feature is faithfully replicated into the hydrogel, and allows for perfusion of media, envisioning the formation of diffusion gradients of drugs/nanoparticles.

We envision mimicking colorectal cancer microenvironment by seeding human colonic microvascular endothelial cells inside the microchannels, invading the matrix in response to VEGF gradients, while HCT-116 colorectal cells are encapsulated in the silk. Due to its implantability, the system can be further implanted in more complex systems.

The importance of oxygen concentrations in cell culture for tissue engineering and regenerative medicine is often underestimated1, although this parameter is crucial for cell fate during differentiation. The environmental oxygen concentration (20.9%) does not represent the physiological condition within human tissue2, such as bone and cartilage. For this reason, real time oxygen monitoring can improve the standardization of stem cell differentiation outcome, both for two-dimensional (2D) and three-dimensional (3D) methods. Therefore, we developed electrochemical oxygen sensors, already successfully applied in other fields3,4, using a copper wire inserted into a silica capillary tube, partly filled with a graphite-loaded epoxy resin. The sensors were introduced into the tissue plates through modified tissue plate lids, and the detection of oxygen was obtained by means of an electrochemical reduction, i.e. applying a cathodic potential to the carbon-disk surface. We tested the sensor stability in cell culture medium and its material cytotoxicity for bone marrow stem cells (BMSCs) cultures. The sensors are proved to be non-cytotoxic for up to 7 days. and were not damaged over a period of 21 days in cell culture medium The sensors were subsequently used to analyze oxygen concentration in 3D cultures of BMSCs embedded in two different hydrogels, gelatin methacryloyl (GelMa) and tyramine functionalized hyaluronic acid (HAT). The embedded stem cells were differentiated in chondrogenic medium for 21 days, both under hypoxic and normal conditions. The proposed system has the potential to represent an easy way of in real time oxygen concentration measurements in 3D constructs during differentiation.

Articular cartilage (AC) repair is the main goal of several regenerative medicine approaches, with autologous chondrocyte implantation (ACI) providing an effective treatment[1]. A new variation on ACI called Chondrosphere™ (or Spherox; developed by CO.DON AG), based on the transplantation of autologous chondrocytes spheroids, has recently been approved and recommended by UK National Institute for Health and Care Excellence to treat symptomatic AC defects of up to 10 cm2[2]. Despite the current progress of Chondrosphere translation into clinical practice, the way the cells form spheroids, their development and their fusion when put together to mature into a tissue are still poorly understood. In this work we developed an in vitro AC repair model as a quality assessment tool for potency, which can be applied to Chondrosphere™ product[3,4]. To achieve the aim, we firstly analysed morphologically the way the cells aggregate in spheroids (by SEM and TEM), and biologically for testing their viability (Live/dead and Apoptosis/Necrosis assay) and metabolic activity (Cell Titer) during 7 days in vitro culture. Then we investigated the spheroids behaviours when placed together (10 spheroids per cm2 per each Chondrosphere) on a gelatin-coated Poly(ε-caprolactone) (PCL) membrane for 21 days. Spheroids tended to arrange in 3D cell aggregates, fusing among themselves and adhering to the gelatin-coated PCL membrane. Finally, chondrospheres showed to produce high amount of collagen II and aggrecan (qPCR) and GAGs (Alcian blue quantification) after long term in vitro cultivation, generating an AC-like tissue.

Three-dimensional bioprinting technology is predicted to radically change regenerative medicine, allowing the manufacture of tissue-engineered constructs with appropriate control over spatial variations and capability of precise deposition of biomaterials, cells and biological molecules[1]. One of the main challenges is to identify bioinks which can to fulfill the requirements for reproducible additive manufacturing as well as the biological requirements for the type of tissue required[2]. With regards to articular cartilage (AC) regeneration, hydrogel-based bioinks are the main formulations used due to their similarity to chondral tissue in terms of mechanical properties. In our work, we propose an innovative photocurable gellan gum methacrylated (GGMA) based bioink suitable for extrusion-based bioprinting technology to generate bioprinted AC tissues constructs of clinically relevant sizes. In particular, we exploited a nature-inspired strategy, adding Manuka Honey (MH) to the GGMA composition (GGMA-MH)[3]. The methacrylation efficiency of GGMA was chemically assessed by means of H-NMR and FTIR. Then, GGMA-based hydrogel formulations were used as chondrocyte laden bioinks, extruded to obtain a grid-shaped construct using a ROKIT INVIVO Bioprinter. The porosity of both compositions (GGMA and GGMA-MH) was investigated using SEM, together with water uptake analysis and mechanical properties via a compression test. The beneficial effect of Manuka Honey incorporation on printability and cells viability and fate was evaluated through cell viability assays. Histological analysis (H&E and Alcian blue stainings) and qPCR analysis (SOX9, COL2A1 and ACAN) were used to assess the chondrogenic potential of the cells-laden GGMA-based bioinks in vitro.

We tested the hypothesis that transplantation of bone marrow stromal stem cells (MSCs) into the spinal cord after a severe cord injury promotes functional outcome.

MSCs cells were harvested from adult Fischer rats and cultivated for transplantation. Before transplantation, MSCs were labeled with green fluorescent protein (GFP). 24 Fischer rats were anesthetized and laminectomy was performed at the T8~T9 level. A full thickness transection of the spinal cord was made at 2 levels, and 5 mm length transected segment of the spinal cord was removed. Cultured MSCs seeded with polyglycolide (PGA) scaffolds were transplanted into the gap of the spinal cord in 8 animals (group 1). Only PGA scaffolds without cells were transplanted into the gap of the spinal cord in 8 animals (group 2). No treatment was done in 8 animals (group 3). Motor functional outcome measurements using Basso-Beattie-Bresnehan (BBB) score were performed weekly to 8 weeks post-injury. Sections of spinal cord tissue including transplanted area were analyzed by H&E staining and immunohistochemical staining for NF, S-100 and NSE.

The results showed significant improvement in functional outcome in animals treated with MSCs transplantation (group 1) compared to group 2 or group 3. In histological analysis, evidence of axonal regeneration into the newly formed tissue at the gap was found in animals treated with MSCs transplantation (group 1), but very weak or no evidence of axonal regeneration was found in group 2 and group 3 animals. These data suggest that transplantation of MSCs may have a therapeutic role after SCI.

GLUTHATHIONE REDUCTASE- AND REDOX-RESPONSIVE POLYMERIC MICELLES FOR A TARGETED AND CONTROLLED DRUG DELIVERY IN ARTHRITIC DISEASES

The inadequate pharmacokinetic profile of arthritic diseases treatments, with low drug bioavailability and off-target biodistribution is a major limitation of their therapeutic efficacy and safety.1,2 Considering the tremendous health and economic impact of those conditions as well as the inflammatory microenvironment at the disease site, glutathione reductase (GR)- and redox-responsive polymeric micelles were designed to provide a targeted and controlled drug release. To establish a sensitive system, a novel polymer composed of methoxypolyethylene glycol amine-glutathione-palmitic acid (mPEG-GSH(n)-PA) was synthetized and after the micelles formation the thiol groups were oxidized intermolecularly to avoid drug leakage under physiological conditions. After passive targeted accumulation in inflamed joints, redox environment and GR activity will destabilize the micellar structure via a thiol-disulfide exchange, triggering a local and controlled drug release.
The micelles presented a uniform size of around 110 nm and 65% entrapment efficiency of dexamethasone (Dex). After demonstrating their hemocompatibility and cytocompatibility in contact with human endothelial cells, chondrocytes and macrophages, in a co-culture model of inflammation and in the presence of GR, polymeric micelles promoted a targeted and controlled drug release. Importantly, as they presented a higher efficacy than the free Dex and were able to reduce its negative effects over normal cells, this strategy may provide important outcomes in arthritis treatment. In conclusion, by increasing the drug therapeutic efficacy and reducing its severe side effects the developed polymeric micelles offer unique advantages for the treatment of arthritic diseases.

Organoids are gaining significant interest in the field of regenerative medicine. Their ability to self-organize from pluripotent stem cells into functional organ-like structures makes them candidates for organ replacement or repair. We aim to produce functional kidney organoids from induced pluripotent stem cells (iPSCs) to build an implantable kidney graft to reduce or replace dialysis for patients with end-stage kidney disease. For this, we differentiate iPSCs and subsequently form organoids by aggregation. After 18 days of culture, these are several millimeters in size and comprise small nephron-like structures, with tubular segments and an immature endothelium. We found that prolonged culture results in diminishing endothelial cells and deteriorating nephrons. Notably, the organoids grow in a transwell setup at an air-liquid interface, and are therefore directly exposed to a hyperoxic (21%) culture environment. This culture method has been used to culture kidney explants since the 1950s, however, there is little understanding of its effects. To gather more insight, we cultured our organoids in a hypoxic environment similar to the physiological range of oxygen in developing human kidneys. We investigate its effect on HIF1/2 pathway activation and hypothesize these pathways lead to an enhanced transcription of VEGFa, consequently enriching the endothelial cell population in the organoid. To confirm transcription of HIF target genes, we use techniques such as qPCR and whole mount imaging facilitated by tissue clearing. Ultimately, we aim to understand the effect of culturing kidney organoids in physiological oxygen concentrations.

Recently, protocols to differentiate human embryonic stem cells (hESCs) into the chondrogenic lineage have been established [1,2]. However, generating 3D articular cartilage tissue from hESCs is still challenging.

This work aims to develop a bioprinted articular cartilage model using hESCs, through the combination of alginate-based hydrogels as an ECM-like microenvironment for cell differentiation, and L-Leucine-based Poly(ester urea) (PEU) scaffolds with adequate biophysical properties to withstand physiological loading.

First, hESCs were differentiated into the chondrogenic lineage using a 2D multi-step protocol. Then, hESC-derived chondroprogenitors were encapsulated in alginate or alginate/type-I collagen hydrogels. Differentiation into the chondrogenic lineage was verified by changes in cell morphology, loss of expression of pluripotency markers, and increased expression of chondrogenic markers SOX9, SOX5, and COL2A1 during 2D differentiation. Further culture in 3D hydrogels for 14 days resulted in high levels of cell viability and increased chondrogenic gene expression.

Then, the ability of bioprinted PEU scaffolds to support chondrogenesis was evaluated. PEU scaffolds had lower nanoindentation hardness and compressive modulus, and were more hydrophilic than poly(caprolactone) (PCL) controls. Human chondrocytes cultured on PEU exhibited increased metabolic activity, expression of chondrogenic markers ACAN and COL2A1, and lower expression of COL1A1, suggesting a more chondrogenic phenotype.

These findings suggest that alginate-based hydrogels are suitable systems to promote chondrogenesis from hESCs. Similarly, PEUs were able to support human chondrocyte phenotype in culture. The combination of these two components could be applied to generate a 3D bioprinted hybrid construct for new applications in cartilage regenerative therapies or in vitro tissue modelling.

There is a need for noninvasive monitoring of cell culture growing and differentiating in bioscaffolds to evaluate their viability and quality before their eventual transplantation to patients.
