However, current cell viability assays are mostly limited to 2D cell culture and make use of destructive imaging technologies (e.g. histology) or chemical probes that are not ideally suited for clinical translation. Here, we developed a biocompatible scaffold that mimics the extracellular matrix and holds the 3D cell culture medium with a design that both optimizes the surface tension power, and allow the assessment of the cell culture with Electrical impedance tomography. We characterized our scaffold as a frequency-independent dielectric material, and we demonstrated both in silico and in vitro that frequency-dependent electrical impedance tomography (fd-EIT) can image and measure in parallel several scaffolds in a single EIT miniature sensor. We retrieved the cell concentration of up to four different scaffolds non-destructively in real-time. Furthermore, quantitative analysis in the field of current density and potential distribution was conducted to explain the feasibility of cell differentiation using fd-EIT. This study paves the way towards EIT imaging and measurements that could help to evaluate quantitatively and noninvasively tissue engineering samples in the production line.

INTRODUCTION: Lactate, an important metabolite during cardiogenesis and cardiac development, has been recently shown to promote cardiomyocyte proliferation and reprogramming towards a dedifferentiated stem cell-like state.1 Non-myocytic cardiac fibroblasts (CFBs) have a key role during cardiac remodeling after myocardial infarction, where they become activated and release extracellular matrix proteins. Excessive extracellular matrix deposition or myofibroblast activation is detrimental to cardiac repair.
The aim of this work is to elucidate the effect of lactate on CFBs for a complete interpretation of its potential proregenerative capabilities. Then, we developed bioactive lactate-releasing scaffolds for cardiac regeneration.

METHODS: CFBs metabolic activity and proliferation were assessed. The inflammatory and fibrotic responses to exogenous lactate were investigated in terms of cytokine and collagen production, migration assays and myofibroblast differentiation. Then, polylactic-acid(PLA) scaffolds were fabricated by electrospinning and physiochemically characterized (SEM, DSC, lactate release,…).

RESULTS: Our results indicate that lactate does not affect fibroblast proliferation, migration, collagen production, or activation and significantly reduces the expression of detrimental cytokines for cardiac repair. Furthermore, our PLA scaffolds are amorphous, biodegradable, nanofibrous materials that release lactate in a sustained manner. They do not affect CFB viability and promote cell attachment.

DISCUSSION: Altogether, this study further supports the prospective use of lactate as a bioactive signal in new endogenous cardiac regeneration therapies. Thus, PLA patches that release lactate as a major product from its breakdown can then be used as an effective source of lactate for alleviating the aftermath of myocardial infarction.

This project was funded by ”LaCaixa” Foundation(LCF/BQ/DR19/11740025) and MINECO/FEDER(RTI2018-096320-B-C21).

Repair of articular cartilage defects remain a major clinical challenge, since there are currently no long-term regenerative options. Implant-based approaches have shown promise but the fixation of the constructs is problematic.[1]The aim of this study was to evaluate the performance of an integrated osteochondral implant in an orthotopic equine model. The construct consisted of a 3D printed low-temperature setting bioceramic bone anchor which was firmly integrated to a cartilage-mimetic compartment consisting of a melt-electrowritten polycaprolactone mesh,[2] with or without seeded articular cartilage progenitor cells. The bone anchor had been previously shown to induce osteoregeneration when implanted in vivo into the tuber coxae of warmblood horses.[3] To maximize cartilage matrix production, the constructs were precultured for 28 days in media supplemented with bone morphogenetic protein-9, resulting in abundant extracellular matrix rich in glycosaminoglycans and type II collagen. The osteochondral plugs were then implanted in the stifle joints of Shetland ponies. Radiographic examinations and quantitative gait analysis were implemented to monitor clinical status. Six months after implantation, histological and biochemical analyses showed minimal amounts of GAGs and type II collagen in the chondral region for cell-laden and cell-free implants, while the microfiber meshes were still present. Quantitative micro-computed tomography showed collapse of the bone anchor and low volume of mineralized neo-bone formation in both groups. It was concluded that the failure of the bone component resulted in the loss of mechanical support and improper fixation, which affected the overall outcome, hindering the evaluation of BMP-9 stimulated cells for in vivo cartilage repair.

3D BIOPRINTING OF QUALITY CONTROL STANDARDS FOR MASS SPECTROMETRY

Berta Cillero-Pastor[P][1], Erik van Zetten[1], Monica Basílio de Sousa Carvalho[2], Carlos Domingues Mota[2]

Mass spectrometry imaging (MSI) has become a powerful method for unbiased tissue-based disease and patient classification (1). By scanning a tissue biopsy with a laser, individual mass spectra are recorded from predefined coordinates providing, within a short time, a detailed spatial molecular fingerprint (2). Recent instrumental improvements have resulted in scan times of just several minutes, making it an ideal candidate for new digital pathology workflows while allowing a fast-clinical diagnosis and intervention in an (unprecedented) precise manner (3). A key factor in the implementation of MSI for routine Digital Molecular Pathology Diagnosis, is the need of robust and precise quality control standards (QCS). Most laboratories employ liquid based (commercially available) compounds, animal-derived organ sections or tissue homogenates. All these solutions are not adequate as QCS, because of batch-to-batch differences, organ/animal heterogeneity and insufficient resemblance with human tissue molecular complexity. The ideal QCS for MSI technology should mimic the structure of biological tissues: a cellular component embedded in an extracellular matrix (ECM). Within our team, we have developed an elegant solution that meets the sketched requirements by 3D bioprinting engineered tissue constructs capable of mimicking both the molecular and topographical biology characteristics for MSI applications.

The formation of vascular sprouts from endothelial cells (ECs) is a necessary step for the creation of micro-vascular networks[1]. To proliferate and sprout, ECs need support from stem cells, degrading the extracellular matrix and providing cues[1–3]. Spontaneous formation of sprouts in hydrogels has already been shown[1], but a fine spatial control of their direction remains challenging.

We used a co-culture of spheroids from human umbilical vein ECs (HUVEC) and adipose stem cells (ASC), embedded in a methacrylamide-functionalized gelatin (GelMA)[4], cross-linked with UV light, as a platform for ECs sprouts formation. After polymerization, the gel has been soaked in 4,4'-diazido-2,2'-stilbenedisulfonic acid (DSSA), and channel-shaped structures have been patterned around the spheroids with an infrared femtosecond laser. DSSA is grafted to the hydrogel backbone only in the patterned regions, locally modifying stiffness and hydrophobicity.

In the following week, we observed preferential migration and alignment of ASCs along the grafted channels, with faster migration and higher cell density compared to non-grafted regions. Also, migration speed increased at higher laser power. HUVECs sprouts formed in the regions with a high number of ASCs, both the grafted channels, and the immediate surroundings of the spheroids, where ASCs spontaneously migrated.

We can conclude that the localized modulation of the mechanical and physical properties of gelatin-derived materials through femtosecond laser light is a powerful tool to guide the growth and spatial organization of support stem cells and endothelial cells. The synthesis and selection of appropriate biocompatible materials will be critical for the advancement of this technique.

To solve the problem of vascular access failure, a novel semi-degradable hybrid vascular graft, manufactured by electrospinning using silk fibroin and polyurethane (Silkothane®), was previously developed and characterized in vitro. In this proof-of-concept animal study, we aimed at evaluating the performances of Silkothane® grafts in a sheep model of arteriovenous shunt, in terms of patency and short-term graft remodeling. Nine Silkothane® grafts were implanted between the common carotid artery and the external jugular vein of nine sheep, which were examined by palpation three times per week, by echo-color Doppler every two weeks, and euthanized at 30, 60 and 90 days (N=3 per group). At sacrifice, graft and anastomoses were harvested and submitted for histopathology and/or scanning electron microscopy (SEM). No cases of graft-related complications were recorded in this study. Eight of nine sheep (89%, one case of surgery-related thrombosis excluded) showed 100% primary unassisted patency at the respective time of sacrifice (flow rate 1.76 ± 0.61 L min-1). Histopathology and SEM analysis evidenced signs of inflammation and pseudointima inside the graft lumen, especially at the venous anastomosis, as it typically happens with other grafts; however, endoluminal stenosis never impaired the functionality of the shunt and coverage by endothelial cells was observed. In our model, Silkothane® grafts granted safety and 100% patency up to 90 days, paving the way for possible in situ engineering strategies of vascular accesses for hemodialysis, aiming to enable early cannulation as synthetic grafts and superior long-term performances as native fistulae.

Large defect repair using nerve guidance conduits (NGCs) remains inconsistent (1). To address this, we have developed a filled NGC with an internal matrix consisting of microporous channels infused with macromolecules abundant in nerve extra-cellular matrix (ECM).

NGCs were produced using an outer collagen conduit and an internal matrix of collagen-chondroitin-6-sulphate (Coll-CS) augmented with ECM combinations of fibronectin, laminin I and laminin II. ECM combinations were assessed for growth and inflammatory biomarkers using primary rat dorsal root ganglia (DRG) cultures over 14 days. Following this, large 15 mm sciatic nerve defects were created in rats and lead candidate NGCs were implanted for 8 weeks. This was again assessed at the clinical limits of efficacy in a 30 mm sciatic nerve defect in rabbits at 6 and 12 weeks. Regeneration was assessed using electrophysiology and immuno-histochemistry.

Highly porous and unidirectional NGCs were formed which significantly improved expression of repair and inflammatory cytokines using ex-vivo DRG culture. When lead candidates were progressed to rat models, regenerating tissue was found to be present throughout the NGC and functional recovery was comparable to autograft controls. Similarly, at 6 weeks post-implantation, numerous myelinated axons were found to be present at over 15 mm distance from the proximal nerve in rabbit models.

The pro-regenerative effects of ECM in peripheral nerve repair were highly combination-dependent. Most promisingly, surgical outcomes were found to be comparable to autograft controls using optimised ECM-NGCs

BIOMECHANICAL EVALUATION OF A TISSUE ENGINEERED INTERVERTEBRAL DISC REPAIR PATCH IN AN OVINE MODEL

Mitchell Page[P][1], Christian Puttlitz[2]

[1] *Orthopaedic Bioengineering Research Laboratory and Translational Medicine Institute, Department of Mechanical Engineering, Colorado State University*

Regenerative strategies for repair of the intervertebral disc's (IVD) annulus fibrosus (AF) require the delivery of mechanical stimuli to resident cells as well as reconsolidation of IVD biomechanics. Accordingly, our group has developed an AF repair scaffold using a previously developed biomimetic architecture and fabricated the implants via fused deposition modelling (FDM) of polycaprolactone (approximately 300µm diameter fibers). Functional spine units (FSUs; level four and five) were dissected from eight (n=8) sheep for biomechanical testing in ±6Nm pure moment loading. Each FSU was tested in three conditions: (1) intact, (2) with an 8mm AF defect, and (3) treated with the repair patch. To assess the regenerative potential of the implant, a computational model was used to predict deformation of the implant and subsequent mechanobiological response. The defect group generated significant increases in FSU range of motion and significant decreases in FSU neutral zone stiffness (α=0.05 for all comparisons). In all cases, the treated group recovered some of the deleterious changes induced by the defect. The predicted implant deformations indicated compressive radial and axial strains (-3.2% to -7.5% and -0.4% to -16.9%, respectively) and tensile circumferential strains (0.2% to 5.0%). These results suggest that a FDM implant can restore spinal biomechanics following an annular defect. However, the associated cellular scale mechanics within the implant may not be conducive for regeneration [2]. Overall, in order to tailor the mechanical loading of AF implants, this work suggests that advanced implant designs and novel attachment techniques (e.g., bioadhesives) may be necessary for effective regeneration.

Immunotherapy has emerged as a novel approach to treat cancer utilizing the patient's own immune system that manages to attack effectively cancer cells. Tumors that are naturally infiltrated by white blood cells like brain tumors, melanomas, kidney cancer, lung cancer, and cervical cancer among others have been the obvious targets of immunotherapy approaches. Immunotherapy approaches include treatments that target the immune system checkpoints. The success of immunotherapy treatments have been linked to the successful activation of the patient's immune system and the tumor microenvironment. The tumor microenvironment includes exosomes released by cancer cells. Exosomes are small membrane vesicles originating from the cell cytoplasm that are released to their microenvironment, carrying parts of the cell membrane. T-cells are responsible for many of the cytotoxic responses in the body, but due to hypothesized immunosuppressive properties of the exosomes they can be silenced. We explored the interactions of cancer cell generated exosomes with activated T-cells in traditional 2D flasks and 3D cultures where T-cells were attached on RGD-modified scaffolds in the presence of flow perfusion. IL-2, a common proliferation cytokine, is released by PMA stimulated T-cells, and the response of T-cells can be correlated to their cytokine production. When co-cultured with exosomes from H1299 and A549 cancer cell lines, T-cells showed decreased IL-2 release when increasing the exosomes from a 1:10 ratio to 1:1000 ratio in 3D cultures with flow perfusion rates of 0.15 mL/min. Our system indicated exosome induced immunosuppression and provides an attractive environment to further explore T-cell immunosuppression in vitro.

Caprine species satisfy the conditions of an ideal donor animal when compared to bovine species that has been extensively studied and commercialized for bone xenograft. Histopathological and radiological evaluations of caprine demineralized bone matrix (CDBM) were therefore carried out for fracture healing properties for its possible use in bone grafting. Twenty-four rabbits were divided randomly into three groups of eight (n=8) rabbits each. Critical bone defect was created on the ulnar diaphysis under xylazine-ketamine anaesthesia for autogenous bone graft (ABG) group, CDBM group and the unfilled group as the negative control (NC). Immediate post-grafting radiograph was taken and repeated on days 14, 28, 42 and 56 to monitor the evidence of radiographic healing. The animals were euthanized on day 56 and defect sites harvested for histopathology. There was progressive evidence of radiographic healing and bone formation in all the groups with significance difference (P=0.0064). When compared with ABG, NC differ significantly (P<0.0001) whereas the CDBM did not differ significantly (P=0.6765). The histopathology sections of ABG and CDBM showed normal bone tissue while the NC section was predominated by fibrous connective tissue. There was, therefore, an overall significant difference (P=0.0001) in which CDBM did not differ from ABG (P=0.2946) while NC did (P=0.0005). The ABG and CDBM groups appeared to have the same healing effect in the critical bone defect. Therefore, CDBM could be used as an effective alternative to ABG in orthopaedics to circumvent the limitations and complications associated with it.

AICAR ENHANCES THE PROLIFERATION OF MSCS INITIALLY, BUT IN THE LONG RUN, IT IS ANTI-PROLIFERATIVE!

Mesenchymal stem cells (MSCs) are limited by the number of passages in-vitro due to aging (1). In our recent study (2), we used 5-Aminoimidazole-4-carboxamide ribonucleotide (AICAR) and nicotinamide (NAM) to attenuate the senescence of MSCs. We demonstrated that AICAR and NAM retain the proliferative capacity of cells lost after prolonged in-vitro culture. To further evaluate the effect of AICAR and NAM on the proliferation of MSCs, we performed MTT assay on passage-10 MSCs, ten days after cell seeding. Our results show that while cell proliferation was increased with NAM treatment ($p<.05$), AICAR significantly inhibited the growth of the cultured cells ($p<.05$) compared to the untreated cells.

To further discuss our findings, as we presented in our study (2), AICAR, NAM, and their combination dramatically increased the number of cells after seven days. However, as we further culture MSCs in the presence of AICAR, the cell density drops after ten days, indicative of the anti-proliferative effect of AICAR after extended in-vitro culture. This observation might be in light of the higher apoptosis rate in AICAR-treated cells. To elucidate, the percentage of Annexin-V positive cells was almost two times that of the untreated cells, and approximately three times higher than the NAM-treated cells. This most likely happens due to a molecular switch between autophagy and apoptosis; if autophagy cannot prevail the damages, then apoptotic mechanisms terminate that cell (3,4). In other words, while AICAR augments autophagy in MSCs to prevent senescence, it increases the rate of apoptosis, as well.

In extrusion-based bioprinters, the stable formation of filaments and high-fidelity deposition of bioinks are the primary challenges in fabrication of physiologically relevant tissue constructs. The two-step crosslinking of Gelatin-Methacryloyl (GelMA), reversible thermal gelation and permanent photo-crosslinking, has attracted researchers to make complex tissue constructs. Despite promising results in filament formation and printability of this hydrogel, the effect of temperature on physicochemical properties, cytocompatibility, and biodegradation of the hydrogel needs to be investigated. The results of 3D printing of GelMA at different temperatures followed by an irreversible chemical photo-crosslinking show that the decrease in temperature improves the filament formation and shape fidelity of the deposited hydrogel, particularly at the temperatures around 15 °C. Time dependant mechanical testing of the printed samples revealed that decreasing the extruding temperature increases the elastic properties of the extruded filaments. Furthermore, our novel approach in minimizing the slippage effect during rheological study enabled us to measure changes in linear and nonlinear viscoelastic properties of the printed samples at different temperatures. A considerable increase in storage modulus of the extruded samples printed at lower temperatures confirms their higher solid behavior. Scanning electron microscopy revealed a remarkable decrease in porosity of the extruded hydrogels by decreasing the temperature. Chemical analysis by Fourier-transform infrared spectroscopy (FTIR) and circular dichroism (CD) showed a direct relationship between the coil-helix transition in hydrogel macromers and its physical alterations. Finally, biodegradation and cytocompatibility of the extruded hydrogels decreased at lower extruding temperatures.

Corresponding author's email: mohsen.janmaleki@ucalgary.ca

Electrospinning is known as an efficient and straightforward approach to fabricate of extremely thin fibers from a rich variety of polymers. Unpredictable deposition of generated nanofibers has limited its applications for precise and reproducible biomaterial fabrications. In this study, a magnetic field-assisted approach has been introduced and its practicality has been evaluated through mathematical modelling. The developed model was employed to study the behavior of the generated polymeric jet numerically using the Runge-Kutta method. The jet was assumed to consist of a number of discrete charged particles connected by viscoelastic segments. The results showed that exerting an appropriate magnetic field (MF) could significantly decrease the radius and the instability of the whipping circles. After fixing the instability as far as possible, it was demonstrated that a properly applied perpendicular MF could largely adjust the target of the polymer jet on the collector.

In this symposium, we will introduce our original biofabrication system called "Kenzan method" including the first clinical results of blood vessel regeneration done in Saga university hospital, and other pipelines which are getting closer to clinical application.

As far as we know, this would be the world first clinical application made with scaffold-free bio 3D printing system.

3D BIOPRINTING COMPLEX TISSUE MODELS FOR DRUG SCREENING

Stephanie Willerth[P][1]

[1] *University of Victoria*

Corresponding author's email: willerth@uvic.ca

3D bioprinting can create living human tissues on demand based on specifications contained in a digital file. Such highly customized, physiologically-relevant 3D human tissue models can screen potential drug candidates as an alternative to expensive pre-clinical animal testing. The Willerth lab has developed a novel fibrin-based bioink for bioprinting neural tissues derived from human induced pluripotent stem cells (hiPSCs), which can become any cell type found in the body. Our team uses Aspect Biosystem's novel RX1 bioprinter featuring Lab-On-a-Printer™ (LOP) technology as it enables us to fabricate complex structures found in healthy neural tissues. We were the first group to use this cutting edge bioprinter to generate tissues from pluripotent stem cells. The microfluidic LOP™ printhead cartridges generate cell-containing hydrogel fibers of defined diameters that are precisely deposited into defined 3D structures using a sheath fluid that triggers hydrogel cross-linking of the bioink. The sheath fluid also insulates cells within the fiber from shear stress, protecting fragile primary cells from shear-induced cell death. This process allows us to maintain high levels of viability (>90% post printing) not previously seen in the literature. Here I will discuss the latest work from our group detailing the composition of our 3D bioprinted tissues and our new spin-off company - Axolotl Biosciences.

Introduction:

Age-related macular degeneration (AMD), according to world health organization, ranks the third leading cause of vision impairment and further causes irreversible blindness. This AMD disease mainly results from the dysfunction of retinal pigmented epithelium (RPE). Fortunately, transplanting human pluripotent stem cells (hPSCs)-derived RPE can serve as regenerative approach to cure AMD disease. However, RPE derived from hPSCs usually suffers from insufficient purity, long culture period and low yield. Therefore, we compared different protocols and cell culture extracellular matrices (ECMs) to investigate which conditions would be the most suitable for hPSCs to differentiate into RPE progenitors.

Method:

We first selected and compared the protocols, (i) N2 protocol [1] and (ii) NIC+CTM protocol [2]. After we found the better protocol, we tried different substrates to culture and induce differentiation of hPSCs into RPEs. We evaluated neural marker of PAX6 expression by using immunostaining and flow cytometry assay to find the best condition for hPSCs to differentiate in to RPE progenitors.

Results and Discussion:

According to epidermal marker of PAX6 analysis from immunostaining and flow cytometry assay, we found NIC+CTM protocol showed the better performance of hPSC differentiation into RPEs compared to N2 protocol. Subsequently, we found the optimal xeno-free culturing surface that could be applied for massive production of high purity of RPE progenitors in NIC+CTM protocol. We are planning to use the same protocol to further investigate the most appropriate substrate for differentiation into mature RPEs, which can benefit AMD patients for clinical treatment.

PROSTAGLANDIN E2 INDUCES SKIN AGING BY E-PROSTANOID 1 RECEPTOR IN NORMAL HUMAN DERMAL STEM/PROGENITOR CELLS

JOONG HYUN SHIM[P][1]

The production of collagen type I is decreased during aging, leading to skin wrinkle and impaired function. PGE2, a lipid derived signaling molecule derived from arachidonic acid by cyclo-oxygenase, inhibits collagen production and induces MMP1 expressions by fibroblasts in vitro. The inhibition of collagen expressions and the promotion of MMP1 by PGE2 have been accepted as the aging mechanisms. I demonstrated that EP1 plays an important role in PGE2 signaling in normal human dermal stem/progenitor cells (hDSPCs). When EP1 expression was suppressed with EP1 siRNA, there were no significant changes in mRNA levels of COL1A1/MMP1 between siRNA-transfected hDSPCs and siRNA-transfected hDSPCs with PGE2. These results show that EP1 is a receptor for PGE2. The phosphorylation of ERK1/2 after PGE2 treatment significantly increased. In addition, the exposure of hDSPCs to PGE2 triggered an increase in intracellular Ca2+ concentrations. These results means that the PGE2 is directly associated with the EP1 receptor pathway-regulated ERK1/2 and IP3 signaling in hDSPCs.

During bone regeneration, innate immune cells not only directly differentiate into osteoclasts to get involved in bone remodeling, but also affect the osteoblastic cell recruitment, migration, and osteogenic differentiation to establish bone formation. This information encourages us to consider immune cell implementation for bone regeneration. On the one hand, immune cells are plastic and sensitive to the local environment1, which provides the potential to modulate the microenvironment to manipulate the immune system in a favorable manner for enhanced bone repair and regeneration. On the other hand, due to the easy isolation procedure and high yield of immune cells2, immune cells have great practical potential to be directly utilized in cell-based approaches given reduced cost and (absence or short time of) in vitro expansion procedures.

In view of this, we investigated the potential to modulate the immune microenvironment by material properties such as roughness and stiffness and by particular cells such as MSCs. Both titanium surface roughness and hydrogel stiffness with or without MSCs positively affected the surrounding immune cell composition and cell phenotype. More importantly, we elucidated the function of macrophages and osteoclasts in bone formation and explored to promote osteogenic differentiation and bone formation by co-culturing and co-seeding MSCs with these immune cells. We also demonstrated that osteoclasts rather than MSCs or macrophages initiated the bone regeneration process, which offered subversive insights into functions of osteoclasts in the biological context of bone regeneration and opens up a new dimension for designing and preparing cell-based constructs for bone regenerative treatment.

INTRODUCTION: Over the past years, biofabrication techniques offer the potential to produce structurally-ordered tissues with new and interesting approaches [1]. Different natural polymers have been studied as bioink for additive manufacturing. Bioinks should be able to be extruded through a thin needle, to retain a three-dimensional (3D) structure and to create a cytocompatible environment. However, their high solubility, high degradation rate and low mechanical properties limit their use. Different chemical strategies have been pursued to endow these materials with a shear thinning behaviour and improve the mechanical properties. In this study, gelatin and gellan-gum were chemically-modified and bioprinted to produce 3D scaffolds.

METHODS: Gelatin and gellan-gum were methacrylated to obtain GEMA and GGMA, respectively. The bioinks were characterized in terms of physico-chemical and rheological behaviour. 3D scaffolds were obtained by processing GGMA. Double network scaffolds were produced by combining GGMA structures with GEMA and alginate. Morphological, mechanical and biological performances were evaluated.

RESULTS: Scanning Electron Microscopy highlighted scaffolds were able to retain their well-ordered structure without collapse in the Z direction. Both kinds of structures showed improved mechanical properties. Furthermore, confocal images demonstrated cells initially adhered as agglomerates and then a spreading was observed.

CONCLUSIONS: The obtained results demonstrated the potential use of these bioinks for tissue engineering applications.

Interest in mesenchymal stem cell derived extracellular vesicles (MSC-EVs) as therapeutic agents has dramatically increased over the last decade. Preclinical studies show that MSC-EVs have anti-apoptotic and neuroprotective effects, boost wound healing, and improve the integration of allogeneic grafts through immunomodulation. Current approaches to the characterization and quality control of EV-based therapeutics include particle tracking techniques, Western blotting, and advanced cytometry, but standardized methods are lacking. In this study, we established and verified quartz crystal microbalance (QCM) as highly sensitive label-free immunosensing technique for characterizing clinically approved umbilical cord MSC-EVs enriched by tangential flow filtration and ultracentrifugation. Using QCM in conjunction with common characterization methods, we were able to specifically detect EVs via EV (CD9, CD63, CD81) and MSC (CD44, CD49e, CD73) markers and gauge their prevalence. Additionally, we characterized the topography and elasticity of these EVs by atomic force microscopy (AFM), enabling us to distinguish between EVs and non-vesicular particles (NVPs) in a therapeutic formulation. This measurement modality makes it possible to identify EV sub-fractions, discriminate between EVs and NVPs, and to characterize EV surface proteins, all with minimal sample preparation and using label-free measurement devices with low barriers of entry for labs looking to widen their spectrum of characterization techniques. Our combination of QCM with impedance measurement (QCM-I) and AFM measurements provides a robust multi-marker approach to the characterization of clinically approved EV formulations and opens the door to improved quality control.

Introduction

Low back pain is strongly associated with degeneration of the intervertebral disc (IVD). During IVD disc degeneration the central nucleus pulposus (NP) is broken down, due to altered matrix synthesis, increased degradation and cell. It has been proposed that the reinjection of Notochordal (NC) cells, are thought to have substantial therapeutic effects in mediating disc regeneration and restoring disc biomechanics. This study investigates the characteristic and behavioural changes of NC cells when cultured over a two-week period within our pNIPAM hydrogel system; otherwise known as NPgel.

Methods

Notochordal cells were extracted from porcine IVDs and incorporated into NPgel. The NC cell and NPgel constructs were cultured for up to two weeks under 21% and 5% oxygen. Histological, immunohistochemical and scanning electron microscopy (SEM) analysis was performed to investigate NC cell viability and altered matrix synthesis.

Results

SEM analysis revealed that NC cells can survive in the NPgel after two weeks under 5% oxygen. Additionally, from analysing the characteristics and phenotype of NC cells, we have found they survive in clusters. Further to this we will determine the expression of NC markers.

Conclusion

NC cells maintain their phenotype in vitro when encapsulated into our novel NPgel scaffold. The delivery of NC cells within NPgel into the degenerate IVD has potential for IVD regeneration.

The composite consisting of a Polyvinylidene fluoride (PVDF) matrix with cobalt ferrites (CFO) nanofiller is one of the most common and effective polymeric magnetoelectric systems. The aim of this work was to produce this composite in the form of microspheres that could be applied for the electro-mechanical stimulation of cells in culture. Microfluidics offer the possibility of high reproducibility and size tunability. A flow-focusing polydimethylsiloxane (PDMS) device was fabricated based on a 3D printed polylactic acid (PLA) master. The device was used to produce microspheres between 79 and 330µm. To obtain an electric response under a magnetic field, processing PVDF into electroactive beta-phase is a mandatory condition for its electroactive behavior. Since processing takes place at a temperature below 60ºC beta-phase crystallization is favored (75%) avoiding the need, time and hassle of post-processing thus producing magnetoelectric microspheres in a one-step approach. Magnetic properties and high encapsulation efficacy of 80% were confirmed by vibrating-sample-magnetometry (VSM). Microstructure and nanoparticle distribution was assessed by scanning electron microscopy (FESEM) and through focused-ion-beam (FIB). Background: Osteoarthritis (OA) is a multifactorial pathology and comprises a wide range of distinct phenotypes (1). In this context, the characterization of the different molecular profiles associated with each phenotype can improve the classification of OA for better therapies. In particular, OA can co-exist with type 2 diabetes mellitus (T2DM). This study investigates lipidomic and proteomic differences between human OA/T2DM- and OA/T2DM+ cartilage through a multimodal mass spectrometry approach.

Methods used: Human cartilage samples were obtained after total knee replacement from OA/T2DM- (n=10) and OA/T2DM+ patients (n=10). Label-free proteomics was employed to study differences in protein abundance and matrix-assisted laser desorption/ionization (MALDI) mass spectrometry imaging (MSI) for spatially resolved-lipid analysis.

Results/central findings: Label-free proteomic analysis showed differences between OA/T2DM- and OA/T2DM+ phenotypes in several metabolic pathways such as lipid regulation. Interestingly, the phospholipase A2 protein was found overexpressed within the OA/T2DM+ cohort. In addition, MALDI-MSI experiments revealed that phosphatidylcholine and sphingomyelin species were characteristic of the OA/T2DM- group whereas lysolipids were more characteristic of the OA/T2DM+ phenotype. The data also pointed out differences in phospholipid content between superficial and deep layers of the cartilage.

Conclusion: Our study shows distinctively different lipid and protein profiles between OA/T2DM- and OA/T2DM+ human cartilage, demonstrating the importance of sub-classification of the OA disease for better personalized treatments.

Human pluripotent stem cells (hPSCs) are a promising source of cells for tissue regeneration. However, histocompatibility of the transplanted cells remains a major challenge to their clinical application where human leukocyte antigen class (HLA) Ia (HLA-A, -B, -C) molecules are the primary mediators of immune reaction. There are many alleles in the HLA genes. Therefore, it is extremely hard to match the same HLA expressions from two different people. It is necessary to establish patient-specific stem cell line or stem cells bank having specific human leukocyte antigen (HLA) to avoid immune response of the patients.

Universal induced pluripotent stem cells (hiPSCs) were established without gene editing, which were reprogrammed from human amniotic fluid stem cells with mixing two allogenic donors; these cells do not or less express human leukocyte antigen (HLA) class Ia (HLA-A, -B, and -C) and class II even after differentiation into cardiomyocytes, embryoid bodies (progenitor cells derived from three germ layers), and mesenchymal stem cells (universal hiPSCs). Cardiomyocytes differentiated from universal hiPSCs survived and continued beating even after treatment with allogenic mononuclear cells derived from different amniotic fluid (AF) donors.

We consider that the mechanism underlying the generation of universal hiPSCs is that fetal stem cells contain a specific group of cells that do not express HLA class Ia and class II but may express HLA-G, PD-L1 and/or CD47, which are expressed in baby tissue to avoid immune rejection with her mother, after the cells are reprogrammed into hiPSCs and subsequently differentiated into tissue cells.

TREATING OBESITY BY ENHANCING FAT THERMOGENESIS WITH NON-VIRAL GENE DELIVERY OF VEGF

Ramyar Chavoshinejad$_P$[1], Michael E Symonds[2], James E. Dixon[1]

Obesity, in which excess body fat accumulates, is the leading preventable cause of death. Metabolic syndrome, with comorbidities such as type-2 diabetes, high blood pressure, and circulating cholesterol and triglyceride also increases the negative effect of excess adipose tissue on health. The browning of white adipocytes would be an innovative intervention to treat these types of metabolic disorders.

We are pioneering the use of non-viral gene therapy to 'convert' white adipose tissue (WAT) to a beige/brown thermogenic, 'energy burning' phenotype. Previous studies have shown that enhanced Vascular endothelial growth factor (VEGF) activity in WAT can induce beige characteristics (Mitochondria and Uncoupling protein-1 (UCP1) abundance). We are therefore adapting our glycosaminoglycan (GAG) binding enhanced transduction (GET) gene therapy system for safe programming of fat to beige characteristics either by in situ delivery or modified autografts. Initially, we have developed a tractable model for adipogenesis, and transdifferentiation to test GET-VEGF gene delivery using human mesenchymal stem cells (MSCs), which can be successfully differentiated to both types of mature adipocytes. Presently, we are testing the influence of known factors to induce beiging, such as cold or caffeine compared to VEGF gene delivery. We characterise the adipocytes generated with immunostaining, gene expression analyses, and mitochondrial seahorse assay to assess their phenotype and thermogenic potential.

Improvements in diet, and exercise are of course necessary to reduce the obesity-related disease epidemic. However, regenerative medicine strategies through patient cell programming could promote transition to balanced metabolism and treat one of the most presentable causes of early death.

Fragility fractures are the main consequence of osteoporosis and their treatment remains a challenge in the orthopedic field. Evidences demonstrate that an impaired periosteal activity is responsible for recurrent fractures. Hence, we suggested the development of a natural-based regenerative membrane fixing biological active capsules for periosteum regeneration purposes. A laminarin hydrogel was microfabricated with suitable mechanical properties and adequate resorbable times for bone regeneration. The membrane acted as on-site fixing agent for biological active capsules and is expected to be implanted by wrapping the membrane around the defect to guide bone regeneration. Alginate liquified capsules were produced via electrohydrodynamic spraying,[1,2] and comprised i) microparticles for cell adhesion and for the transport of osteogenic-differentiating factors, and ii) a cell niche of ASCs and HUVECs. Then, layer-by-layer was performed using 3 different polyelectrolytes until a 10-layered membrane was created. Methacrylated laminarin (MeLam) hydrogels were produced by bringing a solution of MeLam in contact with an optimized PDMS master, followed by UV irradiation. [3] Capsules with optimized sizes were entrapped within the micropillars of the membrane achieving higher entrapments when capsules diameters matched the micropillars spacing. In vitro osteo- and angiogenic potential was assessed in the individual components and after their conjugation (membrane+capsules). The bioactive membrane was also placed in contact with a fibroblast cell monolayer where membrane integration was achieved. In brief this bioactive membrane is expected to induce regional bone formation and an overall stimulation of bone regeneration.

Decellularised heart valves are a promising option for heart valve replacement. A terminal sterilisation method is required to enhance the clinical translation of these novel decellularised biological scaffolds and assure patient safety. Supercritical carbon dioxide (ScCO2) is a robust sterilisation technique that is ideal for the application on biomaterials [1]. Within this study, the impact of ScCO2 sterilisation, supplemented with oxidising agents, on the biological and biomechanical properties of decellularised pulmonary heart valves (PHVs) was explored. There were no observational differences within the histoarchitecture and the microscopic structures of the ScCO2 treated PHVs in comparison to decellularised PHVs, and no reduction in the collagen content. There was, however, a significant reduction in the thermal stability of the ScCO2 treated PHV tissue, significant increase in the elastin phase slope and ultimate tensile strength biomechanical parameters, and poor cytocompatibility. The presence of residual oxidising agents which may be responsible for the cytotoxicity, which may be avoided by rinsing the tissue graft prior to in vitro testing [2]. Therefore, this study concludes that ScCO2 is still a promising sterilisation option for the application on soft tissues.

ADAPTABLE HYDROGELS FOR ORGANOID CULTURE

Sarah Heilshorn[P][1]

[1]*Stanford University*

Corresponding author's email: heilshorn@stanford.edu

While organoid culture has the potential to revolutionize our understanding of human biology, current protocols rely on the use of Matrigel, a complex, heterogeneous material with large batch-to-batch variations that hinder reproducibility. In response, several groups have begun designing synthetic hydrogel systems to enable the reproducible culture of organoids. Recently, the matrix stress relaxation rate (i.e. the ability of a hydrogel to remodel its network connectivity in response to an applied stress) has been demonstrated to have profound effects on encapsulated cells. To date, the role of matrix stress relaxation on organoid cultures has not been explored. Here we present the design of a family of double-network hydrogels that undergo two stages of crosslinking: the first stage uses reversibly dynamic covalent chemistry bonds, while the second stage reinforces the hydrogel through thermal-induced polymer aggregation. This double-network of physical interactions results in a gel a broad dynamic range of tunable mechanical properties, where the gel stiffness is set by the number of crosslinks and the gel stress relaxation rate is independently set by the kinetics of the crosslink binding and unbinding. These novel, double-network hydrogels have been used to study the role of mechanotransduction in the culture of patient-derived, human intestinal organoids. In this system, we find that the organoid cultures display strong phenotypic responses to matrix stress relaxation, which are dependent on cell-matrix interactions with both CD44 and integrin cell-surface receptors.

The mechanosensitivity of osteocytes is affected by their microenvironment, which is changed in metabolic bone disease. However, the native calcified matrix makes the study of osteocytes technically difficult. We aimed to develop a 3D-human osteocyte model to study mechanosensitivity of osteocytes in their native matrix under physiological or pathological loading. Osteocyte viability, osteocyte-specific gene expression, and microdamage under well-defined loading magnitudes was determined.

Small human bone pieces (8x3x1.5 mm; surgical waste) were physiologically (1000 -3000 με) or pathologically (>3000 με) loaded for 5 min by sinusoidal displacement using a micromover. Osteocyte viability was quantified 24 h after loading by LDH staining. Loading-induced microdamage was quantified in BaSO4-stained bone using micro-computed tomography. Besides mechanoresponsiveness, osteocyte responsiveness to 10-7 M 1,25-dihydroxyvitamin D3 for 24 h was assessed.

Loading magnitude (2302-13811 με) or micromover displacement and reaction force exerted by bone were linearly related. Osteocyte viability was not affected by physiological mechanical loading, while pathological loading caused cell death. Microdamage was increasing with increased loading magnitude (2500-7500 με). Osteocytes were responsive to 1,25(OH)2D3, i.e. GALNT3 was downregulated, while CYP24, as well as E11, SOST, and FGF23 gene expression were upregulated.

In conclusion, we developed a 3D-mechanical loading model of osteocytes in their native matrix that allows the application of defined physiological loading magnitudes to human bone while maintaining cell viability without causing microdamage. This model would be useful for studies on osteocyte mechanosensitivity in human metabolic bone disease.

Mesenchymal stem cells (MSCs) are well known to hold great potential to support hematopoietic stem cell (HSC) growth and self-renewal. However, when isolated from their specialized microenvironment in vivo, termed the stem cell niche, both MSCs and HSCs lose their regenerative capacity and niche phenotype. The niche provides both physical and functional regulatory cues that control cell-intrinsic and cell-extrinsic processes, which is a major challenge to be recapitulated in culture. Here, using poly (ethyl acrylate) (PEA) polymers, we develop a high-throughput platform to closely represent main compartments of the bone marrow niche and dissect their roles on MSC fates simultaneously. PEA coated surfaces promote spontaneous unfolding of the ECM proteins Fibronectin (FN) and Laminin (LM), leading to physiological-like nanonetwork formation that exposes key cell- and growth factor (GF)- binding domains. The GF binding domain allows the presentation of ultralow doses of niche GFs, such as bone morphogenetic protein 2 (BMP-2), nerve growth factor (NGF) and C-X-C motif chemokine 12 (CXCL12) to cells alongside a synergistic integrin-binding site1,2. Using this novel high-throughput platform, we assess the combined effects of ECM, GFs as well as hypoxia/normoxia on MSCs behaviours, unveiling the optimal niche conditions to direct MSCs towards HSC-support phenotype in culture. This material-based system provides a high throughput approach to rapidly and efficiently test multiple combinations of biochemical and mechanical niche cues on cell fate regulation. Such novel improved niche-like model could be further utilized to investigate the fundamental mechanisms that control self-renewal in both MSCs and HSCs in the niche.

Cancer stem cells (CSCs, cancer-initiating cells) are responsible for cancer proliferation and show stronger resistance than other cancer cells under conventional cancer therapy. Precision medicine shows positive effect for cancer patients treatment. Therefore, isolation of patient specific primary cancer cell line is important for precision medicine screening. However, CSCs typically comprise 1%–5% of the total tumor cell population. It is hard to distinguish CSCs from other cells in primary tissue. Thus, we have been developing a membrane filtration method to target CSCs and establish primary colon cancer cell line.

This membrane filtration method was performed via Nylon mesh filter or poly(lactic-co-glycolic acid)-silk screen membranes. The primary colon cancer cells were isolated by several steps including washing, mincing and digesting and the cancer cell solution was permeated through these membranes. CSCs and colon cancer cells were characterized using CSC surface marker expression, colony forming assay and expression of carcinoembryonic antigen (CEA) using ELISA assay. We also analyzed colon cancer cell lines using this method as a model of primary colon cancer tissue solution.

This purification method using membrane filtration method has been successfully verified using Lovo cancer cell line and the cells showing high level expression of CSCs marker (CD133, CD44) were isolated where CSC markers were analyzed using flow cytometry. We expect to establish patient specific colon cancer cell line by the membrane filtration method with different pore size, affinity and biocompatibility. This method is a promising approach, which can be applied for precision medicine screening in the future.

It was our aim to develop human tubular bone models to simulate the structural composition and physiological processes as closely as possible to those in natural bone. Taking into account the complexity of natural mammalian bone, we followed a consecutive bottom-up assembly approach using directional electrospinning and drop on demand bio-printing. To mimick bone homeostasis we focused on custom-made bioinks containing stimulated monocytes (hMoCD14+-PD) to form osteoclasts and hMSC derived osteoblasts. 3D bone mimicking constructs were produced by alternating drop on demand layers and pre-cultured for three weeks. Bilayered periosteum was prepared by directional electrospinning of a growth factors enriched medical grade biopolymer. Afterwards fibroblasts and endothelial cells were co-cultered in the bilayered scaffold for two weeks. Assembled multi-cellular tubular constructs were cultivated in a custom-made bioreactor using minimal medium for up to two month. The constructs were IHC stained and analyzed. Mikro-CT over time, SEM-EDX and TEM examinations of the bony constructs were performed. After complete structural, cellular and biochemical characterization of this tubular bone, custom-made 24-well plates were loaded with these specimen, biomaterials to be tested were implanted and then dynamically cultivated for different time periods. To assess in vitro biocompatibility, a comprehensive panel of analyses was used. With the help of this model, significantly fewer animal experiments will be required in the future for the preclinical evaluation of new implant materials, designs or modifications.

This project has received funding from the European Union's Horizon 2020 research and innovation action under grant agreement No. 814495-EVPRO (www.evpro-implant.eu).

Tissue engineers have been working to develop strategies for enthesis regeneration. The patellar (PT), Achilles (AT), and Rotator cuff (RC) tendons are the most relevant sites of injury. We aimed to characterize their entheses concerning genetic signature and biomechanics in rats. RC showed the highest tangent modulus and lowest ultimate strain. This relationship was inverse for AT. PT showed always an intermediate value for both properties. The gene signature was studied for >150 ECM and osteogenic genes. Clear differences were observed. AT showed an upregulation of relevant genes compared to the PT and RC entheses, including collagens (Col I, II, IV, V), BMPs, cadherins, and metalloproteinases. This correlates with the highest ultimate strain obtained for the AT. RC enthesis yielded the lowest overall expression of ECM genes except for the upregulation of Col I and tenascin-C, while PT showed a strong downregulation of osteogenic genes compared to AT and RC. The expression levels for scleraxis and tenomodulin followed the order RC>AT>PT and AT>PT>RC, respectively. The expression of tenomodulin was higher than scleraxis for all the entheses. Interestingly, PT showed the highest difference between tenomodulin and scleraxis expression. Array-based gene expression was validated by qRT-PCR for relevant genes. The data collected here provide valuable insights into the genetic profile of the enthesis in three different anatomic localizations, and their correlation with biomechanical properties. Our results indicate the PT enthesis as optimal localization for an in vivo regeneration model. Furthermore, these data highlight relevant genes that must be stimulated to achieve regeneration.

Coronary diseases affect millions worldwide and are commonly treated with a bypass using autologous tissue, usually from the saphenous vein or the internal thoracic artery. These procedures may induce secondary site morbidity and are not always possible due to insufficient tissue availability. Currently developed tissue engineered grafts rely on lengthy culture periods, which are costly and not always off the shelf. It is for these reasons that in situ tissue engineering approaches are gaining interest. These scaffolds are intended to be implanted acellularly and encourage the body to repopulate and remodel them over time.

In this study we have fabricated scaffolds by Additive Manufacturing of PCL onto a rotating mandrel. The tubular structures were produced with variety of fiber alignments by modifying the extruder speed and increased fiber roughness via sodium hydroxide etching. These scaffolds supported the adhesion and proliferation of HUVECs and hMSCs differentiated into vascular smooth muscle-like cells. Cells repopulating the media layer aligned along the fibers and laid their own extracellular matrix and the intima layer consisted of a fully endothelialized lumen. To improve the mechanical properties of these constructs, an external layer was added with sine auxetic patterns, which intend to replicate the crimped collagen in the vessel wall. Furthermore, a pro-angiogenic hydrogel based on supramolecular non-covalent binding of alginate was used to emulate the adventitia layer. Future work will focus on the introduction of bioactive cues to the scaffolds to promote endogenous cell recruitment upon implantation.

Organs-on-chip offer the opportunity to recreate a variety of biological niches1. However, most materials used to fabricate these systems do not replicate the physical and chemical properties of the native environment. Self-assembly represents an attractive route to develop more biologically relevant materials2 with enhanced modularity, tuneability, and structural hierarchy. Here, we report an elastin-like protein (ELP)-graphene oxide (GO) self-assembling and biofabricated fluidic device with biologically relevant properties for organ-on-chip applications3.

This ELP-GO co-assembling system integrates advantages of self-assembly and additive manufacturing to develop capillary-based fluidic devices exhibiting a series of physiological chemical and physical properties such as no need of toxic cross-linker, stable for at least 1 month, and generating tubular networks down to 10 µm in internal diameter, 2 µm in wall thickness. The liquid-in-liquid process is cell-friendly and facilitates bioprinting, resulting in fluidic structures (assessed via in vitro and ex vivo experiments) that can withstand pulsatile flow immediately after bioprinting. Taking advantage of the self-assembling process, we demonstrate the capacity to tune capillary porosity and permeability by varying the content of GO percentage and cell density and demonstrate that the capillaries exhibit a Young Moduli ~500 kPa. We have also standardized the 3D printing process by optimizing the parameters of 3D printer.

The study introduces an innovative way to grow fluidic devices by self-assembly. This device may offer potential applications in the field of biomedicine such as tissue engineering scaffolds, microfluidic systems, and organ-on-chip devices.

Introduction: Regenerative rehabilitation is an emerging area of regenerative medicine that is raising interest in cancer and orthopaedics. It was recently discovered that mechanically stimulated osteocytes appear to protect the bone against breast cancer metastasis (1). Aiming to further understand how osteocytes may protect bone from cancer, we decided to analyse the transcriptome of human and mouse osteocytic cells after a single bout of mechanical loading. Insights from this study could help the development of regenerative rehabilitation protocols aiming to avoid bone cancer progression.
Methods: The murine osteocytic cell line MLO-Y4 (Kerafast) was cultured according to the supplier instructions. Human stem cells (ATCC) were expanded and differentiated into osteocyte-like cells (hOC) following the manufacturer instructions. Cells were cultured in a computer-controlled bioreactor (Flexcell Int) under cyclic stretch (3.4%, 2Hz, 5h). Samples were analysed by RNA sequencing (Illumina NovaSeq 6000). Differential expression analysis between stretched cells and static control was performed using the DESeq2 R package.
Results: RNA-seq detected ~13,000 gene products in the murine cell line MLO-Y4 and ~14,000 in hOC. A comparative analysis across human and mouse osteocytic cell lines evidenced that the transcriptome was quite distinctive between the two. KEGG analysis of the human transcriptome identified as potential mechanosensitive signalling pathways, FoxO, cell cycle, DNA-repair and cancer, whereas examination of mouse identified, TNF, cytokine-cytokine receptor interactions, PI3K-AKT, Jak-STAT and HIF-1.
Conclusion: Several pathways related to cell cycle, DNA-repair and cancer were found significantly enriched in mechanically stimulated hOC. Functional studies are necessary to confirm a cancer protective effect.

SURFACE FUNCTIONALISED BIOMATERIALS AND NANOSTRUCTURES FOR ADVANCED THERAPIES

Nuno M. Neves[P][1]

[1] *3B's Research Group/University of Minho*

Corresponding author's email: nevesi3bs@gmail.com

Many biomaterials were proposed to produce porous scaffolds, nanofibers and nanoparticles for different medical treatments and applications. Systems combining natural polymers and synthetic biodegradable polymers are particularly adequate for those demanding applications. Those biomaterial systems can be tailored with enhanced mechanical properties, processability, cell-friendly surfaces and tunable biodegradability. Our biomaterials may be processed by melting or solvent routes into devices with wide range of applications such as biodegradable scaffolds, films or particles and adaptable to many biomedical applications.

Non-woven meshes of polymeric ultrafine fibers with fiber diameters in the nanometer range can be produced by electrospinning. Those meshes are highly porous and have a high surface area-to-volume ratio and can mimic the structure of the extracellular matrix of human tissues and can be used as scaffolds for Tissue Engineering (TE). There is a great interest in developing also nanoparticles and hydrogels from those polymeric systems for injectable treatment modalities. All those structures can be used as substrates for specific surface functionalization having fine-tuned biological properties. This strategy enables developing highly controlled devices for exposure, capture and, if needed, inactivation of biological biomolecules relevant for novel treatment modalities in various disease conditions.

This talk will review our latest developments in biomaterials, nanoparticles and nanofibre meshes in the context of novel therapeutic applications.

Human mesenchymal stem cells (hMSCs) are a promising cell source in clinical trials which can protect host tissues from graft-versus-host disease (GVHD). However, hMSC treatment faces limited passage numbers of hMSCs. The goal of this study is that we develop a suitable xeno-free condition protocol of human pluripotent stem cells-derived hMSCs (hPSC-MSCs) and screen the extracellular matrix (ECM) effect for finding appropriate ECM-coated surface for MSC differentiation. In this study, we modified the differentiation protocol [1] of hPSCs-MSCs by using inhibitors. We changed the protocol of the usage of ECM from xeno-containing Matrigel to five different xeno-free ECMs, including recombinant vitronectin, laminin-511, laminin-521, fibronectin, and collagen, and analyzed the characterization of MSCs from morphologies, MSC surface markers expression (CD44, CD73, CD90, and CD105), and tri-lineages differentiation.

We found that Laminin-521 and Collagen type I were the top two biomaterials for hPSCs differentiation into hMSCs. Comparing to the hPSC morphology, hPSC-MSCs have already become spindle shapes morphologies. The result of the cells cultured on these two conditions showed better double cells population and the highest MSC marker expression. Therefore, Laminin-521 and Collagen type I coated surfaces are considered to be the most reliable and xeno-free cell culture substrates for hPSC-hMSCs differentiation.

We are evaluating the differentiation ability of hPSC-MSCs into tri-lineage differentiation. We will further analyze the human leukocyte antigen (HLA) expression after hPSC-MSCs are treated with mononuclear cells to evaluate the protective effect from GVHD. We expect that our hPSC-MSCs can be widely applied for regenerative medicine in the future.

CULTURES AND CURES: NEURODIVERSITY AND BRAIN ORGANOIDS

Andrew J. Barnhart[P][1], Kris Dierickx[1]

[1] *Centre for Biomedical Ethics & Law KU Leuven*

Corresponding author's email: andrew.barnhart@kuleuven.be

Research with cerebral organoids is beginning to make significant progress in understanding the etiology of Autism Spectrum Disorder (ASD). Yet in doing so, researchers often incorporate the medical model of disability into the conceptual framework of their research, with a specific aim of potentially finding personalized treatments for individuals with ASD. The neurodiversity movement – a developmental disability movement that understands autism as a form of natural human diversity – will potentially disagree with approaches or aims of cerebral organoid research on ASD, since these advocates incorporate the social model of disability into their movement. Therefore, a potential conflict may arise between these perspectives over how to proceed with cerebral organoid research in regard to neurodevelopmental conditions. Here, we present these perspectives and give recommendations to achieve a more holistic and inclusive approach to cerebral organoid research on ASD.

IRON NANOPARTICLE-LOADED HYDROGELS AS FUNCTIONAL COMPOSITE MATERIALS FOR 3D BIOFABRICATION

Christoph Rehbock[P][1], Yaya Li[1], Stephan Barcikowski[1]

[1] *Technical Chemistry I and Center for Nanointegration Duisburg-Essen, University of Duisburg-Essen, Essen, Germany*

Corresponding author's email: christoph.rehbock@uni-due.de

Nanocomposites constitute an interesting class of materials for tissue engineering , where the embedding of nanoparticles into a biocompatible polymer adds novel functionality and hence, improves viability and proliferation of relevant adhered cells. Our group has developed an elegant method for the fabrication of nanocomposites based on laser ablation in liquids in polymer and monomer solutions, yielding nanocomposites with outstanding purity and biocompatibility [1]. In previous works we could already demonstrate improved cytocompatibility of these materials through two separate pathways I) local changes in surface charge and stiffness [2] and II) Release of metal ions [3].

In our most recent work we focused on alginate and PEG hydrogel-based biomaterials loaded with iron nanoparticles. We examined the mechanism of metal ion release from these biomaterials and could find a significantly enhanced adhesion of model serum proteins to the biomaterial surface, which, interestingly already occur at very low nanoparticle loadings (< 0.1 wt%). This seems to indicate a mechanism based on locally elevated iron ion concentrations. [4] We further verified the suitability of these materials for 3D bioprinting applications where the nanoparticles had no adverse effects on printability. [3] [4] These findings were complemented by recent examinations with hematopoietic stem and progenitor cells in 2D and 3D culture. Here we found a significant influence of iron nanoparticles in the biomaterial on the early stage of in vitro erythropoiesis relevant for applications in in vitro blood farming.[5]

Introduction: Chronic wounds represent a major burden in human society, with high costs associated with extensive care treatments. Research has focussed on the development of new wound healing devices. However, a device that enables fast-effective closure, low cost, and scalability is still missing.

Ions such as calcium and zinc are essential for skin homeostasis. Calcium regulates a plethora of skin vital functions. We have shown that calcium releasing platforms such as calcium phosphate nanoparticles (NPs) stimulate in vitro and in vivo wound healing [1,2]. On the other hand, zinc deficiencies are associated with impaired wound healing. zinc's antimicrobial properties make this ion a potential substitute for antibiotics.

This work aims to develop different ion releasing platforms based on nanocomposites for local and sustained ion release at the wound site.

Methods: NPs incorporating Zn2+ and Ca2+ were synthesized by double emulsification, nanoprecipitation and sol-gel synthesis. Ion release was measured by colorimetric methods. NPs were encapsulated in 3D printed gelatine scaffolds.

Results: NPs were synthesized with diameters ~300 nm and narrow size dispersity. Both ions were successfully incorporated into the carrier NPs. Scaffolds showed good particle distribution. The release of zinc ions showed enhanced antibacterial activity.

Discussion and Conclusion: Ion releasing platforms were successfully produced. Their composition, size, and ion release profiles indicate their potential use in soft tissue applications such as wound healing therapies.

Acknowledgments: This work was supported by the Spanish Ministry and the EuroNanomed3 program through the project nAngioDerm

IN SITU DETECTION OF INFECTIONS IN BURN WOUNDS BY DIAGNOSTIC HYDROGEL WOUND DRESSINGS

Arn Mignon$_P$[1], Josefien Schietse[1], Manon Minsart[1], Sandra Van Vlierberghe[1], Peter Dubruel[1]

[1] Polymer Chemistry & Biomaterials Research Group, Centre of Macromolecular Chemistry (CMaC), Ghent University, Krijgslaan 281, S4 bis, 9000 Gent, Belgium

In Belgium, around 120 000 people suffer from burns yearly. Burns still remain a major clinical challenge, mainly due to bacterial infection. Nowadays, infections are diagnosed by removing the wound dressing followed by wound sampling and sample analysis. In situ detection of infection by means of a color signal can alert health care staff in an early state and improve clinical outcomes. In the current work, different acrylate endcapped urethane based precursors (AUP) were combined with diagnostic compounds. AUP with a poly(ethylene glycol) backbone molar mass of 20 kg/mol (AUP20k) was combined with three cross-linkers (pentaerythritol tetraacrylate, ethylene glycol diacrylate and AUP2k) in different double bond ratios (1:1 and 1:4). AUP20k hydrogels with the crosslinker AUP2k in a 1:1 double bond ratio revealed to have the most optimal mechanical and swelling properties. These had an absorption capacity of 32±1.6 times its own weight and a gel fraction of 80.2±4.1%. Moreover, their compressive modulus in dry and wet state was 52.4±1.0 kPa and 35.7±3.0 kPa respectively. Subsequently, the potential of Ellman's reagent and bacteria-responsive liposomes to induce a color signal upon bacterial infection was investigated. Both the Ellman's reagent and the bacteria-responsive phospholipid liposomes with the self-quenching dye 5(6)carboxyfluorescein were successfully incorporated in the hydrogels. Especially the latter showed great diagnostic potential as a fluorescent yellow signal of the hydrogel was demonstrated and quantified by colorimetry upon simulation of infection. Hydrogel wound dressings with a controlled diagnostic potential can thus early identify infections and better control the healing of burn wounds.

CHITOSAN-BASED SELF-HEALING HYDROGEL FOR LIVER TISSUE ENGINEERING

Yu-Chai Tai[P][1], Yung-Te Hou[1]

[1] *Biomechatronics Engineering, National Taiwan University*

Corresponding author's email: R08631014@ntu.edu.tw

Chitosan-based hydrogels are suitable material for liver tissue engineering (LTE) owing to the similar mechanical property to native liver tissue. However, liver contains a large number of resident immune cells, which may interfere the gelation ability of highly positive-charged, chitosan-based hydrogels in vivo study. For the purpose mentioned above, we developed an injectable, chitosan-phenol (CP)-based self-healing hydrogel in this study. CP hydrogels constructed by Schiff base linkage could have responsive shape-memory ability. Besides, they could also be injected into organism without any unexpected degradation due to the in vivo influence. Primary rat hepatocytes encapsulated in CP hydrogels was carried out as an in vitro platform for evaluating cytotoxicity and hepatic functions. Our results revealed that CP hydrogels significantly enhanced the hepatocyte viability by 12.68 fold comparing to collagen hydrogels at day 5. Refer to our previous study, liver extracellular matrix (LECM) was added in CP hydrogels to create suitable microenvironment and sustain the phenotype of encapsulated hepatocytes. Interestingly, albumin synthesis of hepatocytes encapsulated in CP-LECM hydrogels was improved by 1.13 fold comparing to CP hydrogels without LECM at day 5.

In summary, CP-LECM hydrogel as a 3D culture environment can effectively enhance the viability and functions of hepatocytes. Besides, injection of self-healing hydrogels only needs simple preparation and the good biocompatibility as well as automatic reparability of self-healing hydrogel under physiological conditions also show promising potential in LTE. The dual utility of CP-LECM hydrogel may have high potential for future clinical application.

NOVEL MICROFLUIDIC PROTEIN PATTERNING TECHNIQUE FOR ORGANS-ON-CHIP APPLIED TO THE FABRICATION OF A FUNCTIONAL LIVER MODEL

Erika Ferrari[1], Giovanni Stefano Ugolini[1], Marco Rasponi[1]
[1] *Department of Electronics, Information and Bioengineering. Politecnico di Milano. Via Golgi 39, 20133, Italy*
Corresponding author's email: erika1.ferrari@polimi.it

It is well known that controlling cell-cell interactions and localization in in vitro models is paramount to better recapitulate patho-physiological conditions of human organs [1]. For instance, liver models based on micropatterned co-cultures (MPCCs) can maintain higher hepatic functions for several days in vitro compared to standard culture techniques [2]. Despite their micrometer resolution, so far MPCCs have been used in standard multi-well plates or glass substrates only. Indeed, protein patterns have never been integrated in permanently bonded microfluidic systems, thus limiting their application in miniaturized organs-on-chip models. Here we developed a novel technique that allows culture and analysis of MPCCs within a microdevice specifically designed for liver-tumor compartmentalized cultures. HepG2 cells and 3T3 fibroblast were seeded the liver compartment of the platform to generate MPCCs and HCT-116 colon cancer cells were seeded in the tumor compartment. The device was validated for pharmacokinetic-based drug screenings involving diffusion of the anticancer drug Tegafur (UFT, 100 µM) after liver metabolism (UFTL) and LIVE/DEAD observations at 24, 48 and 72h validated the hypothesis that UFT was converted into the toxic metabolite 5-Fluorouracil (5FU) by MPCCs in the liver compartment, exerting then the toxic effect on HCT-116 cells.

A MECHANICALLY ACTIVE 3D GUT-ON-CHIP TO STUDY INTESTINE-MICROBIOME-TUMOR INTERACTIONS

Mattia Ballerini[P][1,2], Carlotta Catozzi[2], Paola Occhetta[1], Luigi Nezi[2], Marco Rasponi[1]

It is now evident that the gastrointestinal bacteria contribute in shaping the immune system in both physiological and pathological conditions [1]. Traditional in vitro and in vivo co-culture models suffer from intrinsic limitations [2-3]. 3D-microfluidic culture systems may overcome these limitations, because they recreate complex multicellular architectures in a finely controlled dynamic environment [3-4].

In early gut-on-chip devices, relying on 2D cellular monolayers seeded on thin porous PDMS membranes, peristalsis-like mechanical actuation demonstrated to play a crucial role in model maturation [3]. More recently, the recapitulation of a 3D microenvironment proved increased faithfulness to the in vivo condition in terms of shape, functionality, and polarity [5].

Here we report a novel gut-on-chip device combining for the first time a 3D architecture with a controlled mechanical actuation. The device contains 3 independent culture units. Each unit is composed by two chambers: a cell culture compartment, containing epithelial and vascular layers separated by ECM gel, and an actuation chamber. Once the pressure in the actuation chamber increases, a controlled uniaxial strain (10%, 0.15Hz) is transferred to the epithelium layer, enhancing its maturation. Complex microbiota communities collected from healthy and pathological tissues were introduced in the gut-on-chips to evaluate the influence of different bacterial consortia on intestinal epithelium integrity.

In parallel, we developed a tumor-on-chip device consisting of patient-derived tumor spheroids embedded in ECM gel and different therapies were tested on-chip. The two modules will be integrated to study the role of gut microbiota in shaping immune system and anti-tumor therapy.

Allogeneic (unrelated donor) stem cells including bone marrow derived mesenchymal stem cells (MSCs) and induced pluripotent stem cells (iPSC) have emerged as a novel therapy for cardiac regeneration. The outcome of initial allogeneic stem cells based clinical trials was encouraging. There were no major side effects observed after transplantation of cells and implanted cells were able to improve cardiac function. However, the overall enthusiasm of lately has come down due to failure of long-term survival of transplanted cells in the recipient heart. We have performed extensive investigations to understand the mechanisms of poor survival of transplanted stem cells in the heart and demonstrated that after transplantation in the ischemic heart stem cells turn immunogenic and are rejected by host immune system. In our ongoing studies, we are interested in developing strategies to prevent immune-rejection and improve survival of transplanted stem cells in the heart. We synthesized and characterized 0D titanium carbide (Ti3C2) MXene quantum dots (MQDs). We found that MQDs possess intrinsic immunomodulatory properties and selectively reduce activation of human CD4+IFN-γ+ T-lymphocytes while promoting expansion of immunosuppressive CD4+CD25+FoxP3+ regulatory T-cells in a stimulated lymphocyte population. Furthermore, MQDs are biocompatible with MSCs and iPSC. Next, MQDs were incorporated into a chitosan-based hydrogel to create a 3D platform for stem cell delivery to the heart. This composite immunomodulatory hydrogel-based platform improved survival of stem cells and mitigated allo-immune responses. These findings suggest that this new class of biomaterials may bridge the translational gap in biomaterial and stem cell-based therapies for cardiac regeneration.

Posterolateral spinal fusion (PLF) is a therapeutic approach used for treatment of various orthopedic indication including degenerative disc disease, spondylolisthesis, spinal instability and symptomatic scoliosis. In this study we evaluated usage of a novel autologous bone graft substitute (ABGS) containing rhBMP6 (in two doses, 125 and 250 µg) in autologous blood coagulum (ABC) with synthetic ceramic particles (TCP or BCP) as compression resistant matrix (CRM). ABGS implants (4 per group) were implanted bilaterally between transverse processes of the lumbar vertebrae (L5-L6) following exposition and decortication in 8 New Zealand White Rabbits. Outcome of the spinal fusion was analysed after 14 weeks by microCT analyses, biomechanical testing (three-point bending test) and histologically. Successful spinal fusion was achieved in all samples. MicroCT analyses revealed that neither chemical composition of particles nor BMP dose did not affect the amount of newly formed bone. However, amount of unresorbed CRM was significantly higher in groups containing biphasic ceramics than pure TCP. Histological analysis revealed that successful osseointegration of newly formed bone with adjacent transverse processes was achieved in all specimens. Moreover, we have found that fused bone had superior biomechanical properties compared to properties of ABGS containing the same ceramics as CRM on week 7 and allograft on week 14. In this study the use of a novel ABGS formulations in a rabbit PLF model promoted the spinal fusion in rabbits and should be furher explored on larger animals.

Recreating the healing microenvironment of bone tissue is of paramount importance to ensure the success of implantable materials. In this regard, surface biofunctionalization with integrin-binding molecules combined with growth factor derived sequences stands out as a promising approach [1-2].

Herein, the synthesis of a multifunctional peptidic platform, composed of the cell adhesive RGD peptide and the DWIVA sequence, derived from the wrist epitope of BMP-2 [3], and its application to diverse biomaterials, is presented.

Preliminary experiments with C2C12 myoblasts on glass model substrates demonstrated the ability of the biomimetic interface to enhance cell adhesion, their transdifferentiation capacity to the osteoblastic lineage and BMP-2 dependent signaling through a Smad-independent pathway [4]. These results were further supported by human mesenchymal stem cells (hMSCs) studies, in which cell adhesion and mineralization were enhanced in comparison to the controls [4]. Interestingly, the translation of this strategy to clinically relevant biomaterials, such as titanium and hydrogels, was successfully performed. In detail, the MSC behavior on both biomaterials was assessed by means of cell adhesion, proliferation and osteodifferentiation (ALP activity, mineralization and gene expression) [5]. Due to satisfactory results, in vivo experiments were also done: coated titanium screws were implanted on rat calvaria, to assess osteointegration, while the functionalized hydrogels were used to evaluate stem cell mineralization and bone formation on a non-osseous ectopic environment in mouse [5].

In summary, our experimental data proved the feasibility of our strategy and highlights the potential of biomimetic peptides on bone tissue engineering.

The main contributors of the immunological response towards an implant are monocytes and monocyte-derived macrophages (MDM), cells that are highly sensitive to material features such as surface structure, chemistry and wettability.

By adopting different polarization states, such as inflammatory (M1), regenerative (M2a) or fibrotic (M2c), MDMs can substantially influence the healing process around an implant.

However, existing methods that can comprehensively analyze the molecular response of these cells towards an implant are invasive and in most cases marker-based. Aggressive treatments to detach adherent cells such as scraping or digestion with enzymes alter the cell surface proteins, impair cell viability and ultimately limit the ability to accurately characterize adherent cells.

Raman spectroscopy is a marker-independent, non-invasive imaging method that allows the analysis of either fixed or living cells without the need for staining or processing. It is a powerful tool to localize and characterize biochemical components such as proteins, lipids and nucleic acids in single cells, making it an ideal method to reveal differences in the chemical composition of MDM subsets.

In this work, in vitro cultured human MDMs were polarized towards M1, M2a and M2c and analyzed by Raman spectroscopy.

Our findings reveal major differences across donors between MDM subtypes and provide new insights into physiological differences between macrophage polarization states. In addition, we could show that Raman spectroscopy can be employed on MDMs adherent to common implant materials to further characterize MDM-material interaction in vitro.

LONG-TERM MECHANICAL LOADING IS REQUIRED FOR THE FORMATION OF 3D BIOPRINTED FUNCTIONAL OSTEOCYTE BONE ORGANOIDS

Jianhua Zhang$_P$[1], Marsel Ganeyev[1], Anna-Katharina Zehnder[1], Anke de Leeuw[1], Gian Nutal Schädli[1], Julia Griesbach[1], Marina Rubert[1], Ralph Müller[1]

Organoids are 3D in vitro culture systems derived from self-organizing stem cells, which have been rapidly applied to understanding stem cell biology, organogenesis, and various human pathologies. However, developing an in vitro 3D osteogenic organoid that supports osteoblast-osteocyte differentiation and mimicks the in vivo conditions has not been achieved yet. Here, 3D bioprinted human mesenchymal stem cells (hMSC)-laden graphene oxide composite scaffolds were cultured in cyclic-loading bioreactors for up to 56 days to investigate the influence of mechanical loading on development of an osteogenic organoid. Our results showed that mechanical loading significantly enhanced collagen I maturation with a higher percentage of matured collagen I, fiber width and length. Mechanical loading from day 1 (ML01) significantly increased early cell proliferation, cell spreading morphology (day 31), scaffold mineral density (day 49 and 56), stiffness (day 56), as well as osteocalcin gene and protein expression (day 56) compared to non-loading (NL) and mechanical loading from day 21 (ML21). Importantly, ML01 stimulated osteocyte differentiation with significantly more osteocyte-related genes (DMP1 and SOST) and higher osteocyte-related proteins (PDPN and SOST) expression at day 56 than NL and ML21. Meanwhile, mechanical loading up-regulated YAP expression in the cytoplasm and extracellular matrix. Our results demonstrate that mechanical loading and loading initiation time play a critical role in the regulation of self-organizing osteogenic organoid formation exhibiting high mineralization and a co-culture of differentiated osteoblasts and osteocytes. Such 3D osteogenic organoids may serve as a human-specific alternative to animal testing for the study of bone pathophysiology and drug screening.

Despite advances, myocardial infarction (MI) remains a leading cause of death in western countries [1]. Current treatments act to curb symptoms and progression of the eminent scar tissue but a true tissue engineering platform is challenging due to the low regeneration potential of the myocardium. Electroconductive biomaterial scaffolds and electrical stimulation can improve the differentiation of progenitor stem cell sources into cardiomyocytes and the maturation of cardiac engineered organoids that could realise more effective therapies [2].

In this study, poly (3,4-ethylenedioxy thiophene):polystyrenesulfonate (PEDOT:PSS) was functionalized with a novel combination of stabilizing molecules and processed into three-dimensional scaffolds using freeze-drying. The optimization of different manufacturing parameters resulted in highly porous constructs with tailored dimensions and aligned or isotropic micro-architecture that could be created repeatably with ease. In particular, three-dimensional electroconductive scaffolds showed biomimetic anisotropy typical of the human myocardium, in terms of mechanical and electrical features within ranges that meet that of the myocardium to induce myogenic maturation [3, 4]. These platforms were seeded with cardiomyocytes and incorporated into a custom-made electrical pacing bioreactor for investigation of the effects of scaffold features and field direction on cells orientation and tissue maturation via fluorescent imaging and quantitative assays . Finally, the combination of these electroconductive substrates with a biologically derived component generated a biohybrid platform able to perform as an optimal substrate for cardiac tissue engineering applications.

Keywords

Three-dimensional electroconductive scaffolds; Cardioinductive matrix; PEDOT:PSS

MESENCHYMAL STEM/STROMAL CELLS IN CLINICAL TRIALS: CRITICAL ANALYSIS OF BIOLOGICAL CHARACTERISATION AND ITS IMPLICATIONS FOR REGENERATIVE MEDICINE

Alison Wilson[P][1], Emma Rand[1], Andrew Webster[1], Paul Genever[1]

[1] *University Of York*

Corresponding author's email: ajw638@york.ac.uk

We analysed the extent of characterisation data reported in mesenchymal stem/stromal cell (MSC) clinical trials. In this widely used and heterogeneous cell type, the extent of data defining identity, purity and functionality of the investigational medicinal product (IMP) is extremely variable.

Our dataset of 84 clinical studies covered reports from 27 countries across 35 indications. 64% of trials were Phase 1, 33% Phase II and 2% Phase III. MSC characterisation was absent in 32 studies (38.1%). The majority (41 studies, 48.8%) reported average values per cell surface marker for all cell lots used in the trial, with 11 (13.1%) studies reporting actual values for each cell lot. 48 studies (57%) discussed cell viability. Although multi-potency is a key characteristic of MSCs, only 29% discussed osteogenesis, with chondrogenesis being assessed in 20% of studies. Potency assays were addressed in 7 papers. Extent of characterisation was not related to clinical phase of development.

A subset of markers recommended by the International Society Cell and Gene Therapy Society (ISCT)[1] for identification of MSCs formed the most frequently reported characteristic: CD45 in 56 studies, CD105 (51 studies), CD90 (49 studies), CD34 and CD73 (48 studies). Overall, only 62% of the studies reported critical attributes of the IMP.

Characterisation of the IMP was poorly established in this dataset. The term “MSC” is insufficient to define key attributes including identity, purity and biological activity: we strongly recommend that clinical trial papers report a minimal level of consistent characterisation data to enable assessment of results in context.

ENGINEERING AN EX-VIVO PERFUSION-BASED BIOREACTOR SYSTEM FOR DRUG-TESTING ON PATIENT-SPECIFIC CANCER SPECIMENS

Corresponding author's email: manuele.muraro@usb.ch

INTRODUCTION: Close mimicking of pathophysiological features of diseased tissue is key for drug discovery and precision medicine. Ex-vivo models represent a promising possibility to assess patient-specific drug response, allowing the preservation of cancer, stromal and immune cells, and tissue extracellular matrix. Here, we developed perfusion bioreactor-based engineered models able to culture patient-derived cancer tissues and to test the sensitivity to chemotherapies in use for breast and colorectal cancer.

METHODS: Freshly excised tissue specimens fragments were inserted between two collagen type-I sponges and cultured for up to 10 days in a perfused-based system. Static and perfused cultures are compared on proliferation (Ki67), apoptosis (cC3), and maintenance of the cellular components (EpCAM, Vim, CD45) via histomorphological analysis. In a second step, hormonal (Fulvestrant), or anti-proliferative (5FU) treatment was tested.

RESULTS: We observed cellular and architectural cancer tissue maintenance over 14 and 5 days with breast1 and colorectal2, respectively, allowing clinically relevant tissue responses and the study of the interactions between stromal, immune and cancer cells under different treatment regimes.

CONCLUSION & FUTURE PERSPECTIVE: In the era of personalized medicine, ex-vivo culture of cancer tissue represents a promising approach to generate clinically relevant responses to drugs or immunotherapy strategies, which 2D cultures cannot mimic. We will further develop the bioreactor to investigate the influence of bone microenvironment on metastatic process and to be fit for smart throughput drug-testing on patient-derived ex-vivo tumor samples.

ACKNOWLEDGEMENT: This project is funded by EU's Horizon2020 research and innovation programme under the Marie Skłodowska-Curie GA No 860715.

TRILINEAGE POTENCY OF HUMAN NUCLEUS PULPOSUS CELLS BEFORE AND AFTER CRYOPRESERVATION

Andreas Croft$_P$[1]

[1] *Tissue Engineering for Orthopaedics & Mechanobiology (TOM), Department for BioMedical Research (DBMR) of the Medical Faculty of the University of Bern, University of Bern, Bern, Switzerland.*

Corresponding author's email: andreas.croft@dbmr.unibe.ch

Recently, various progenitor cells have been found within the nucleus pulposus (NP) of human intervertebral discs (IVD). However, little is known about the effect of expansion and cryopreservation on here called “heterogenic” human NP cells (hNPCs) and their stemness. Therefore, we aimed to expand hNPCs while investigating their differentiation potential before and after cryopreservation and to find an optimal approach to cryo-preserve them.

HNPCs were obtained from six patients undergoing spinal surgery. Cells were then differentiated into osteogenic, adipogenic or chondrogenic lineages for 21 days or were cryo-preserved for one week at -150°C with five different cryopreservation media to compare their effect on the cell’s viability and differentiation potential. Cell viability was determined by cytometry using propidium iodide. The differentiation potential was assessed using qPCR and histology.

HNPCs showed the presence of lipid droplets and upregulated adiponectin (up to 3,000-fold). Furthermore, cells cultured in chondrogenic medium expressed up to 1,000-fold more collagen type 2 and released up to 13% more glycosaminoglycans into the supernatant than controls. However, osteogenic differentiation was less pronounced and was subjected to large donor variability. Nevertheless, calcium deposits were occasionally visible. After cryopreservation, the hNPCs’ cell viability was comparable for all five tested cryopreservation media (~82% cell viability) and cryopreservation did not significantly affect the cell’s stemness.

HNPCs can differentiate into a chondrogenic lineage and more unexpectedly, also into an adipogenic and partially osteogenic lineage. Furthermore, all five tested cryopreservation media seem to perform the same in terms of cell viability and maintaining hNPCs' stemness.

ELECTROSPUN 3D OPEN-NETWORK SCAFFOLDS SUPPORT PENETRATION AND VIABILITY OF TRABECULAR MESHWORK CELLS

Devon Crouch[P][1], Carl Sheridan[1], Raechelle D'Sa[2], Lucy Bosworth[1]

In 2020, an estimated 76 million people will be diagnosed with glaucoma, which remains the second leading cause of irreversible blindness worldwide1. The trabecular meshwork (TM) - a highly porous tissue located in the anterior chamber of the eye - drains fluid from the eye, which thus maintains intraocular pressure. However, the TM can become blocked, which raises this pressure and causes compression of the optic nerve, ultimately leading to sight loss.
Electrospun scaffolds closely mimic the porous 3D architecture of TM tissue and can be further tailored to influence depth of cell penetration and material properties, such as stiffness. Conventional electrospinning was compared to cryo-electrospinning (mandrel collector containing dry ice). Poly(ε-caprolactone) yielded fibres of comparable diameter (0.64±0.14 µm conventional vs. 0.56±12 µm cryo) but significant changes to the tensile stiffness were observed (4.12±1.50 MPa conventional vs. 0.79±0.41 MPa cryo). Yet, cryo-scaffolds remained handle-able. Human TM cells adhered and proliferated on both scaffolds but stayed localised to the outer fibre surface for conventional scaffolds, whereas cells penetrated to 54% of the total depth for cryo-scaffolds after 7 days in culture. Further studies will continue to optimise a scaffold that is supportive of TM cell function that may be used in a reproducible in vitro model and as a potential tissue-engineered device to restore and regenerate the TM, and hence prevent the onset of glaucoma.

VISCOSITY MATTERS: VISCOELASTIC HYDROGELS DRIVE CHONDROGENESIS OF MESENCHYMAL STEM CELLS

Matthew Walker$_P$[1], Marco Cantini[1]

[1] *Centre for the Cellular Microenvironment, University of Glasgow, UK*

Corresponding author's email: matthew.walker@glasgow.ac.uk

While the stiffness of elastic hydrogels has been long recognized to determine human mesenchymal stem cell (hMSC) differentiation, viscous interactions are only recently emerging as powerful regulators of stem cell fate (1). Indeed, viscoelastic hydrogels, where mechanical stresses relax over time, have been shown to promote hMSC spreading and proliferation, as well as formation of an interconnected bone matrix from osteoblasts. On the other hand, elastic hydrogels can inhibit cell proliferation and, in the case of chondrocytes, limit cartilage matrix formation (2). Hydrogels can also be functionalized with peptide motifs to improve hMSC attachment, as well as influence cell fate: for example, chondrogenesis can be controlled by peptide gradients using integrin receptor RGD and cadherin ligand HAVDI (3). However, investigations into how the viscoelastic properties of hydrogels influence the chondrogenic differentiation of hMSCs are lacking. In this work, we investigate whether viscoelastic hydrogels, functionalized with specific peptide combinations, can provide a cellular microenvironment conducive to the chondrogenic differentiation of hMSCs. We designed RGD-functionalized polyacrylamide hydrogels with variable viscous properties and consistent elasticity and we found that an increase in viscosity promoted the expression of both early and late chondrogenesis markers, while preventing chondrocyte hypertrophy, via the modulation of mechanosensitive pathways (adhesion proteins, YAP and nuclear lamins). Promotion of cadherin ligation via HAVDI/RGD functionalization of the gels further affected mechanotransduction and promoted chondrogenesis. Finally, translation of these optimal chondrogenic gel properties to biodegradable polyethylene glycol hydrogels demonstrated that increased substrate viscosity promotes enhanced 3D chondrogenesis by hMSCs.

The long-term function of biohybrid implants (e.g. heart valves) is significantly related to the production of the extracellular matrix (ECM) with regard to the quantity and quality. The integration of a load oriented textile structure into the implant serves as (i) a biomimetic reinforcement and (ii) a guide for the direction of growth of the ECM. There is an urgent demand for suitable models to simulate the implant under in vitro and in vivo conditions and to further support the design planning phase.In the presentation, we will focus at first on the constitutive modeling of growth and remodeling of ECM. The densities of collagen and elastin are treated as internal variables. Additionally, anisotropic growth is considered by means of a multiplicative decomposition of the deformation gradient into an elastic and a growth part. The textile reinforcement causes macroscopically anisotropic behaviour which is taken into account by means of structural tensors. The entire constitutive framework is embedded into a special finite element technology which enables the efficient computation of thin structures like heart valves. The contribution ends with a finite element simulation of an idealized heart valve. The results are compared with experimental data available at BioTex (Institute of Applied Medical Engineering, RWTH Aachen University, Germany).

In articular cartilage, the collagen arcades provide the tissue with its extraordinary mechanical properties. As these structures cannot be restored once damaged, functional restoration of articular cartilage defects remains a major challenge. We report that the use of a reinforced osteochondral implant, based on a gelatin methacryloyl cartilage phase, reinforced with precisely patterned melt electrowritten polycaprolactone micrometer-scale fibres in a zonal, cartilage-mimicking fashion, can provide long-term mechanically stable neo-tissue in an orthotopic large animal model. Interestingly, the cell-free implants, used as a control in this study, showed abundant cell ingrowth and similar favourable results as the cell-containing implants. Our findings underscore the hypothesis that mechanical stability is more determining for the success of the implant than the presence of cells and pre-cultured extracellular matrix. This observation is of great translational importance and highlights the aptness of advanced 3D (bio)fabrication technologies for functional tissue restoration in the harsh articular joint mechanical environment.

Articular cartilage defects are common and current surgical treatments provide sub-optimal tissue repair. Multiple biofabrication approaches have tried to recreate the chondral architecture in biochemical and structural composition and this has frequently been combined with an osteal anchor in the form of an osteochondral plug. In this study, the translation from this relatively small plug to larger clinically-relevant and patient-specific implants is explored. Osteochondral patient-specific large (surface area = 469 mm2) implants consisted of a porous bone component, close cartilage-to-bone interface, and a microfibre reinforced cell-laden gelatin methacryloyl (gelMA) cartilage component. The effect of implant size (bone component only) on stress-strain distribution and cartilage-like tissue formation is studied by means of axial compression and compression under 50° and 60° flexion angles using a robotic arm system. The implant stiffness decreased with increased implant size. An increase in size of the cartilage component (from 6 mm diameter discs to 24 mm diameter discs) did not hamper cartilage-like tissue formation in vitro. As the larger implants include a patient-specific complex shaped geometry, a software tool has been developed and validated to automatically generate a numerical control programming language (i.e., g-code) that resurfaces a bone structure with melt electrowritten (MEW) microfibres based on a 3D-standard tessellation language (.STL) file. As a proof of principle, a large complex shaped implant was fabricated and cultured in vitro to assess 3D matrix distribution. This study shows the first steps in translating from osteochondral plugs to larger patient-specific implants.

Various structural cues present in the extracellular matrix (ECM), e.g. topography and ligand distribution, have been shown to influence cell behavior and function [1]. Until now, these structural cues are studied using single-cue platforms that lack the complexity of the multi-cue ECM. In order to overcome this limitation, we developed an approach that combines optics-based protein patterning (resembling contact-guidance cues) and lithography-based microfabrication (resembling topographical cues) enabling the high-throughput investigation of multi-cue cellular environments.

We first explored the versatility of the approach in terms of chip material (PDMS, polystyrene) in combination with ECM proteins for patterning (fibronectin, collagen type I and IV, gelatin). In order to investigate cellular responses to the multi-cue substrates, human bone marrow stromal cells and vascular-derived human myofibroblasts were cultured on the physiologically relevant multi-cue environments and cell orientation was quantified. On concave, patterned structures ($1/2500 \leq \kappa \leq 1/125$ µm-1), human myofibroblasts predominantly oriented in the direction of the contact-guidance pattern. In contrast, for myofibroblasts and human bone marrow stromal cells on micropatterned convex substrates with curvatures of $\kappa \geq 1/1000$ µm-1 and $\kappa \geq 1/500$ µm-1 respectively, the majority of cells aligned into the longitudinal direction of the 2.5D features, indicating that cells followed the structural cues from the curvature instead.

These findings reveal non-trivial and non-additive effects of multiple environmental cues on cell adhesion and phenotype. Drawing comparisons from the responses of other cell types (endothelial cells/corneal keratocytes) for which tissue curvature is equally crucial, we will discuss the relevance of this approach for understanding how multiple cues shape cellular response.

With a growing demand for highly effective therapies, more sophisticated tissue-engineered models are required for a better understanding of the fundamental biological processes that underlie regeneration. The state-of-the-art technology of 3D bioprinting has the scope to achieve well-defined biological structures by printing cell-embedded hydrogels or bioinks. One of the main challenges in obtaining fully functional constructs is the lack of optimal bioinks, which not only require good fabrication properties but also a cell-friendly extracellular matrix (ECM)-like microenvironment. Self-assembling peptide hydrogels (SAPHs) are fully defined and nature occurring hydrogels with tuneable mechanical properties. As a result, SAPHs stand as a powerful alternative to existing hydrogels in biofabrication.

Due to the lack of suitable biomaterials for 3D bioprinting applications, this research aims to design SAPHs as advanced bioinks for extrusion-based 3D bioprinting. Printability was assessed for the Manchester BIOGEL family of SAPHs, PeptiGel® hydrogels. Rheological analyses showed that peptide-based hydrogels are shear thinning and recover well under shear stress. Relaxation times fitting revealed the characteristic dynamic times in which our hydrogels recovered following the classical mechanical model. Printability experiments showed PeptiGels® are favourable in enhancing high-resolution constructs and therefore, comparable to materials with good fabrication properties. Furthermore, PeptiGels® were modified with sodium chloride, which tuned the ionic strength and therefore the hydrophobicity of the fibres within the hydrogel increasing its mechanical strength.

Thus far, we have successfully developed and tested peptide-based biomaterial inks. Current work aims to investigate their biocompatibility and potential as prospective cell-embedded bioinks for bone and cartilage fabrication.

Objective:

Large skull bone defects of the cranial vault can result from various reasons. Reconstruction of these defects is performed for protective and aesthetic reasons but is also required for adequate intracranial homeostasis. Autogenous bone has traditionally been used as the material of first choice. Complications like resorption or infection of the bone specimen, or just the extent or complex anatomy of the defect, frequently form the necessity of an alternative. In recent years patient-specific skull implants have become the most valuable alternative. We reviewed our own patient data to assess pre- and intraoperative aspects, complications en experiences in PSI cranioplasty

Methods:

We retrospectively evaluated all patients receiving a PSI between 2004 and 2020 at Maastricht University Medical Center. These cases were analyzed for demographics, perioperative surgical and medical aspects and costs.

Results:

37 consecutive patients receiving PSI cranioplasty were included. Twenty-five patients received PEEK implants and twelve patients received titanium implants. 28 patients have had at least one previous reconstruction. Postoperatively, two patients experienced complications (5.4%). The average costs of a PSI skull implant was €7598 euro (range € 3876 -€10846).

Conclusion:

Treatment of neurocranial defects requires an optimal preoperative planning and intraoperative procedure. The number of complications was relatively low compared to reports in literature. PSI cranioplasty can be regarded as a valuable alternative to the tradional methods of reconstruction and may be seen as the new gold standard.

The increased risk of fragility fractures (fractures that occur from minimal trauma) has recently been recognized as a significant complication of type diabetes (T2D). Given the complexity of diabetes, no single factor or pathway has been identified to govern T2D-induced bone fragility. Recently, factors produced by the adipose tissue, adipokines, have drawn more attention due to often observed fat dysfunction in T2D. In this study, our goal is to create a human micro-adipose (μAD)/micro-bone (μBO) tissue chip, which will provide a model to study the interplay between these two tissues in T2D, and also serve as a high-throughput platform for specialized drug screening. Specially, μAD and μBO tissues are housed in a customized bioreactor and microfluidically connected to each other. With this novel tissue chip, we hypothesize that the dysfunction of adipose tissues in T2D will result in diminished bone turnover. Given the importance of adiponectin on bone health, we also hypothesize that increasing adiponectin expression by pharmacologically enhancing T2D adipose health will reduce T2D-induced bone fragility. Currently, the normal μADs/μBOs tissue chip has been created from human stem cells, in which μADs and μBOs are able to maintain respective phenotype up to 4 weeks, as confirmed by real time-PCR and histology assay. Currently, we are examining the role of adiponectin on bone health through gain or loss-of-function test. Next, we will investigate the impact of T2D μADs on the health of μBOs, and test the applicability of targeting adipose tissues as a new treatment strategy for T2D-associated bone fragility.

Tumor resection is incomplete in 75% of craniofacial osteosarcoma patients. The remaining osteosarcoma causes tumor-recurrence. There is an urgent need for new treatment modalities to prevent this tumor-recurrence. The aim of this study was to develop an anticancer-drug local sustained-slow-release-system. We incorporated modified-curcumin (mCur) into octacalcium phosphate (OCP), determined release kinetics of mCur from mCur-incorporated OCP (mCurOCP) granules, and tested the effect of mCurOCPgranules on MG63 human osteosarcoma cell growth.

mCur release from mCurOCP granules was assessed at pH7.4 (simulating healthy tissue) and pH6.5 (simulating tumor tissue) up to 6 weeks. Osteosarcoma cells were cultured in the presence of OCP-granules with/without mCurOCP for 48h. Cell number was assessed by light microscopy, and cell metabolic activity by MTT-assay.

A linear relationship was found between the mCur concentration in the calcium phosphate-containing solution and mCur incorporated in mCurOCP (R2=99%). mCur release was significantly higher at pH6.5 (76.4±4.9%; mean±SEM) than at pH7.4 (28.5±1.1%). Cell metabolic activity was not affected by OCP-granules. However, mCurOCP-granules (0.1mg/well) decreased cell density by 2.1-fold. mCurOCPgranules at 0.8mg/well significantly inhibited osteosarcoma cell metabolic activity (8.2±1.3% of control), while 0.05, 0.1, 0.2, and 0.4mg/well had less effect.

In conclusion, our data show that mCur was successfully incorporated in OCP, and mCur was slowly and sustained released from mCurOCP granules, while its release rate was pH-dependent. The inhibitory effect of mCurOCP granules on osteosarcoma cell growth suggests that this innovative anticancer bone-substitute is promising for local application in the surgical area to prevent tumor-recurrence.

Corresponding author's email: r08631039@ntu.edu.tw

Traditional Chinese herbal medicine has been promoted as a new drug for many applications. In this research, we aimed to develop a new application in liver tissue engineering of tannic acid (TA), which is a plant polyphenol commonly used in food chemistry. TA is a nature substance in green tea, and some researches indicated that polyphenols in tea might have some hepatoprotective effect in vitro, but the mechanism of these polyphenols on liver tissue engineering are still unclear. In this study, the benefit of TA for improving hepatics functions and alleviating the hepatotoxicity was investigated in vitro for further clarifying the mechanism of polyphenol.

Results have revealed that: (1) The optimized concentration of TA for enhancing hepatic functions were around 0.5 to 5 μg/mL; (2) TA was effective for hepatocyte culture (relative viability was increased by 10% at day 3; albumin synthesis was increased by 18%from day 2 to day 3; and albumin expression was increased by 210% at day 2) and repaired injured hepatocytes from CCl4 (cytotoxicity was decreased by 40% to 90% when the hepatocytes was treated with CCl4 for 10 to 18 hr, separately).

In conclusion, this study showed that TA have the potential for enhancing the hepatic functions in a specific concentration, furthermore, the hepatocytes injured by CCl4-containing medium (for simulating the toxin-mediated liver fibrosis in vitro) could be recovered to the preinjury state after TA-containing medium treatment. TA may also have promising effects against hepatic fibrosis in vivo.

THE INTERACTION BETWEEN SUN1 AND NUP153 MAY RESULT IN THE TRANSMISSION OF EXTERNAL FORCES TO THE NUCLEAR PORE COMPLEX

Stem cell fate strongly correlates to nuclear morphology. We have previously shown that stem cells cultured in a 3D artificial "nichoid" microscaffold maintain a roundish configuration, a higher level of stemness and a reduced molecular exchange with the nucleus when compared with cells spread on 2D controls [1]. We hypothesize that forces transmitted to the nucleus via integrins, actins, nesprins and SUN proteins affects the nuclear pore complex (NPC) architecture and transcription factor import/export through the nuclear envelope [2]. Here, we investigate the interaction of the nuclear envelope protein SUN1 with Nup153, protein of the nuclear portion of the NPC.

We designed several Nup153 constructs that spanned the entire protein sequence. For SUN1, we identified its nucleoplasmic domain as the region of interest for interaction with Nup153. We tested Nup153-SUN1 protein interactions using Bio-layer interferometry. We detected at least 2 different binding sites in the N-terminal region of Nup153. Neither the C-terminal nor the Zinc-finger domain of Nup153 interacts with SUN1. This result suggests that SUN1 could transmit external forces directly to the nuclear basket at Nup153. These forces may be responsible, at least in part, in a rearrangement of the nuclear basket affecting the molecular flux through the nuclear envelope shown in literature. Our next steps will be to crystallize the SUN1-Nup153 complex to solve its structure and to implement a molecular dynamics simulation able to predict how the force transmission affects the basket architecture.

This project has received funding from the ERC (GA No 646990 – NICHOID)

Electrical Impedance Tomography (EIT) is a prevailing imaging modality that can visualize conductivity distribution in a fast, non-radiative, non-intrusive manner [1]. Recently, it has been identified as a promising technique to monitor the electrical property distribution of 3D cell spheroids and infers their physiological properties throughout the growth [2, 3]. However, the EIT image reconstruction problem is severely non-linear and ill-posed, leading to the issue of low spatial resolution. In the past, the main efforts to improve the spatial resolution of the reconstructed conductivity images have been focusing on regularization-based single-modal methods [4-7] and regularization-based dual-modal or multi-modal methods [8-9]. The latter usually shows better performance but is still far from satisfactory. In this paper, a novel impedance-optical dual-modal sensor and a Multi-Scale Cross Feature Fusion Convolutional Neural Network (MSCFF-CNN) are proposed to improve the spatial resolution of EIT for 3D cell culture imaging. We validate the performance of the proposed method via simulation data and MCF-7 cell spheroids imaging experiments. The results suggest the combination of the dual-modal sensor and MSCFF-CNN outperforms the state-of-art regularization-based methods, which indicate the potential of a new structure-function joint imaging modality for 3D cell culture.

Ovarian cancer is a lethal gynecological disease, histological subtypes of ovarian cancer differ in their biology and clinical behavior. To better understand the behavior of ovarian tumors we are developing an in vitro model that can be monitored noninvasively in a time-lapsed manner to investigate the tumor invasion and eventually response to therapy over time.

Real time live imaging over 5 days was established on a commercial OCT system with novel image processing [1] using non-serous (NS) ovarian cancer cell lines TOV21G and A2780 seeded onto a collagen/fibroblast matrix. Using live OCT imaging we are able to reveal that TOV21G cells invade into collagen with a spindle-like morphology characteristic of sarcomatous tumor cell invasion whereas A2780 invade in clusters characteristic of epithelial tumor cells, in good agreement with histological observation, and how these different invasive patterns develop over time. We developed a pipeline of image processing algorithms that can quantitatively analyze the speed, depth and frequency of invasion over time. The Anisotropic Diffusion (AD) filtering [2] followed by Median filtering [3] can effectively remove speckle noise from the original OCT images and simultaneously preserve the edges. After locating the surface of the gel by Otsu's thresholding [4], a simplified one-dimensional Active Contour Model (s1-ACM) can locate the lower bound of the ovarian cancer layer. The combination of above three steps can automatically segment the ovarian cancer layer in this specific case and allow quantitative time-lapse imaging of its invasion.

A major challenge in nerve tissue engineering and regeneration is the complexity of the nervous system and its associated biological processes. Peripheral nerve injuries (PNIs) less than 5 mm in length self-repair compared with those with wider gaps 1,2. Traditionally, PNIs of 20 mm or less have been repaired either by suturing nerves end-to-end, or by grafting. However, these techniques present surgical and patient recovery drawbacks, prompting the search for better technologies. Nerve guidance conduits (NGCs) have showed promise to mitigate these limitations but are still deficient in supporting satisfactory recovery of PNIs due to poor fit between the NGCs and the local environment. In this work, we have aimed to address this by developing a biomimetic nerve guidance prototype with improved physical and biochemical support for optimal PNI recovery. To achieve this goal, bacterial cellulose (BC) 3 , a versatile hydrogel, and a relatively unexplored family of natural, biocompatible, and bioresorbable polymers called Polyhydroxyalkanoates (PHAs) 4,5 have been produced via microbial fermentation. Our lab has recently optimized the production of PHAs resulting in about 10-fold increase in yield compared to the average values reported in literature. Additionally, a variety of constructs based on computer aided designs (CAD) ranging from multi-channel to internally grooved designs have been successfully 3D printed via fused deposition modelling (FDM) for their initial biocompatibility assessment with NG108-15 neuronal and Schwann cells. Preliminary results from our lab showed that PHAs supported superior neuronal proliferation and neurite extension over some of the commercially available state-of-the-art materials 5.

Esophageal adenocarcinoma (EAC) has a 20% 5-year survival rate despite the current standard of care. EAC progresses in response to microenvironmental change, i.e., chronic gastric reflux and associated inflammation. A primary component of the microenvironment is the extracellular matrix (ECM), which directs cell phenotype by bi-directional crosstalk ("dynamic reciprocity"). The present study evaluated the effect of non-malignant esophageal ECM (eECM) hydrogel, delivered orally in vivo upon carcinoma in situ, without mucosal resection.

EAC developed for 24 weeks in a rat surgical model, and then eECM hydrogel, heterologous urinary bladder matrix (UBM-ECM) hydrogel, or buffer control, was delivered orally, twice daily, for 3 weeks (n=6-7/group). Gastrointestinal physicians who evaluated endoscopic videos before and after treatment were blinded. Five of 7 eECM treated animals, and 5 of 6 UBM-ECM treated animals, showed disease state reversion, while 4 of 6 buffer control animals showed no improvement. In the eECM and UBM-ECM responders, immunolabeling showed macrophages were modulated toward CD68+/TNFalpha+/IL1B+/CD206- compared to buffer control; suggesting a pro-inflammatory response at the tumor region is associated with improved outcome.

The direct effect of eECM and UBM-ECM hydrogel upon esophageal cancer cell (OE33) function and signaling was further investigated in vitro. Both eECM and UBM-ECM inhibited OE33 cell proliferation, and downregulated CD164/CXCR4 upstream of PI3K-Akt. However, only eECM decreased OE33 cell migration and BMP4/Snail2 signaling upstream of epithelial-mesenchymal transition, suggesting an enhanced tissue-specific effect.

The present study supports the use of eECM hydrogel as an alternative, safely tolerated, therapy for EAC that is based upon dynamic reciprocity.

For both in vitro applications and in vivo implantation, there is an enduring need to perfuse the tissue engineered constructs with vascular-like channels, optimized for distribution of nutrient-containing fluids. To address this 'vascular challenge', we explored the use for bioprinting of anatomically realistic patterns derived from macroscopic and microscopic images of human or animal vasculature. Moreover, to assign them organ-specific branching topology, and eventually a vessel size-appropriate cellular composition, we employed the image analysis program VESGEN 2D to assign branch generations to both arborescent and network microvascular fields. Here, we present workflows starting with primary image processing up to direct-write printing with model bioinks, of human ocular fundus, as well as rat mesentery and mouse intestine vascular patterns. For an even more accurate representation, we also generated hemispherical and cylindrical projections of the retinal and intestinal images, respectively. This work paves the way towards the incorporation within bioprinted constructs of anatomically realistic vasculature.

In vitro tumor models consisting of cell spheroids are increasingly used for mechanistic studies and pharmacological testing. However, unless vascularized, the availability of nutrients such as glucose to deeper layers of multicellular aggregates is limited. In addition, recent developments in 'scaffold-free' (cells-only) biofabrication, allow the creation of more complex spheroid-based structures, further exposing the cells within these constructs to nutrient deprivation. To explore the impact of glucose availability on such tumor-like structures, we used the computer simulation platform CompuCell3D. By monitoring the types of cells and the distance between spheroids centers of mass, we studied how binary- and multi-spheroid fusions are impacted by glucose availability. At limiting glucose concentrations mimicking hypoglycemia we noted an abrupt collapse of the tumor spheroids, a process amplified by the contact with normal cell spheroids. At higher glucose concentrations, we found an increased intermixing of cancerous cells, anti-phase oscillations between proliferating and quiescent tumor cells and a structural instability of fusing tumor spheroids, leading to their fragmentation. In a model of tumor microenvironment composed of normal cell spheroids fusing around a tumoral one, the competition for glucose lead to either the tumor's disappearance, or to its steady expansion. Moreover, the invasion of this microenvironment by individual tumor cells also directly depended on the available glucose. In conclusion, we demonstrate the heuristic value of computational simulations for anticipating the properties of biofabricated tumor models, and in generating testable hypotheses regarding the relationship between cancer, nutrition and diabetes.

HARNESSING NATIVE EXTRACELLULAR MATRIX FOR BONE REGENERATION: A COMPREHENSIVE STUDY

Fanny Blaudez[P][1,2]

[1] *Griffith university*

[2] *University of Queensland*

Corresponding author's email: fanny.blaudez@gmail.com

Bone regeneration in the craniofacial area is challenging and tissue engineering strategies have been developed in order to increase efficacy and predictability of osteogenesis. However, these approaches rely on the utilisation of autologous cell sources, associated with high cost, hence detrimental for economically viable clinical translation. In this study, we explored the concept of extracellular matrix (ECM) decoration to enhance the bioactivity of polycaprolactone (PCL) scaffolds manufactured by melt-electrowriting. To this end, scaffolds of various pore sizes were seeded with human primary osteoblasts and cultured for 1, 2 or 4 weeks to allow bone-specific ECM deposition. Mature constructs were subsequently decellularised, resulting in an acellular ECM-decorated scaffold. Matrices were characterised before and after decellularisation and were recellularised to characterise the in vitro behaviour of human primary osteoblasts. Bone healing potential was then assessed in vivo in a rodent calvarial model. The various culture periods demonstrated that ECM composition was significantly impacted by the scaffold porosity and the culture time. ECM-decoration was observed at early time points, gradually mineralising and leading to obstruction in smaller pores. This influenced cellular infiltration and metabolic activity of reseeded cells. In vivo,bone regeneration was enhanced by specimen cultured 1 week prior to decellularisation, indicating that short/mid-term in vitro decoration is beneficial for osteogenesis. This research investigated the influence of in vitro maturation on the composition and osteogenic capacity of ECM-decorated scaffolds and demonstrated that the optimisation of culture time prior to decellularisation is essential to maximise cell infiltration, and differentiation towards the osteogenic lineage.

Towards the development of in vivo-mimicking tumor model for extensive study of tumorigenesis and establishment of personalized therapy, patient-derived primary tumor cells were employed in this work for three-dimensional (3D) bioprinting. Cholangiocarcinoma cells isolated from patient were bioprinted using a composite hydrogel system of gelatin-alginate-MatrigelTM into pre-designed grid architecture. Cholangiocarcinoma cells were observed to process a colony forming ability with high survival rate and active proliferation. Expressions of tumor markers, cancer stem cell markers, matrix metalloproteinase protein, index of tumor fibrosis, index of liver function, and epithelial-mesenchymal transition (EMT) regulatory proteins confirmed the development of the invasive and metastatic phenotype of the cholangiocarcinoma cells in the 3D printed tumor microenvironment. Similar results were obtained in anti-cancer drug resistance of the cholangiocarcinoma cells in the 3D bioprinted construct that demonstrated stem-like properties, which suggested the promising potential of current 3D printed tumor model in the development of personalized therapy, especially for discovery of more conducive targeted drugs.

The design and synthesis of multifunctional nanoparticles (NPs) for drug delivery, imaging, and phototherapy has been investigated widely in past several years. However, inadequate drug loading, limited imaging capabilities in the near-infrared fluorescence region (NIRF), and complete tumor eradication is still a major challenge. To resolve aforementioned issues, a most commonly used photosensitizer, porphyrin, was first chemically modified to porphyrin grafted lipids (PGLs) having a hydrophobic head and a long hydrophilic tail. Similar to liposomes, such PGL NPs self-assembled together with a lipophilic cyanine dye, DiR resulting in a new combination NPs (PGL-DiR NPs) of average size 156 nm. Importantly, this technique addresses issues related to limited loading capacities of hydrophobic porphyrins and DiR as well. In addition, the strategic combination of PGL-DiR NPs was further utilized to trigger a light-activatable photoresponsive (photothermal therapy, PTT; photodynamic therapy, PDT) properties. The amount of DiR loading was optimized to induce quenching of singlet oxygen (1O2) from PGL followed by subsequent recovery after irradiation of appropriate laser. Such activatable NPs are of key importance to realize synergistic phototherapy i.e. PTT and PDT without affecting nearby normal cells. After intravenous administration of PGL-DiR NPs in a PC3 tumor xenograft mice, a high accumulation in tumor until 24 hrs was clearly evident via NIRF imaging. With the successive laser irradiation, these NPs effectively suppressed the tumor growth synergistically while compared to monotherapies such as PTT or PDT alone.

Introduction: 3D biomaterials are increasingly being used to control stem cell fate in vitro. To modulate cell-substrate interaction we developed an isotropic 3D-microstructured substrate nanoengineered via two-photon-laser polymerization [1]. We studied its influence on cell mechanotransduction pathway modulation, gene expression and cell migration.
Methods: Scaffolds are microfabricated structure composed by cubic pore with dimension 15x15x15µm^3. Results were compared with those obtained on 2D glass-coverslip. 10^4MSCs were cultured for 24 hours, for each experiment. Cells were processed for immunofluorescence analysis to characterize cytoskeleton and chromatin organization. Timelapse microscopy and DNA methylation were performed to analyse cell migration and DNA activity.
Results: MSC grown into our 3D-substrates show:
1. Remodulation of the nuclear shape from a thin disk to a roundish ellipsoid.
3. Reorganization of the DNA: DNA methylation is lower and euchromatin is more homogeneously distributed.
4. Strong reduction in cell capability to migrate.
Discussion and conclusion. Results show that our 3D-microstructured scaffolds affect migratory cell behaviour and gene activity, suggesting that MSCs grown in this culture condition could maintain cellular stemness. We are evaluating cell potency by analysing the activity of fundamental genes such as SOX2, NANOG, OCT4.

The first step of the hearing process takes place at the tympanic membrane (TM), a thin and tough, concave-shaped membrane composed of three different layers [1], which is responsible for transmitting air pressure weaves collected in the ear canal into vibrations of the ossicular chain [2]. The pars tensa is considered the main actor of the TM acoustic response and is composed of two differently oriented layers of collagen fibers: radial and circular [1, 3].

We developed a specific electrospinning collector and setup able to produce an anatomically consistent scaffold, composed of two layers, deposited one onto each other, of ultrafine fibers with radial and circular orientations. The polymer used was poly(ethylene oxide terephthalate)/poly(butylene terephthalate) [2, 4]. Finite Element Analysis of the electrostatic field was performed to design the optimal collector shape (i.e. able to generate the correct electric field spatial distribution) to reach the desired alignments. The fiber diameter distribution and morphology were characterized by scanning electron microscopy. Radial fibers had 1.00 ± 0.15 µm, whereas circular fibers had 0.8 ± 0.4 µm size. All the main anatomical features of the TM (e.g. thickness variability) were successfully reproduced in this scaffold. Cytocompatibility studies performed with human mesenchymal stromal cells revealed excellent cellular adhesion and proliferation. Fluorescence microscopy observation of the cytoplasm and nuclei indicated that the cell grew in an aligned fashion, consistently with the underlying fibers.

The obtained fiber size and alignment revealed potential for eardrum regeneration.

Nanoclays have attracted attention in the regenerative medicine field for their self-assembly properties, protein interactions, and intrinsic osteogenic bioactivity. While nanoclay-localised BMP-2 displays bone formation ability [1,2], to date, no studies have explored whether nanoclays and BMP-2 molecules distribute to other organs/tissues following implantation and during biodegradation.

We have evaluated the biodistribution of nanoclays and BMP-2 by tracking nanoclay elements and BMP-2 molecules specifically in the blood and organs such as heart, kidney, liver, lung, spleen, stomach, and bladder. Nanoclay gels with/without fluorescently labelled BMP-2 were subcutaneously injected to female MF-1 wild type mice. Over the course of 8 weeks BMP2 biodistribution was tracked using an in vivo imaging system (IVIS) alongside micro-computed tomography (μ-CT) and histological analysis of new bone formation. Nanoclay elements in harvested tissues were quantified using inductively coupled plasma mass spectrometry (ICP-MS)

In the absence of nanoclay, BMP2 rapidly dispersed to below the detection threshold after 4 hours and no bone formation was observed at week 8. In contrast, BMP-2 with nanoclay was detectable even at 8 weeks and induced ectopic bone. Nanoclay was progressively removed from the implant site correlating with cellular invasion and replacement by new bone tissue. Nanoclay did not accumulate in lung, heart, blood or stomach and temporal distribution in liver and bladder was consistent with excretion via liver and urinary systems. These studies demonstrate that nanoclay can maximise bone formation efficacy of BMP-2 with no side effects on internal organs by BMP-2 localisation, offering a safe delivery approach for this biologic.

Decellularised tissue provides a promising biological material for tissue regeneration. A central feature of decellularised tissue is the elimination of the cellular components from the native tissues while retaining the complex compositions and architecture of extracellular matrix (ECM) [1]. While decellularised ECM hydrogels from bovine and porcine bone tissues have been examined in the field of tissue regeneration [2], to date, no studies have sourced or evaluated decellularised matrices from human bone tissue.

The objective of this study was to evaluate the hypothesis that physiochemical and biological properties of ECM hydrogel derived from demineralised and decellularised human bone matrix could be controlled through modulation of bone powder size and digestion time for enhanced bone repair. Trabecular bone from human femoral head samples following hip arthroplasty were collected and demineralised human bone powders at various sizes (45-250 µm, 250-1000 µm, and 1000-2000 µm) prepared. After decellularisation, the powders were treated with pepsin solution for 3, 5, and 7 days. The concentration of proteins and gelation strength significantly increased as bone powder size decreased and digestion time increased. Evaluation of cultured human bone marrow-derived stromal cells on the ECM hydrogel derived from 45-250 µm bone powder size and treated for 7 days exhibited significantly enhanced cell proliferation and lineage differentiation. Taken together, a defined digestion time and powder size are crucial factors for generating human bone ECM hydrogels with a high concentration of proteins and rheological property for augmentation of bone repair.

Osteoarthritis (OA), the most diffused musculoskeletal pathology, is a whole joint disease affecting articular cartilage (AC) but also subchondral layers. Most OA in vitro models, however, do not account for the multiplicity of tissues affected, nor for the mechanically active joint environment. In this work we present an Organ on chip model of OA enabling the subjection of multi-layer tissues to cyclical compression.

Starting from a cartilage on chip model [1], human articular chondrocytes laden hydrogels were differentiated into AC. Hypertrophic cartilage (HC) was, instead, obtained from MSCs. A direct interface between co-cultured 3D micro-constructs was achieved through removable PDMS molds permitting sequential substrates injections. [2]. Aggrecan and Collagen type-II characterized the AC matrix, while the HC matrix, still Col2a1 positive, was also rich in collagen type-X and calcium deposits, hallmarks of the hypertrophic tissue. The culture chamber was coupled with a mechanical actuation compartment through a pressure sensitive adhesive based mechanism. This way vertically stacked constructs can be exposed to defined levels of mechanical compression during culture, allowing for the study of biomechanics role in OA onset. Indeed, these results could bring to a more complex and representative in vitro representation of OA joints, easing the investigation of the causes leading to OA (e.g. mechanical injury), but also of the role of interplays between different tissues (e.g. the advancement of HC into AC). Such a model could be a powerful tool for both basic research and drug screening.

Tissue engineering has yet to reach its ideal goal, i.e. creating profitable off-the-shelf tissues and organs (1,2). One of the major challenges of this field that affects the outcome of the cell transplantation is the in-vitro aging and replicative senescence of the cell source #. In the present work, Passage 5 (P5) adipose-derived mesenchymal stem cells (MSCs) were treated with control media, nicotinamide (NAM), AICAR, or the combination of AICAR+NAM till P10. Proliferative capacity, senescence-associated changes, multi-lineage differentiation potential, CDK-inhibitors -P16 and P21-, ROS, and apoptotic markers were compared between cells of P5 and P10. Furthermore, we studied the effects of AICAR and NAM on mTORC1 activity, and autophagy.

Our results showed that MSCs treated with NAM, AICAR, or both demonstrated an increase in proliferation and osteogenic differentiation potential, which was amplified in the group receiving both. AICAR or NAM treatment resulted in reduced expression of β-galactosidase and decreased accumulation of dysfunctional lysosomes. Also, NAM or AICAR+NAM significantly reduced the cellular ROS in aged MSCs. Moreover, AICAR and NAM administration attenuated mTORC1 activity and boosted autophagy.

In general, inhibition of mTORC1 by AICAR and NAM upregulates autophagy, retains MSCs' self-renewal capacity, and delays senescence of MSCs after prolonged in-vitro culture. Furthermore, our findings showed that concomitant use of AICAR and NAM shows a synergistic effect on the attenuation of cellular senescence. Our findings provide a viable option to slow down the in-vitro aging of the stem cells and conquer aging as a limiting factor in tissue engineering.

CaP coating on melt electrowritten (MEW) substrates demonstrated itself as a potential candidate for bone regeneration due to mimick the natural bone tissue. It increased the osteoblast cells - implanted scaffolds interactions and improved bone ingrowth. This study aims to evaluate the stability and structural properties of CaP coating on melt electrowritten PCL scaffolds following pre-treatments of Ar- O2 plasma and NaOH solution to improve the wettability.
The plasma-treated fibers were uniformly coated after one hour. The surface wettability enhanced through the mineralization of both plasma and NaOH pre-treated scaffolds. Mechanical properties of the scaffolds degraded through the plasma and NaOH treatment. However, tensile stability was improved following mineralization in plasma-treated scaffolds due to the smaller crystal size and a dense CaP layer, which leads to the higher solubility. We demonstrated that the plasma pre-treated mineralized surface is stable enough to be potentially useful for the further development of bone regeneration. and could successfully direct cells toward an osteogenic lineage with resulting mineralization.

The use of injectable gels derived from the natural extracellular matrix (ECM) to deliver proteins has attracted much interest in the field of regenerative medicine. We have previously demonstrated that hyaluronic acid (HA) hydrogel could be used for efficient delivery of recombinant human bone morphogenetic protein-2 (rhBMP-2) and induce bone formation within 6 weeks when injected below the rat periostium.[1] Though rhBMP-2 is very potent for inducing bone formation, the dose dependent toxicity is a major concern.[2] This is mainly due to supraphysiological dose that is clinically used since the collagen-based BMP-2 carrier is inefficient and does not stabilize rhBMP-2 in vivo. We have devised a new strategy to stabilize BMP-2 and improve bone formation with a minimal dose of the protein.

To develop HA-based hydrogel materials we tested two types of crosslinking chemistry, namely hydrazone and thiol-Michael coupling reaction.[3] These materials were evaluated to deliver rhBMP2 in vitro as well as in vivo in a rat ectopic model. Since the ECM in the living system is known to stabilize growth factors by electrostatic and hydrophobic interactions, we also developed 'acidic' and 'neutral' form of HA by changing the protonation/deprotonation of the carboxylic groups and evaluated the protein interaction with HA at different pH.[4] Such manipulation of charge of the biopolymer had a profound impact on protein release at physiological pH as determined using cell-based ALP assay. The effect of BMP-2 stability and function was quantified in vivo by measuring the bone volume after 6 weeks of implantation.

Abstract **#1065**

THE HYBRID BILAYER BIOMATRIX OF FUNCTIONALIZED CELLULOSE HYDROGEL LAYERED ON COLLAGEN SCAFFOLD FOR WOUND HEALING APPLICATION

Atiqah Salleh[P][1], Fauzi Mh Busra[1]

[1] *Centre for Tissue Engineering and Regenerative Medicine, Faculty of Medicine, Universiti Kebangsaan Malaysia, 56000 Kuala Lumpur, Malaysia*

Corresponding author's email: atqhsalleh@gmail.com

Tissue engineering technologies are well-established alternative approaches currently available for wound applications either chronic or acute injuries. However, the success rate post-implantation is still low due to high susceptibility of severe bacterial infections. Thus, a relevant improvement still required to accelerate wound healing for better recovery. This study aimed to fabricate a bilayer hybrid scaffold containing ovine collagen type-I (OCT-I) sponge and functionalized-cellulose hydrogel (CH) at top layer. Briefly, the OCT-I was freeze-dried and crosslinked with 0.1% of genipin (GNP), natural crosslinking agent, for 6 hours. Meanwhile, the CH was prepared, and integrated with graphene oxide-silver nanoparticles (GO-Ag) prior to hybridization. The fabricated hybrid biomatrix further investigated for 3D-microstructure, biodegradability, surface wettability, anti-bacterial activity, and its biocompatibility towards human skin cells. The degree of crosslinking between GNP and OTC-I sponge exceed 90% which showed that GNP is favorable as crosslinker. The results revealed that GNP crosslinked OTC-I scaffold showed better physicochemical and mechanical properties compared with the non-crosslinked OTC-I scaffold. Even though, the non-crosslinked OTC-I scaffold great swelling ability (1638.89 ± 1.76%) than GNP crosslinked OTC-I scaffold (1214.56 ± 1.05%) in 24h, GNP crosslinked had lower biodegradability (18.32 ± 8.53%) and good hydrophilicity (77.54 ± 1.62°). The CH also showed great anti-antimicrobial activity as well as good physicochemical properties. Moreover, the fabricated bilayer scaffold showed good cell adhesion and proliferation with human epidermal keratinocytes and human dermal fibroblasts. In conclusion, the fabricated bioscaffold potentially a good candidate for the wound healing application.

A recent strategy to design functional injectable hydrogels relies on the incorporation of nanofillers into the hydrogel matrix to add functionalities [1,2]. Intervertebral disc degeneration (IVDD), initiating in the nucleus pulposus (NP), represents a clinically relevant example where injectable systems could bring significant benefits. Here we designed an injectable cell carrier for NP repair by exploiting graphene oxide (GO) as nanofiller of FEFKFEFK (F8) peptide hydrogels and as delivery cargo for transforming growth factor beta-3 (TGF-β3).

Hydrogel nanocomposites were prepared with non-covalent synthesis and hydrogel structure was assessed via spectroscopy and microscopy techniques (FTIR, AFM and TEM), while gel stiffness and injectability were measured via oscillatory rheometry. Bovine NP cells were cultured in the nanocomposites by supplying TGF-β3 exogenously, endogenously (10 ng/ml) or by exploiting GO as drug delivery platform. Cell viability, metabolic activity, gene and protein expression of encapsulated NP cells were assessed.

Incorporation of GO promoted strong peptide-GO molecular interactions leading to storage moduli (~12.8 kPa) comparable to the human NP (~10 kPa). Nanocomposites showed ease of injectability, with a minimal release of TGF-β3 over 3 weeks (<3%). Having TGF-β3 complexed on GO led to an increased gene expression and deposition of characteristic NP matrix components after 21 days of 3D cell culture, compared with peptide only or with nanocomposites having TGF-β3 as free molecule. Collectively, the triad peptide-GO-TGF-β3 provided a suitable cocktail of mechanical and biochemical cues to promote cell proliferation and enhanced matrix deposition, harbouring therefore significant potential as functional biomaterial for IVD repair.

Clinical treatments for tendon lacerations can be compromised by adhesion formation[1] due to tendon synovial sheath disruption and aberrant healing. One of the most promising anti-adhesion approaches relies on the introduction of a biomembrane as physical barrier for adhesion-forming cells whilst regenerating the tendon synovial sheath[2]. Here, we propose a novel hybrid approach that combines electrospinning and 3D bioprinting techniques to produce a bilayer biomembrane for restoration of tendon synovial sheath integrity and prevention of post-operative adhesions.

Polymeric meshes were prepared by electrospinning, using 10% w/v poly(ε-caprolactone) (PCL) in 1,1,1,3,3,3,-hexafluoro-2-propanol. Samples were imaged using SEM and mechanically tested under tension. Migratory ability of human dermal fibroblasts through the mesh was studied using a double chamber system. Alpha4® peptide hydrogel was loaded with HIG-82s (synoviocytes) and printed using a 3D Discovery bioprinter. Cell viability and metabolic activity were evaluated over 4 weeks. Production of extracellular matrix (ECM) proteins and hyaluronic acid (HA) was assessed using histology and immunocytochemistry. Membrane's frictional properties on porcine tendon were evaluated by oscillatory rheology.

Results show that the nanofibrous mesh (Mean=0.25µm) can withstand the forces generated in vivo and prevents fibroblast infiltration in vitro due to its small pores (<3µm). 3D bioprinting allows for accurate spatial distribution of the hydrogel phase without affecting synoviocyte viability and proliferation. Moreover, Alpha4® supports cells to produce an ECM that mimics the native tissue and possesses anti-adhesive properties. In conclusion, the biomembrane acts as physical barrier and has the potential to restore the native content of HA for long-term lubrication.

SCALABILITY OF HUMAN INDUCED PLURIPOTENT STEM CELL DERIVED KIDNEY TISSUE ORGANOIDS, A STEP TOWARDS CLINICAL APPLICATION

Loes Wiersma[P][1], Cathelijne van den Berg[1], Ellen Lievers[1], Ton Rabelink[1]

Corresponding author's email: l.e.wiersma@lumc.nl

The generation of human induced pluripotent stem cells (hiPSCs) has opened up a world of opportunities for stem cell based therapies in regenerative medicine. These cells have the unique potential to become any cell of the human body. Worldwide there are many people suffering from reduced kidney function, and thousands are in need of a donor kidney. Currently there are several human kidney organoid protocols available that generate organoids containing kidney structures. In our lab we generate kidney organoids from hiPSCs that contain glomerular, proximal tubular and more distal tubular structures. These kidney organoids are relatively small ranging up to 4 mm in diameter in vitro. Here we show a scalable and reproducible method to increase the size of the organoid up to 1.5 cm in diameter. Confocal microscopy showed that all structures, e.g. NPHS1, LTL and ECAD for glomerular, proximal and distal tubular structures respectively remained evenly distributed throughout the entire sheet. Analysis of these sheet organoids shows that they can attain at least 14.000 NPHS1 positive glomerular structures. Upon transplantation in immunodeficient mice the organoids became vascularized and further matured. These sheet organoids also showed reuptake of injected low-molecular mass dextran molecules in the tubular structures upon filtration in the glomeruli. The scalability of the procedures is an important step forward in the translation of these differentiation protocols to future clinical applications in the development of a bioengineered kidney.

3D BIOPRINTING TECHNOLOGY FOR BUILDING MICROPHYSIOLOGICAL SYSTEMS OF HUMAN CANCER

Hee-Gyeong Yi[1]

[1] *Department of Rural and Biosystems Engineering, College of Agricultural Science, Chonnam National University*

Corresponding author's email: hgyi@jnu.ac.kr

Microphysiological systems of human cancer are emerging platforms for better cancer research. Conventional cancer models have failed in capturing the underlying mechanisms of how cancer reacts to the current anti-cancer approaches due to the lack of similarities with the original cancer of the patient. The challenge is to model a complex and heterogeneous cancer environment where every element contributes to cancer hallmarks development. Recently, biofabrication technologies have been advanced to spatially control multiple types of cells and biomaterials to mimic the native physiology of tissue and organs. In particular, 3D bioprinting has beauty in manipulating the 3D anatomical structure of cancerous tissue through a layer-by-layer process that stacks up cells and bioinks following precisely designed sequences. The 3D bioprinted microphysiological system of human cancer has recapitulated the pathology and aggressiveness of original cancer. In addition, 3D bioprinting has shown the possibilities in modeling various types of cancers for future cancer research.

C2C12 cell line (mouse myoblast cell line) that differentiates into myotubes (muscle cell) upon confluency or transdifferentiates into osteoblasts (bone cells) upon Bone Morphogenetic (BMP) 2 induction. Such characteristic has made C2C12 a stem cell-like cell line that is ideal for myotubes/osteoblast research model. Current literature shows BMP2 and BMP7 heterodimers are present and important in the early mouse embryo and Xenopus embryo development (1-2). It is not yet clear how spatially controlled BMP2/7 chimera presentation, in soluble and immobilised forms, influence C2C12 cells morphology and cell signalling any differently. As a start, we compare Smad 1/5/9 signalling activity when C2C12 cells were presented to a soluble form of the BMP: sBMP2/7 chimera, sBMP2 or sBMP7 alone. Only 7.5nM BMP2 and BMP2/7 chimera while 22.5nM BMP7 were needed to exert significant differences (**P < 0.005) in Smad 1/5/9 activities with their respective negative control within 45 mins. Next, diblockcopolymer micelle nanolithography (BCMN) technique was used to generate spatially controlled of approximately 8 nm gold nanoparticles and they were biofunctionalised after. Two different types of spacings were generated: 49.00 +/- 1.95 nm with an order of 0.5, and 95.82 +/- 0.92 nm with an order of 0.70. Quantitation of BMP immobilisation via mu N-hydroxysuccinamide reaction was done on gold monolayer of quartz crystal microbalance – dissipation (QCM-D). Next, C2C12 cells' morphology on the immobilised BMPs, Smad 1/5/9 expressions and involvement of certain integrin subunits will be tested.

Electrospinning is a widespread technique used in the tissue engineering field, due to the fabrication of nanoscale/microscale fibrous structures similar to the native extracellular matrix morphology. Polycaprolactone (PCL) is biocompatible aliphatic polyester with high potential usage in medical applications. On the other hand, Gelatin (GE) type A is used as an additive in order to increased nanofibers degradation and hydrophilicity, and also improve solution viscosity. In this study, nanofibrous scaffolds based on PCL/Ge containing TiO2 nanoparticles were fabricated by electrospinning method.

The main objective of this study is to investigate the effect of Tio2 NPs on human mesenchymal stem cell-derived bone marrow, in terms of cytotoxicity, releasing reactive oxygen specious (ROS), adhesiveness, and survival.

the advantageous properties of Tio2 NPs such as light weight, bioactivity, biocompatible, antibacterial, corrosion protecting have made it an interesting material to be considering in compositing with polymers.

The results demonstrated that the addition of TiO2 NPs improved the mechanical strength, hydrophilicity, and cellular attachments of scaffolds.

Objective: Due to the easy access and low cost, use of animal or plant exosomes in cancer treatment is promising. Fresh water crab had been used in traditional Iranian medicine to treat cancer. This study aimed to separate the exosome from the crab and investigate its anti-cancer properties on breast cancer cell line (4T1).

Materials and Methods: In this in vitro experimental study, crab hemolymph exosomes were isolated via precipitation method and characterized using electron microscopy, dynamic light scattering (DLS), and western blot. The protein concentration and total antioxidant capacity of exosomes were determined by bicinchoninic acid (BCA) and cupric reducing antioxidant capacity (CUPRAC). 4T1 cells and bone marrow mesenchymal stem cells (BMSCs) were treated with exosomes and the cell survival was assessed by RESAZURIN and MTT assays. Nitric oxide (NO) secretion from 4T1 cells, after treatment with exosomes was determined.

Results: Electron microscopy, DLS and western blotting for CD63, confirmed isolation of exosomes under the size range <100 nm. The total antioxidant capacity and protein concentration in exosomes were 1.003µM/ml and 650mg/ml respectively. RESAZURIN and MTT assays showed a decrease in cell survival of 4T1 ($p \leq 0.001$) after treatment with the exosomes. However, cell growth was observed in the exosomes treated BMSCs.

Conclusion: Crab hemolymph has protein-rich exosomes with antioxidant activity, therefore, it can have anti-cancer effects on 4T1 cells. These exosomes can be suggested for breast cancer therapeutics.

Glycosaminoglycans are key components of the extracellular matrix that regulate several cellular processes such as cell signaling, proliferation, and migration. We harness the intrinsic biological properties of these polymers for engineering immunomodulatory nanomaterials and bulk hydrogels. We have recently discovered the unique property of hyaluronic acid (HA), to deliver siRNA across cellular barrier resulting in the development of the first biomimetic anionic transfection method for mammalian cells. We have also recently engineered HA-derived self-assembled nanocarriers by conjugating dexamethasone as the hydrophobic group and loaded the nanoparticles (NPs) with doxorubicin to obtain a size of 252 nm. These NPs specifically target the CD44 positive tumor cells and facilitated apoptosis. Interestingly, HA-NPs polarized the M2 macrophages to pro-inflammatory M1 phenotype with the upregulation of key cytokines thereby enhancing anti-tumor immunity. Finally, when we tested our HA-NPs in human whole blood, we found that HA-NPs mitigated the drug-mediated complement and coagulation cascade and suppressed platelet aggregation.

INVESTIGATION OF UV CROSSLINKED KONJAC GLUCOMANNAN COMPOSITE FOR BIOMEDICAL ENGINEERING APPLICATIONS

Asdani Saifullah Dolbashid[1]

[1] *University of Malaya*

Corresponding author's email: asdanisaifullah@gmail.com

In this study, methyl acrylates (MA) and konjac glucomannan (KGM) were mixed together and UV-polymerized to obtain a layer of film that can be potentially used as artificial skin. UV polymerization provides high rates of polymerization thus allowing for a more efficient crosslinking of the monomers. For UV polymerization of the film, polyethylene glycol diacrylate (PEGDA) acted as crosslinker and Irgacure 2959 was used as photoinitiator in the experiment. All of the other components were kept at the same concentrations except for MA. The film was then left under UV light for 6-15 minutes for it to be polymerized.

The films were developed using three concentrations of MA (30%, 40%, and 50%). Degradation test, differential scanning calorimetry (DSC), Fourier transform infrared spectroscopy (FTIR), and contact angle measurement were used as parameters to determine the suitability of the film to be used as artificial skin. FTIR results showed both MA and KGM in the films, which proved the mixability and presence of both substances. Higher concentration of MA slows down degradation rate of the film, as the crosslink density of the polymers was higher. The wettability of the films also decreased with increased concentration of MA. Results from this experiment showed the effect of MA concentration on the composition and crosslink density of the films. The variation in concentration of MA used in this study had produced KGM-MA films with different characteristics which in turn will greatly helps in determining its potential use as artificial skin in the future.

Bioscaffolds and cells are two main components in the regeneration of damaged tissues via cell therapies. Migration and homing of cells are known as critical steps in this field. Umbilical cord stem cells are among the most well-known cell types for this purpose, with high benefits. The main objective of the present study was to evaluate the effect of the pretreatment of the foreskin acellular matrix (FAM) by monophosphoryl lipid A (MPLA) on the attraction of the human umbilical cord mesenchymal stem cells (hucMSC).

The expression of certain cell migration genes (VCAM-1, MMP-2) was studied using qRT-PCR. In addition to cell migration, transdifferentiation of these cells to the epidermal like cells were evaluated via immunohistochemistry of CK19 protein. The hucMSC showed more tissue tropism in the presence of MPLA pretreated FAM compared to the untreated control group. We confirmed this result by scanning electron microscopy (SEM). Furthermore, IHC data demonstrated that MPLA treatment increases the protein expression level of CK19.

In conclusion, pretreatment of acellular bioscaffolds by MPLA can increase the migration rate of cells and also transdifferentiation of hucMSC to epidermal like cells without growth factors. This strategy suggests a new approach in regenerative medicine

In the last decades, tissue engineering has an effective role in introducing osteo bioimplants.1
Co-cell polymer with nano-clay can be one of the best implants for taking the place of bone failing and defecting in patients. 2,3
Human mesenchymal stem cells (hMSCs) and nano clay polymeric scaffolds can be biocompatible and biodegradable in the body.4
The nano clay_enriched polycaprolactone (PCL) scaffolds aid hMSCs proliferation and adhesion 5
Layered double hydroxide (LDH) nano clay can improve PCL properties in stem cells differentiation.3
Therefore the aim of this study is to fabricate bioactive, biointeractive highly porous(more than 94%) PCL scaffolds composited with different amounts of LDH at low temperatures.
In this study, highly porous PCL scaffold doped with different contents of LDH (ranging from (0.1 wt.% to 10 wt.%) simultaneously and the LDH attended smoothly dispersed throughout the PCL scaffold as confirmed by Energy dispersive X_ray analysis (EDX).
The viability, proliferation, morphology, attachment, and osteogenic differentiation of hMScs were assessed, and also mechanical behavior, degradation, and porosity of scaffold were examined. The osteo genes expression also approved osteogenic differentiation of hMSCs. These results demonstrated that the addition of LDH improved the osteogenic differentiation while compression strength, hydrophilicity, and degradation rate were also increased.

Recently, surgical intervention has been the gold standard for breast tumor ablation, however, tumor recurrence and loss of adipose tissue decrease the progression-free survival (PFS) among patients. Photothermal therapy has been established as a safe modality of tumor ablation, while most of the photothermal agents are non-degradable, thus limiting its clinical application. Black phosphorus (BP) has attracted increasing attention due to its photothermal conversion efficiency, good biocompatibility and biodegradability. Due to the limited accumulation and easy diffusion of free nanoparticles, immobilization of nanoparticles into porous scaffolds for direct local implantation has become an attractive way for cancer cell ablation and simultaneous promotion of adipose tissue regeneration. In this study, composite porous scaffolds of gelatin and BP nanosheets were successfully prepared. The BP-gelatin composite scaffolds had a high photothermal ablation efficiency against MDA-MB231-Luc in vitro and in vivo. Furthermore, in vitro cell culture and in vivo implantation results revealed that the BP-gelatin composite scaffolds could up-regulate formation of lipid vacuoles and adipogenic-related gene expression for promoting adipogenic differentiation of hMSCs. Considering the ablation effect of tumor cells and promotive effect on adipogenic differentiation of hMSCs, the BP-gelatin composite porous scaffolds may offer a facile strategy to treat breast tumors.

We present a brain-on-a-chip platform in which multiple types of human brain-originated brain cells were cocultured in a 3D microenvironment with perfusable brain microvasculature. The brain microvasculature was fabricated by using microneedles as templates. The removal of microneedles after the gelation of the collagen matrix allowed the formation of collagen channels. By seeding the brain microvascular endothelial cells in the luminal surface of the channel and embedding other neural cells in the collagen, a 3D brain model was prepared. The brain microvasculature physiology was confirmed through transendothelial permeability, immunofluorescence imaging, and cytokine assay. Neuropathology such as brain tumor and infectious diseases were recapitulated in the brain-on-a-chip platform and pathophysiological features, as well as the pharmaceutical candidates, were evaluated in the platforms. We believe that the brain-on-a-chip technology can not only help the unraveling of underlying mechanisms of brain diseases but also testing the efficacy of potential pharmaceutic candidates.

Corresponding author's email: yoosy2@gmail.com

Instructive biomaterials provide a vascular niche and protect oxidative stress in injured tissue. Herein, we demonstrated that Arg-Gly- Asp (RGD)-engineered bacteriophage nanofibers, furtherly modified with antioxidant/anti-inflammatory peptides, provide a vascular and anti-oxidant niche, thereby having cytoprotective functions against cellular oxidative stress. These bioinspired RGD-engineered bacteriophage nanofibers can serve as a novel therpeutic platform for ischemic diseases.

Implanted stem cell survival/proliferation is the major challenge in stem cell therapy for ischemic disease treatment. Extracellular niche plays a crucial role in overcoming surrounding harsh pathological environments as well as in stem cell differentiation and other important functions. However, an artificial niche achieved so far is not successful especially to fulfill the soft tissue niche. Herein, we exploited an engineered phage displaying cell adhesive peptides with a suitable structural cue can provide a controlled soft tissue niche to increase the angiogenic efficacy of endothelial progenitor cell (EPC) and to improve the survival of the implanted EPC at the ischemic site. Engineered phage successfully modulates physical and biochemical cues to achieve an appropriate niche in the functioning of implanted EPC, thus providing a convenient vascular soft tissue niche. These biomimetic phages may serve as a promising therapeutic option for curing ischemic diseases.

NOVEL ONCOLYTIC VIRUS ARMED WITH CANCER SUICIDE GENE AND NORMAL VASCULOGENIC GENE

So Young Yoo$_P$[1], Su-Nam Jeong[1]

[1] *Pusan National University*

Corresponding author's email: yoosy2@gmail.com

Here, we developed a novel oncolytic vaccinia virus (NOV) with the dual advantages of cancer selectivity and normal vessel reconstructive activity by replacing the viral thymidine kinase (vTk) and vaccinia growth factor (VGF) genes with genes encoding TNF-related apoptosis-inducing ligand (TRAIL) and angiopoietin 1 (Ang1), respectively. The pan-cancer-specific oncolytic potency of NOV was confirmed in various human and mouse cancer cell lines (colon, liver, pancreas, cholangiocarcinoma, cervical cancer, osteosarcoma, and melanoma). Vaccinia virus (VV) treatment directly induced early apoptosis in tumors within 24 h, and this effect was enhanced with further engineering; VGF and Tk deletion with Ang1 and TRAIL insertion. Meanwhile, treatment with the conventional anti-cancer drug cisplatin did not induce apoptosis. A virus-treated CT26 mouse colon cancer syngeneic model showed attenuated tumor growth, which was in accordance with the results of percent survival measurement, CD8 expression analysis, and TUNEL staining with advanced genetic engineering (vAng1 < vTRAIL < NOV). Taken together, our results indicate that NOV induces cancer tissue apoptosis and anti-tumor immunity and may constitute a highly advantageous therapeutic agent for next-generation solid tumor virotherapy with pan-cancer-specific oncolytic activity and high biosafety.

There a lot of membranes types have been used in Guided Bone Regeneration (GBR) surgery procedure. The issue of using the membrane implantation are it can cause infection and contributes to the cause for the procedure failure. In order to prevent bacterial colonisation, multiple antibiotics have been used. Nevertheless, it contributes to the side-effects and bacterial resistance. Hence, the idea of triple layered and functionally graded antimicrobial biocomposite membrane comprising of poly (lactic-co-glycolic acid) (PLGA) matrix with bioactive apatite filling and lauric acid (LA) has been proposed as a potential to provide a solution to this problem. Using the Critical Size Defect (CSD) technique in the New Zealand White Rabbit, this study seeks to investigate the biocompatibility and potential effect of the antimicrobial bio composite membrane through in vivo analysis. Eight New Zealand White Rabbits were used in this study. A CSD of approximately was surgically drilled at the proximal tibial metaphysis, approximately 1 cm from the knee joint. 1 cm x 2 cm of the bio composite antimicrobial membrane was inserted at the tibia site. The rabbits were euthanized then the bone samples were taken for further analysis. Gross observation conducted showed a very good contact between the bone and implant membrane for all rabbit models. Bone cortical rim is visible in the radiographic images assessment. Histological analysis indicates that a section of material in close contact with the new bone. Close-up view of new bone shows the presence of osteoid with adjacent osteoblasts.

The mortality rate for pancreatic cancer is high due to lack of powerful early diagnosis technologies. Main obstacles for improving clinical trial result are a diagnosis at an early stage and limited therapeutic efficacy. To overcoming this problem, recently tumor-derived exosomes are attracting interest in cancer diagnosis and treatment field. Membranous vesicles that may include novel markers same as proteins, RNAs and DNA, can be found in the circulating blood. Here we demonstrate recent technologies highlighting the cancer exosome detection by introducing lectin and Janus nanoparticles. Lectins are glycoproteins that exhibit specific binding affinity for the saccharide moiety of glycoproteins. Cancer cells are known to express or secrete glycoproteins with specific saccharide chain like sialic acid in pancreatic cancer. Therefore, in this study, we introduce the pancreatic cancer cell-derived exosome detection technology based on the specific binding of lectins to the characteristic glycan profiles on the surface of exosomes for the first time. Lectins with a high and specific affinity to sialic acid or fucose were attached on the bifunctional nanoparticles (i.e., Janus nanoparticles) to interact with pancreatic cancer cell-derived exosomes in a microfluidic device. Pancreatic cancer cell-derived exosomes from both cell-lines and patient's plasma samples were successfully captured on the lectin-conjugated Janus. In addition, exosome detection using our platform was able to differentiate between metastatic and non-metastatic pancreatic cancer cells. This study opens the possibility to achieve a new early diagnosis marker based on the glycan properties of pancreatic cancer-derived exosomes.

Encapsulation devices are an emerging technology designed to prevent the immunorejection of replacement cells in regenerative therapies. However, traditional polymers used in current devices are poor substrates for cell attachment and induce fibrosis upon implantation, impacting long-term therapeutic cell viability. Bioactivation of polymer surfaces improves local host responses to materials and here we make the first steps towards demonstrating the utility of this approach to improve cell survival within encapsulation implants. Using therapeutic islet cells as an exemplar cell therapy, we show that internal surface coatings improve islet cell attachment and viability while distinct external coatings modulate local foreign body responses. Using plasma surface functionalisation (PIII), we employ hollow semi-porous polyethersulfone (PES) fibres and coat the internal surfaces with the extracellular matrix protein fibronectin (FN) to enhance islet cell attachment. Separately, the external fibre surface is coated with the anti-inflammatory cytokine interleukin-4 (IL-4) to polarise local macrophages to an M2 (anti-inflammatory) phenotype, muting the fibrotic response. Bioluminescent murine islet cells were then loaded into dual FN/IL-4 coated fibers and evaluated in a mouseback model for 14 days. Dual FN/IL-4 fibers showed striking reductions in immune cell accumulation and elevated levels of the M2 macrophage phenotype, consistent with suppression of fibrotic encapsulation and enhanced angiogenesis. These changes led to markedly enhanced islet cell survival and importantly to functional integration of the implant with the host vasculature. Dual FN/IL-4 surface coatings drive multi-faceted improvements in islet cell survival and function, with significant implications for improving clinical translation of therapeutic macroencapsulation devices.

DEVELOPMENTS OF BIOFABRICATED STRUCTURES IN NOVEL TREATMENTS FOR LOWER URINARY TRACT SYMPTOMS

Tetsuya Imamura$_P$[1]

[1] *Shinshu University School of Medicine*

Corresponding author's email: imatetu@shinshu-u.ac.jp

We have vigorously investigated treatments of lower urinary tract symptoms (LUTS) with “next generation tissue engineering”, which are composed of three concepts, conventional tissue engineering-based methodology, construction of suitable technology according to microenvironment, and incorporation of novel biotechnology. We showed that bone marrow- or adipose-derived cells these cells had the potential to reconstruct functional urinary bladders with frozen- and/or radiation-injury models. The cells were delivered into recipient bladders by using two methods, direct-injection of single cells and patch-transplantation of cell sheets produced in temperature-responsive culture dishes. Both methods successfully reconstructed bladder tissues and restored the functions. However, there are some limitations for each method. In the direct-injection method, survival rates of the implanted cells were very low within the recipient tissues. For the cell sheet patch-transplantation method, the sheets were too thin and weak to be reliably delivered to the recipient tissues. To overcome these limitations, we have attempted to biofabricate structures with a three-dimensional (3D) bioprinting robot system. Previously, we transplanted the biofabricate structures, which were composed of bone marrow-derived cells, into the irradiation-injured rat urinary bladders(1). We showed that the structures survived, and blood vessels invaded them from the adjacent recipient tissues. The bone marrow-derived cells constructing the structures differentiated into smooth muscle cells and formed smooth muscle clusters. In addition, the structure-transplanted rats had improved urinary frequency symptoms and decreased residual volume. In this symposium, we would like to indicate that the biofabricated structures have great potentials to treat patients with LUTS.

In recent years, cell-based assays have been attracting attention due to the growing expectations for animal replacement experiments. The development of a drug Responses evaluation system for neural cells has been progressing toward the treatment of neurodegenerative diseases using such techniques.

Human neural cells are highly heterogeneous within a population, resulting in various, sometimes non-reproducible, drug response as a bulk population. Therefore, it has been difficult to evaluate drug sensitivity using the averaged values from bulk cells. To breakthrough such difficulty, it is expected to establish an evaluation system that can sensitively focus on the rare population cells that reacts to the drug, and objectively and quantitatively extract their reaction within the heterogeneous population.

Our research group has been developing morphology-based drug response profiling by combining image processing and machine learning technologies [1,2]. In this analysis, all the individual cells are quantitated through the live time-course phase contrast images and total population data were numerically accumulated in the database. We developed a new algorithm to focus on the “rare population of cells that shows great morphological changes”, designated as “in silico FOCUS”. By this new analysis method, we show that the expected responses of neural model cells to the drug can be sensitively and quantitatively predicted. This method can contribute to new morphological analysis that can quantify rare populational reactions in bulk cells.

Gelatin has been widely used in hydrogel form for drug delivery and as cutaneous template for skin wound applications. Unfortunately, gelatin hydrogel (GH) has low mechanical strength and thermally unstable at body temperature of 37°C. Therefore, a crosslinking agent is required to increase the mechanical properties and thermal stability of gelatin hydrogel. This study was conducted to characterize the mechanical and thermal properties of polymerized gelatin hydrogel crosslinked with genipin (GNP). The fabricated hydrogel was tested by texture analyzer, differential scanning calorimetry (DSC) and thermogravimetric analysis (TGA). The GNP-crosslinked GH (GNP_GH) scaffolds were synthesized by mixing different ratios of gelatin (w/v; 5%, 10% and 15%) and GNP (w/v; final concentration of 0.1% and 0.5%) to achieve gelation time within 3 minutes. The results revealed that 0.1%GNP_GH 10%, 0.1%GNP_GH15% and 0.5%GNP_GH15% turned to hydrogel form within 3 minutes at 22ºC. All groups exhibited higher stiffness, resilience, adhesive force and adhesiveness compared to the non-crosslinked. The DSC and TGA thermogram shown that genipin crosslinking successfully enhance the thermal stability of gelatin bioscaffolds. These results demonstrated that gelatin hydrogel could be used as acellular treatment for full-thickness skin loss.

Corresponding author's email: j0617johnny@gmail.com

Intervertebral disk diseases (IDD) describe the breakdown of intervertebral disc (IVD) of the spine. Tissue engineering has provided an alternative therapeutic possibility for degenerative disc diseases. Currently, clinical treatments have limitations that cannot fully reconstruct the hierarchical structure and mimic the function of native intervertebral disc (IVD). In this study, we develop an IVD scaffold based on cellulose and alginate. A total IVD is created with the combination of cellulose-based nucleus pulposus (NP) and annulus fibrosus (AF) composed of cellulose-alginate double network for mimicking native IVD tissue. Moreover, mesenchymal stem cell (MSC) homing peptide and RGD cell adhesion peptide are modified on the NP part and AF part of the IVD scaffold, respectively, to promote endogenous stem cells recruitment and enhance cell adhesion as well as proliferation. Additionally, with the addition of growth and differentiation factor-5 (GDF-5), the recruiting MSCs can differentiate into an NP-like phenotype. The mechanical property of the reported hydrogel was enhanced via the addition of alginate network and drying in confined condition method. The grafting ratio of functional peptide motifs was further determined by NMR and FTIR spectra. The present work suggests that the reported double network hydrogel may serve as a promising candidate for the applications in IVD regeneration as well as for other biomedical applications in tissue engineering.

Mesenchymal stem cells (MSCs) were proposed as a critical therapeutic candidate in diabetic nephropathy (DN). Renal stem cells as a source for repairing are controversial. The purpose of the present study was to evaluate the effect of kidney rat stem cells on DN. After evaluation of surface stem cell markers by flow cytometry analysis, MSCs that were labeled with CM-Dil were injected to experimental groups via tail vein (2×106cells/rat). To establish the diabetic nephropathy rat model STZ(60mg/kg) was used. The IL1-β, TGF-β, miRNA 192, miRNA29a gene expression were assessed three weeks after induction of early diabetic nephropathy by using quantitative Real-time PCR. The renal stem cells 24 h after labelling with CM-Dil fluorescent dye were detected in the renal tissues. miRNA192, TGF-β and IL1-β Genes expression upregulated in diabetic group. The expression of miRNA29a significantly down-regulated 21 days after injection of STZ. H and E staining showed in the presence of adult kidney stem cells histopathological changes were improved. The protective effect of MSCs was closely related to the inactivation inflammatory factors. Therefore, the MSCs may be a promising novel treatment for early DN.

Vascular grafts with long-term patency are in great clinical demand. With current limitations in the use of autologous grafts, biofabrication offers a suitable alternative. Specifically a four-axis fused deposition modeling (FDM) system has the ability to create tubular constructs with a broad range of mechanical properties. The formation of a tight endothelial barrier and having a surrounding smooth muscle cell layer is vital for vascular graft patency. Here we used a four-axis FDM system to create a vascular construct with matching mechanical properties that supports the formation of an endothelial monolayer in the lumen and surrounding smooth muscle cell layer.

A 2 mm diameter mandrel was attached to a DC-motor with a rotational speed of 3000 RPM. Polycaprolactone was molten in a syringe and dispensed on the mandrel while it was rotating. After deposition of the thin fibres, the mandrel with the fibers was transferred to a custom CNC-machine with a controllable fourth rotary axis where a script was generated to create the pathway for the supporting fibers. Scaffolds were disinfected with 70% ethanol before a combination of smooth muscle cells (A10) and endothelial cells (HUVEC) were seeded on the outside and the lumen of the scaffold respectively.

During this study, a four axis fiber extrusion technique was used to fabricate a vascular scaffold with defined mechanical properties. In addition endothelial cells were able to form a monolayer in the lumen of the scaffold while smooth muscle cells migrated from the outside of the scaffold towards the lumen.

[1] *Universiti Kebangsaan Malaysia*

Corresponding author's email: lawjx@ppukm.ukm.edu.my

Foetal bovine serum (FBS) has been used for in vitro expansion of primary human cells for decades. However, the use of FBS is controversial as it has been linked with safety issues related to the contamination of cultured cells with animal proteins and risk of zoonotic pathogen transmission. In this study, we examined the potential of using human platelet lysate (HPL) prepared from expired human platelet concentrates for the xenogeneic expansion of primary human cells, i.e. Wharton's jelly-derived mesenchymal stem cells (WJ-MSCs), dermal fibroblasts (DF) and chondrocytes. From the results, we found that HPL was superior compared to the FBS in promoting the WJ-MSC, DF and chondrocyte proliferation whereby the population doubling time was significantly shorter. In addition, we also observed that WJ-MSCs, DF and chondrocytes cultured with HPL were smaller in size compared those expanded with FBS. As a result, significantly higher cell yield was obtained with HPL compared to FBS. Nonetheless, just like FBS, HPL cannot prevent dedifferentiation of chondrocytes. As for fibroblasts, we observed that HPL reduced the extracellular matrix gene expression and slowed down the cell migration. In conclusion, HPL can be used for the expansion of primary cells especially those expanded for clinical use.

Optimal wound dressings for skin wounds can mimic the native extracellular matrix and act as a barrier between the wound bed and the external environment. Infection from chronic wounds can delay progression and lead to debilitation. This study aimed to evaluate the antibacterial essential oil (R)- (-)-Carvone coating of a monolayer ovine collagen type I (OCT-I) biomatrix. Genipin (GNP) and dehydrothermal treatment (DHT) were used to crosslink OTC-I scaffold to improve its thermal and enzyme stability. Carvone has antimicrobial properties, and its functional groups are deposited to coat lyophilised porous OTC-I scaffold through plasma polymerisation treatment (OTC-I_ppCar). The physicochemical, biodegradation, biomechanical, biocompatibility, and antibacterial properties for composite biomatrix were evaluated. The results revealed that GNP crosslinked OTC-I scaffold (OTC-I_GNP) showed better physicochemical and mechanical properties compared to DHT crosslinked OTC-I scaffold (OTC-I_DHT) and non-crosslinked OTC-I scaffold (OTC-I_NC). Both composited biomatrix with Carvone deposition OTC-I_GNP_ppCar and OTC-I_DHT_ppCar demonstrated antibacterial properties and are compatible with human dermal skin fibroblasts (HDF) as it showed cell attachment and proliferation. The composite biomatrix shows potential for management of future treatment of chronic wounds such as diabetic ulcers.

MICROFLOW REACTOR HYPHENATED WITH ION MOBILITY-MASS SPECTROMETRY FOR DRUG DISCOVERY

Darya Hadavi[1], Peiliang Han[1], Maarten Honing[1]

[1] *Maastricht MultiModal Molecular Imaging Institute (M4I), Maastricht University, The Netherlands*

Corresponding author's email: d.hadavi@maastrichtuniversity.nl

Continuous flow chemistry is an efficient, sustainable and green approach for chemical synthesis that surpasses some of the limitations of the traditional batch chemistry. Along with the multiple advantages of a flow reactor, it could be directly connected to the analytical techniques for on-line monitoring of a chemical reaction and ensure the quality by design. Here, we aim to use ion mobility, mass and tandem mass spectrometry (IMS-MS and MS/MS) for the on-line analysis of a pharmaceutically relevant chemical reaction. We carried out a model hetero-Diels Alder reaction in a microflow reactor directly connected to the IMS-MS and MS/MS using either electrospray or atmospheric pressure photo ionization methods. We were able to monitor the reaction mechanism of the Diels Alder reaction and structurally characterize the reaction product and synthesis side-products. The chosen approach enabled identification of two isomers of the main reaction product. A new strategy to annotate the ion mobility spectrum in the absence of standard molecules was introduced and tested for its validity. This was achieved by determining the survival yield of each isomer upon ion mobility separation and density functional theory calculations. This approach was verified by comparing the theoretically driven collision cross section values to the experimental data. In this paper, we demonstrated the potential of combined IMS-MS and MS/MS on-line analysis platform to investigate, monitor and characterize structural isomers in the millisecond time scale.

Our ability to create physiological tissues with complex architectures, including spatial distribution of cells and extracellular matrix components, remains a challenge. The intervertebral disc (IVD), a fibro-cartilaginous structure acting as a natural shock absorber, contains an outer network of collagen fibers (Annulus fibrosus, AF) surrounding a central gelatinous (Nucleus pulposus, NP). Current approaches to engineer a functional IVD model, as an alternative to animal experiments, fail to recapitulate the physiological AF-NP gradient.

In this context, we have developed an in-house extrusion bioprinter with temperature controllers for both the printing stage and dispensing syringes and a pneumatic control allowing high spatial displacement resolution (0.1µm). A gelatin-alginate (7%:1%) bioink was optimized with the addition of hyaluronic acid (1%) and RGD adhesion groups to promote cell proliferation. The printability and long-term stability of bioprinted constructs were assessed by generating 1x1x0.5 cm3 cubes with high shape fidelity. Disc cells were harvested from young sheep (n=6) and were used to evaluate the bioink cytocompatibility. Disc cells were bioprinted and cell viability (Live&Dead), cell shape (actin immunostaining) and proliferation (EdU staining) were assessed after 1 month. Over 90% of cells were viable, proliferation was evidenced, with elongated cells observed within the constructs. Finally, MRI data from sheep IVDs were used to generate a full IVD model. Current efforts are focused on a mixing nozzle to generate the AF-NP gradient. Bioinks will be printed according to pre-defined trajectories built upon a gradient analysis of the distribution of collagen type II/type I on immunohistochemical sections of sheep IVDs.

Tissue engineering has long championed the importance of 3D culture models which mimic physiological form and function. While 3D cultures platforms can achieve higher product quality and quantity, few 3D platforms have been translated from the research bench, and industrial cell and tissue biomanufacturers remain smitten with stirred tank reactors due to ease of monitoring, reproducibility, and scalability. Here we illustrate recent work leveraging image-based mathematical models of cell culture to design and engineer better culture platforms. Platforms include marrow-mimicry hollow fibre perfusion reactors to biomanufacture red blood cells [1], patient-specific 3D printed bone reactors to optimise medium transport at scale [2], and melt-electrowritten microscaffolds to optimise pore bridging kinetics [3], among others. In all cases, custom-programmed confocal image analyses captured hundreds to millions of individual cell positions, shapes, and types to understand the spatial distribution of tissue growth. These large imaging datasets, with additional culture assays, were leveraged to parameterise mathematical models of scaffold tissue growth. This approach was able to enhance culture design through predictive modelling. Specific 3D printed scaffolds pore sizes and shapes could be selected for rapid tissue proliferation or desired morphology. Bioreactor medium composition and perfusion could be tailored to leverage autonomous cytokine release and minimize supplemented biofactor expense. Altogether, quantitative confocal image analysis offers a methodology to better monitor 3D culture kinetics to improve biomanufacturing process reproducibility and understand challenges in scalability.

Corresponding author's email: itomana@cc.saga-u.ac.jp

Conventional small caliber synthetic vascular graft with a diameter of less than 6 mm made of foreign substances such as PTFE (polytetrafluoroethylene) have many problems to be solved in terms of antithrombogenicity, anti-infectivity, biocompatibility, etc. Stem cell technology and tissue engineering technology have remarkably developed in recent years. Especially, 3D bioprinting is an emerging and rapidly expanding field with many exciting applications. We used a “Kenzan method Bio-3D Printer” to assemble multicellular spheroids to construct a three-dimensional structure predesigned on a computer system. This technique has enabled the production of tubular tissues only containing cells, without any exogenous scaffolds. Currently, we have started clinical research of autologous cell-based artificial blood vessels made with this Bio-3D printer as arteriovenous shunt used for hemodialysis. In this symposium, we will introduce the current situation, challenges, and future perspective of the clinical development of artificial blood vessels made of cells of small caliber using Kenzan method Bio-3D printers.

Spinal fusion surgery connects two or more vertebrae to stabilize a damaged spine; however, the rate of failure of fusion (Pseudarthrosis) is still high. The bone morphogenetic protein-2 (BMP2) has been approved to minimize pseudarthrosis for use in humans. Here in, we developed a poly(lactide-co-glycolide) (PLGA) composite incorporated with magnesium hydroxide (MH) nanoparticles for the delivery of BMP2. This study was evaluated the effects of released BMP2 from BMP2-immobilized PLGA/MH composite scaffold in an in vitro analysis and an in vivo mice spinal fusion model. The PLGA/MH composite films were fabricated via solvent casting technique. The surface of the PLGA/MH composite scaffold was modified with polydopamine (PDA) to effectively immobilize BMP2 on the PLGA/MH composite scaffold. Analysis of the scaffold revealed that PDA modified PLGA/MH composite improved hydrophilicity, degradation performance, neutralization effects, and increased BMP2 loading efficiency. Additionally, releasing BMP2 from the PLGA/MH scaffold significantly promoted the proliferation and osteogenic differentiation of MC3T3-E1 cells. The pH neutralization effect significantly increased in MC3T3-E1 cells cultured on the BMP2-immobilized PLGA/MH scaffold. In our animal study, the BMP2-immobilized PLGA/MH scaffold significantly enhanced bone regeneration by increasing osteogenesis and suppressing inflammatory responses. These results collectively demonstrate that the BMP2-immobilized PLGA/MH scaffold offers great potential in effectively inducing bone formation as a bioinspired material for spinal fusion surgery.

Recently, electrospun conduits have attracted considerable attention for nerve regeneration owing to their similarity to the nerve-extracellular matrix. To precisely mimic the nerve structure, these constructs should provide a challenging structure: random nanofibers in the outer layer and aligned ones on the inner side. It has been stated that piezoelectric materials can actively stimulate nerve regeneration as they create transient charges in response to mechanical strain. In addition, surface chemical properties play a leading role in cell-biomaterials interactions. Non-thermal plasma treatment is a well-known technique to change the surface chemical properties of the material, however, the incorporation of different functional groups by this method on piezoelectric nerve conduits is poorly investigated in the literature.

Therefore, in this research, polyvinylidene fluoride trifluoroethylene (PVDF-TrFe) conduits were fabricated by a novel two-pole structure electrospinning collector after which they were exposed to an atmospheric pressure plasma jet. The morphology, mechanical properties, wettability, chemical characteristics and cell affinity of the conduits before and after plasma treatment were assessed comprehensively.

The obtained images by scanning electron microscopy demonstrated that the designed collector is successful in obtaining the required nanofibers arrangement on the conduit walls. Furthermore, the hydrophilicity of the PVDF-TrFe conduits can be significantly increased due to the incorporation of polar oxygen-containing groups after plasma modification. In addition, it was also observed that cell-material interactions were improved due to applied plasma treatment. As such, the combination of using the fabricated piezoelectric nanofibrous conduits with plasma modification ensures a bright future for these constructs in nerve regeneration.

ANTAGONISTIC EFFECT OF MAGNESIUM HYDROXIDE NANOPARTICLE ON VASCULAR ENDOTHELIAL ACTIVATION INDUCED BY ACIDIC PLGA DEGRADATION PRODUCT

Dong Keun Han[P][1], Kyoung-Won Ko[1]

[1] *CHA university*

Corresponding author's email: dkhan@cha.ac.kr

Although drug-eluting stents (DESs) are mainly coated with biodegradable polymers such as poly(lactic-co-glycolic acid (PLGA) and poly(L-lactic acid) (PLLA), their acidic degradation products can affect homeostasis of adjacent tissue. Previously, we developed anti-inflammatory PLGA-based materials including magnesium hydroxide (MH) to relieve the side effects caused by PLGA degradation. However, the underlying molecular mechanism of its protective effects has not yet been clarified. Here, we demonstrated the molecular mechanism of vascular endothelial activation caused by PLGA byproducts. The degradation products of PLGA accumulated in HCAECs through the MCT1, followed by oxidative stress and the activation of the MAPK/NF-κB signaling pathway. Finally, the PLGA byproducts increased the expression of VCAM-1 as well as the secretion of pro-inflammatory cytokines. On the other hand, the addition of MH nanoparticles significantly diminished the activation of this pathological pathway and the expression of inflammation-related factors induced by PLGA byproducts. Furthermore, Mg2+ released from MH nanoparticles restored endothelial function in both intracellular and extracellular space. Taken together, MH nanoparticles prevent the accumulation of PLGA degradation products in HCAECs, thereby repressing the associated vascular endothelial activation. These findings on the biochemical mechanisms are expected to provide important clues for addressing the safety issues in nearly all biodegradable polymer-based implants.

LOADING INDUCED SELF-HEATING OF ARTICULAR CARTILAGE AND ASSOCIATED SIGNALING MECHANISM

Chondrocytes in cartilage receive ample biophysical stimuli through normal physical activities. While temperature of knee intra-articular region is around 32°C at rest, a temperature evolution was recorded in vivo following joint loading during jogging[1]. This self-heating phenomenon is associated with the viscoelasticity of cartilage and conversion of the dissipated energy to heat following cyclic deformation[2]. Despite co-existence of thermo-mechanical cues in cartilage, it isn't known how the synergy of temperature increase and mechanical loading may contribute to chondrogenesis.

To study cartilage thermo-mechanobiology, a customized in vitro system was firstly developed to simulate respective biophysical cues in cartilage tissue. Combined or decomposed effects of temperature and loading on cells biophysical response were evaluated by using a poro-viscoelastic hydrogel[3] and a novel modular bioreactor. We also studied the contribution of calcium signaling and Transient Receptor Potential Vanilloid (TRPV) 4 channels to thermo-mechano transduction process.

The applied intermittent biophysical stimulus had a positive impact on chondrogenic response of human progenitor cells in all groups. In particular, expression of the transcription factor Sox9, one of the main regulators of early stage chondrogensis, was positively upregulated by application of combined thermo-mechanical cues. Moreover, a higher expression following thermo-mechanical stimulation was observed for main chondrogenic markers compared to thermal and mechanical cues alone. It was shown that calcium is a major signaling mechanism for translation of thermo-mechanical cues and there are parallel pathways to make this process more effective. TRPV4, as a thermo-mechano responsive ion channel, is a key mediator in transduction of loading induced self-heating.

The general health in ageing population is a problematic issue in orthopedic and dental fields. Accordingly, the use of bone biomaterials has become a widely accepted treatment option. The healing of bone biomaterials is strongly influenced by local and systemic factors, which are related either to the materials itself or to the medical condition. For example, an altered bone metabolism due to osteoporosis can negatively affect bone-implant healing. In an attempt to enhance bone regeneration related to biomaterials in osteoporotic condition, several approaches have been reported in terms of material design, surgical techniques, and therapeutic additives. Nowadays, research efforts increasingly focus on the use of anti-osteoporotic drugs to promote bone response related to biomaterials in an impaired bone condition. Beside their role in the treatment of osteoporosis, systemic administration of anti-osteoporotic drugs is suggested to maintain a balance between bone resorption by osteoclasts and bone formation by osteoblasts around bone biomaterials.

In view of this, we have performed several preclinical studies to investigate the role of anti-osteoporotic drugs on bone healing around biomaterials in healthy and osteoporotic condition. The data of our preclinical studies indicate positive effects of anti-osteoporotic drugs on bone healing related to biomaterials (titanium implants and bone grafts). Although our results suggest that anti-osteoporotic drugs might reverse the negative impact of osteoporotic conditions on the peri-implant bone healing, more information is required from long-term implantation studies using standardized protocols for administration route, dosage and anti-osteoporotic drug before translational steps toward clinics.

Tissue engineering aims to develop biological substitutes for the repair or complete replacement of injured tissues and organs [1]. In this field, spheroid has been drawing attention due to its regenerative properties. Spheroid defined as ball-shaped compacted cell aggregates consisting of monotypic or heterotypic living cells. Two interactions within the spheroid cause the improvement in biological properties compared to monolayer cultured cells. Cell-to-cell and cell-to-extracellular matrix interactions occurring within the spheroid mimics the in vivo environment. In this study, we successfully fabricated ASC spheroid entrapped scaffold using a combined system composed of 3D printing and electrospinning methods. The spheroids were positioned and entrapped in the pore of the scaffolds using electrospinning method. Angiogenic, wound healing-related gene expression analysis and tube formation assay were conducted to evaluate the properties of the fabricated scaffold. The ASC entrapped scaffold showed higher tube formation and better skin regeneration related gene expression compared to single cell entrapped scaffold. The angiogenic and wound healing gene expression results indicated that the hereby developed scaffold revealed to maintain the properties of spheroid. From those results, we conclude that the ASC spheroid entrapped alginate scaffold could be a new strategy for skin tissue regeneration.

1. Introduction

Hair regenerative medicine has been investigated as a promising approach for the treatment of hair loss. Recent studies reported that transplantation of follicular stem cells resulted in regeneration of hair follicles and hairs. However, hair induction ability of dermal papilla cells (DPCs) is declining drastically after isolation from in vivo tissues and during expansion culture. In this research, we propose an electrical stimulation culture to recover the hair induction ability of DPCs using a conductive polymer polypyrrole (PPy).

2. Experimental

A culture device for electrical stimulation was built by electrochemically synthesizing PPy on a slide grass. DPCs at passage 4 were seeded onto the PPy membrane and applied electrical stimulation under several conditions. Gene expressions associated with hair follicle morphogenesis were evaluated. Furthermore, to examine de novo hair generation ability, the cells were collected after electrical stimulation and mixed with embryonic epidermal cells in a commercial non-cell-adhesive round-bottom 96 well plate (1). The aggregates were then transplanted on the back of mice. Hair shaft generation was evaluated for up to 3 weeks.

3. Results and discussion

The application of electrical stimulation significantly promoted alkaline phosphatase gene expression. The mixture of DPCs and epidermal cells exhibited typical morphological features of hair follicle germ in three days of culture. On intracutaneous transplantation into the backs of nude mice, the hair follicle germs prepared with the electrical stimulation efficiently generated hair follicles.

Hydrogels have been used in tissue engineering extensively for cell container or niche. However, they have limitation in diffusible distances (0.2-0.4 mm) and researchers have tried to overcome this issue by mimicking the vascularized structure of our body [1-4]. However, vascularization of the artificial tissues usually needs additional processes and materials to compose a vasculature in the 3D structure. Here, we have developed a functional cell-laden bioink with meringue-like structure using collagen, which is the most common protein component in our body. Meringue has interconnected structure composed of air, liquid, and protein chains. With turbulent whipping process, air bubbles are introduced into the protein hydrogels and entrapped by the hydrophobic parts of the untangled protein chains, forming a highly macro/microporous structure. In the meringue-like structure, cells (MG63) could survive not only for more than 4 weeks, but also in about 2-mm depth or deeper, which is more than 10-fold deeper than the hydrogel diffusion limits (0.2 mm). In addition, this meringue-like bioink is injectable through gauge nozzles without structural destruction or cell damages. The advantages of the meringue bioink can be used to surpass the uppermost limit of bioprinting and tissue regeneration technologies.

Keywords

meringue; collagen; bioink

Despite increasing evidence that mechanical[1] and electrical[2] stimuli have positive effects on chondrogenesis, to date, the coupling effect of them has received a very limited attention. In articular cartilage, the electric potential is generated upon tissue deformation following the movement of the positive mobile ions away from the fixed negative charges[3]. Designing a 3D biomaterials with relatively stiff structure and capable for simulating the electrical signals of native cartilage is central to study cartilage electro-mechanobiology (stress-generated electric potential) in vitro. To address this challenge, we proposed a novel strategy to control both the mechanical and electrical performances of a hydrogel system. Accordingly, a 3D porous piezo-composite hydrogel with electro-mechanical properties within the range of cartilage is developed based on combination of fiber-reinforcement technique, electrospinning, and salt leaching methods. Despite traditional method used for in vitro electrical stimulation which are not biomimetic (e.g., using an external power supply), we employ electrospun piezoelectric polyvinylidene nanofibers in the hydrogel structure as an electroactive phase to generate electric signals upon mechanical loading. It is shown that incorporation of nanofibers into hydrogel networks significantly increase their mechanical properties and enhance cells adhesion and proliferation inside composite constructs thanks to the implemented nano-topographic structure. We present that piezoelectric effects promote cells growth and metabolic activity compared to respective control groups. The expression of chondrogenic markers following applied stimulation is also higher for the piezo-composite hydrogel compared to the pure hydrogels. This approach allow us to evaluate the synergistic effect of electro-mechanical cues on chondrocyte biological response.

The need for 3D culture of cells is emerging in the field of tissue regeneration. The three-dimensional (3D) cell culture systems are emerging as a powerful tool with enormous translational potential, especially for cancer and stem cell research. The 3D cell culture model can better reproduce not only morphology in the body but also cellular connectivity, polarity, gene expression and tissue structure, so it can have more physiological characteristics dynamically relevant and predictable compared to 2D models1. In this study, a microfluidic approach is presented that rapidly generates structure containing hydrogel micro bead that create 3D environment that enhances osteogenesis. Gelatin methacryloyl mixed with MG 63 cells and the prepared bio-ink were inserted with mineral oil into microfluidic. The microfluidics device was fabricated from polydimethylsiloxane to produce a water-in-oil emulsion containing GelMA and a photoinitiator in the aqueous phase and oil phase. Fabricated Gel-MA beads were crosslinked via UV light and inserted into second aqueous phase. The mixture was crosslinked by CaCl2 and alginate strut containing cell laden microbead was fabricated. The cell viability was measured by using live/dead staining. Rt-pcr test was performed to check cell differentiation. Enough cell viability (>90%) was observed after the bioprinting process. In this study, we developed a heterogeneous bioprinting strategy for the composite structure fabrication. The cell-laden heterogeneous strands were successfully printed by using the developed method. We expected that this new fabrication method can be used for the research about composite tissue and has the potential.

A PROTEOMIC APPROACH TO UNRAVEL THE ROLE OF THE EXTRACELLULAR MATRIX DURING KIDNEY ORGANOID MATURATION.

Virginie Joris[P][1]

[1] *Maastricht University*

Corresponding author's email: v.joris@maastrichtuniversity.nl

Two million people worldwide are dependent on dialysis with no option for renal transplantation. Alternatives are needed to address the medical demands and lessen the economic burden. One such alternative is a therapeutic engrafting of human induced pluripotent stem cell (iPSC)-derived kidney organoids to the dysfunctional kidney. We are generating kidney organoids, starting from human iPSCs, that consist of the major cell types present in adult human kidney. While robust differentiation protocols exist, relatively little is known about the events that lead to organoid maturation and vascularization. In contrast to what has been observed in vivo where transplanted kidney organoids further mature and vascularize, kidney organoids maintained in vitro fail this maturation step. It is known that the extracellular matrix (ECM) is a key component in embryonic kidney development and fetal maturation. Aberrant changes to its composition and organization have been linked to fibrosis and other diseases. We show that kidney organoids aged in vitro have an incomplete ECM that is associated with an abnormal spatial deposition. We performed a proteomic analysis on kidney organoids cultured for a prolonged culture time and found a specific change in the ECM composition with an increased expression of type 1a1, 2 and 6a1 collagen. Such an excessive accumulation of specific collagen types is a hallmark of renal fibrosis that causes a life-threatening pathological condition by compromising key functions of the human kidney. We believe that by controlling the expression of these proteins, we will be able to create a more mature kidney organoid.

Abstract **#1110**

REDUCING NON-RENAL CELL DIFFERENTIATION FORMING CHONDROGENIC CELL POPULATIONS IN KIDNEY ORGANOIDS.

Thomas Geuens[1], Virginie Joris[P][1]

[1] *Maastricht University*

Corresponding author's email: v.joris@maastrichtuniversity.nl

Kidney organoids derived from induced pluripotent stem cells (iPSC) are three-dimensional, mini kidney-like structures that aims to resemble human renal physiology. They form the important renal structures necessary for renal filtration such as glomeruli and proximal and distal tubuli. These organoids provide opportunities to study (genetic) renal diseases, renal development, and drug toxicity, but also as a potential clinical solution for patients with kidney failure. Two million people worldwide are dependent on dialysis with no option for renal transplantation. Alternatives are needed to address the medical demands and lessen the economic burden. One such alternative is a therapeutic engrafting of iPSC-derived kidney organoids to the dysfunctional kidney. However, these kidney organoids are not yet suitable for regenerative medicine as they bear non-renal cell differentiation, such as the appearance of chondrogenic cell populations upon aging and after in vivo transplantation. In order to enhance the renal phenotype of these kidney organoids we need to prevent the emergence of the non-renal phenotype. Therefore, we will mine existing single cell RNA sequencing datasets to form a hypothesis about which pathways are involved in forming the cells with the cartilage phenotype. These new data will allow us to screen for small molecule modulators of the identified pathway(s), which will first be tested for efficacy in vitro during iPSC differentiation and/or organoid development. In a final stage, our findings will be validated in vivo to check for the reduction of the cartilage phenotype and to determine if the renal phenotype has not been affected.

ESA 3D BIOPRINTER FACILITY FOR THE INTERNATIONAL SPACE STATION

Leonardo Surdo[P][1]

[1] *European Space Agency*

Corresponding author's email: leonardo.surdo@esa.int

3D printing is rapidly expanding: almost every week new printers and printing materials offering novel possibilities as well as new exciting applications appear. Within the life sciences and healthcare domains, numerous applications belong to the cell and tissue biology research as well as regenerative and personalized medicine applications.

3D bioprinting is steadily progressing on Earth and could find a further technological push and research achievements through its utilization in human space exploration.

Likewise, 3D cell cultures provide experimental models which more closely approach the structure and composition of organs and tissues. Studies with 3D cell culture models may be useful for understanding how processes in the whole organism are affected by microgravity or spaceflight conditions, which otherwise cannot be readily investigated in monolayer (2D) culture systems on Earth, animal or human subject studies.

ESA is planning to enhance the BIOLAB rack inside the ISS' Columbus module with a 3D bioprinting and 3D cell cultures capability to enable additional, state-of-art biology research in human spaceflight and to prepare biomedical applications for potential health emergency issues in anticipation of human long-term deep space exploration missions.

The ESA 3D bioprinting and 3D cell cultures capabilities will enable research investigations including, but not limited to fundamental and applied biotechnology, cell and tissue biology, regenerative and personalized medicine. The research performed with the 3D bioprinter and 3D cell cultures system on-board the ISS will build knowledge and technological advancement for future utilisation beyond the ISS, e.g. on Gateway, Moon and Mars human space exploration missions.

Magnesium(Mg) alloys have attracted attention in biomedical applications due to their biodegradability and satisfying mechanical properties (1). Mg alloy implants have been shown to reduce stress shielding when compared to other non-degradable metal implants due to its low young's modulus. Mechanical properties of the widely used degradable polymers such as polylactic acid, polycaprolactone are about a half of the those of Mg alloys (2). Recently, a few groups attempted additive manufacturing (AM) of Mg alloys and showed promising results (3). Nevertheless, AM of Mg remains challenging due to its high vapor pressure and high oxidation affinity (4). In this study, 3D fiber deposition (3DF) was applied as AM technology to fabricate porous AZ91D scaffolds by using a slurry of MgAl powder at RT in a cost effective way. First, binder system for MgAl slurry was developed to avoid any reaction with Mg. Second, the rheological properties of slurry were optimized to allow printing and avoid sagging and shape deformation of the fibers. Finally, debinding and sintering process was set up to prevent contamination during sintering. The resulting 3D porous MgAl scaffolds had hierarchical structure with interconnected pores and fusion between metal particles. The chemical analysis indicated the no contamination occurred during debinding and sintering process. The compressive strength and Young's modulus with porosity of 30% were 89±9 MPa and 0.6±0.12GPa, respectively. The in vitro degradation study of the scaffolds is ongoing. 3DF may be a useful methods for manufacturing 3D porous MgAl scaffolds for biomedical application.

Scaffolds consisting of native tissue-derived hydrogel is gradually approaching the golden standard for tissue engineering for its close approximation to the target tissue via mirroring the architecture and intricate composition. However, scaffold with appropriate geometries and materials are often challenging and difficult. To overcome this issue, we introduced a micro-channeled native-derived hydrogel/biceramics composite scaffold. Briefly, a sacrificial fibrous PCL structure was fabricated via conventional 3D printing. Then, followed by coating the sacrificial structure with native-derived hydrogel and bioceramics, the PCL fibers were removed for achieving the micro-channeled composite scaffold (mCCS). The mCCS showed highly porous mesh structure consisting of micro-channeled structs. The channels evoked high capillary pressure, resulting in efficient angiogenic properties within the scaffold. Consequently, immunofluorescent staining results revealed that angiogenesis was achieved in the micro-channels, while osteogenesis was achieved on the surface of the scaffold. Based on the promising in vitro results, the purposed mCCS would increase the efficacy of bone tissue regeneration.

Myocardial infarction (MI) causes irreversible damage to the heart, resulting in impaired heart function. Recently, cardiac tissue engineering has emerged as a novel therapeutic approach for functional repair post-MI. Specifically, electroconductive bioengineered tissues could improve the effects of cardiac cell therapy. In this study, we aimed to use a mechanically stable, crosslinked form of polypyrrole (PPy) incorporated cardiogel (CG) for in vivo transplantation of cardiac progenitor cells (CPCs) in rat hearts post-MI. The crosslinked CG-PPy scaffold (P1) showed a three-dimensional (3D) interconnected porous structure in which vital extracellular matrix (ECM) components were preserved while attained appropriate mechanical properties as well as significantly greater electrical conductivity (9-fold) compared to a crosslinked CG scaffold (C1). Transplantation of CPC-loaded P1 on the rat hearts post-MI led to substantial improvement of some cardiac functional and morphological features such as left ventricular ejection fraction (LVEF), fractional shortening (FS) and left ventricular inner diameter at systole (LVIDs) compared to the vehicle receiving group (Ctrl), while forming considerably lower fibrotic tissue. Grafted cells revealed cardiomyocyte–characteristics as per staining with antibodies against human cardiac troponin T (hcTNT) and human connexin43 (hCx43). Furthermore, higher number of α-SMA positive vessels were observed in the heart sections of P1-CPC transplanted rats compared to all other treatments four-week post-surgery. These findings highlight the potency of a crosslinked CG-PPy scaffold as CPCs carrier for regenerative therapy of the heart post-MI.

Alginate is an attractive candidate in the formulation of bioinks. However, the lack of cell adhesive moieties requires additional processing strategies that usually affect the rheological properties of the bioink and, in turn, their manipulation and in vitro performance. Therefore, the main goal of the present work was to design simple, robust and tuneable cell-laden inks through the incorporation of microspheres of different nature for bone regeneration applications.

Three types of microspheres (i.e. gelatine, gelatine containing hydroxyapatite nanoparticles and hydroxyapatite) were synthesised and incorporated into an alginate/gelatine ink loaded with cells. Immediately after, the mixtures were extruded, cross-linked and incubated in cell culture media for different days. Cell viability and proliferation were assessed at different time points by live/dead and Alamar Blue assays, respectively. Furthermore, the differentiation to osteoblastic lineage was studied by measuring gene expression of osteogenic markers through RT-qPCR and immunofluorescence assays.

The results confirmed the cytocompatibility of all bioinks. On the one hand, the incorporation of gelatine microspheres promoted cell migration and adhesion at short time points, as well as cell proliferation throughout the whole experiment. On the other hand, hydroxyapatite-containing microspheres induced the differentiation of the cells to osteoblastic phenotype for both, early and late genes.

In conclusion, we have developed robust and tuneable alginate-based bioinks with improved biological features by simply adding microspheres of different composition in the ink formulation. This strategy efficiently overcomes the limitations arising from chemical modifications of current alginate bioinks and can easily be applied to other biomedical fields.

Introduction. The low success of anti-cancer drugs in clinical trials evidence that current 2D in vitro models used in preclinical studies cannot fully mimic the 3D tumor microenvironment. Therefore, more predictive 3D in vitro models are needed. Among them, cancer spheroids (cS) recapitulate many tumor characteristics. Peptide hydrogels (HGs) have been shily explored as platforms for cS production. Particularly, elastin-inspired peptides are an interesting approach for cancer research due to their tunable properties. Elastin-like recombinamers (ELR) self-assemble above certain temperatures forming biocompatible gels, that can be cross-linked by click chemistry.[1]

The aim of this work is to assess the potential of ELR HGs to create breast cancer cS for drug screening.

Methods. Breast cancer (MCF-7, MDA-MB-231) or non-tumor breast (MCF10A) cells were encapsulated within ELR hydrogels. Cells were dispersed in an MMP-sensitive ELR with cyclooctine groups, and then mixed with an ELR carrying azide groups and RGD. Cell proliferation, viability, cell morphology and ECM deposition were evaluated. Doxorubicin IC50´s were measured after 48h in hydrogels and 2D cultures.

Results and discussion. Hydrogels were biocompatible and enabled a homogeneous cell distribution. MCF-7 and MCF10A formed cS whereas MDA-MB-231 formed cell networks. All cell types deposited ECM proteins after 7d. Cells cultured in the hydrogels were more resistant to doxorubicin than the 2D counterpart.

Conclusions. ELR HGs are a promising material for developing in vitro breast cancer models for drug screening.

EXPLORING THE ROLE OF PERIPHERAL MYELIN PROTEIN 22 EXPRESSION IN ORDERED MEMBRANE DOMAINS OF SCHWANN CELL DIFFERENTIATED DENTAL PULP STEM CELLS AND HOW IT AFFECTS CELL-MATRIX INTERACTIONS

New therapeutic strategies to establish repair of injured peripheral nerves are desperately needed. For this purpose, our group developed Engineered Neural Tissue with Schwann cell differentiated human dental pulp stem cells (SC-hDPSC) embedded in an aligned collagen hydrogel 1, 2. The use of SC-DPSCs as a cell source for nerve repair has several advantages but there is a need to better understand how they interact with the extracellular matrix (ECM) and how this affects their myelinating behavior. We aim to investigate the role of peripheral myelin protein 22 (PMP22) in the interaction of SC-hDPSCs with an endoneurial-like ECM.

SC-hDPSC were cultured on 2D coated surfaces and by performing immunostainings combined with confocal- and super resolution STORM microscopy we showed that PMP22 is expressed in lipid rafts of the plasma membrane. Live cell/TIRF imaging experiments with cholera toxin b showed that these lipid rafts are highly dynamic. We also observed a strong colocalization between PMP22 and integrin β1, α6, and β4 in the membrane of SC-hDPSC. In addition, SC DPSC cultured in aligned or free floating hydrogels strongly interact with collagen I fibres via these integrins, which was confirmed macroscopically and with label-free second harmonic generation microscopy.

In conclusion, we showed that PMP22 is expressed in ordered regions in the SC-hDPSC membrane together with integrins that are important for cell interactions with the ECM and in myelination. This implicates that PMP22 may play a role in controlling myelination, but this will be explored in future experiments.

DEVELOPING A SOFT-HARD COMPOSITE SCAFFOLD USING ELECTROSPINNING AND 3D PRINTING

Rand Alkaissy$_P$[1], Pierre-Alexis Mouthuy[1], Andrew Carr[1]

[1] *Nuffield Department of Orthopaedics, Rheumatology and Musculoskeletal Sciences (NDORMS)*

Corresponding author's email: rand.alkaissy@ndorms.ox.ac.uk

Rotator cuff tendon tears are one of the most common injuries of the musculoskeletal system, resulting in 40,000 surgical re-attachment repairs in the United States alone[1]. Re-tearing following rotator cuff repair is a significant clinical problem, with a failure rate of up to 40%[1], notably at the transition from bone to tendon (enthesis)[2]. The aim of this project is to develop a biphasic scaffold consisting of a soft and hard component, which can recapitulate this interface.

To achieve this, a novel manufacturing approach was developed, combining 3D printing and electrospinning. A porotype scaffold was created by bonding together polydioxanone (PDO) fibres and polycaprolactone (PCL) lattice structures. Firstly, PDO fibres were continuously produced by electrospinning on a metal wire collector[3,4], after which PCL lattice structures were extruded at a temperature of 120 °C on top of the pre-assembled electrospun fibres to complete the scaffold. No additional post-processing was required to use the scaffolds for further characterization.

SEM imaging of the PDO fibers showed an alignment that resembles fibrils within a tendon. Micro-CT imaging of the prototype scaffold revealed intact PDO fibers within the 3D printed construct. Preliminary mechanical testing showed an ultimate failure force at 47.4 +/- 2.2 N. Biocompatibility of the scaffold will be tested in a second phase.

While preliminary results show mechanical properties not yet representative of the full rotator cuff force, we suggest that combining electrospinning and 3D printing is a feasible and easy approach with room for optimization to create a mechanically robust soft-to-hard biphasic scaffold.

Conductive hearing loss affects middle ear functionality in more than 5% of the population worldwide. To replace damaged ossicles, surgical approaches use piston-like prostheses, made of biological grafts or alloplastic biomaterials, to restore the mechanical continuity between the tympanic membrane and the oval window (1). However, many of these fall off after a period of time requiring revision surgery. We present a new generation of partial ossicular replacement prostheses (PORPs) shaped like scaffolds made of poly(ethylene oxide terephthalate)/poly(butylene terephthalate) (PEOT/PBT) copolymer, and fabricated via three-dimensional fiber deposition. Dimensional and porosity features of the scaffolds are characterized. Human mesenchymal stromal cells are then osteo-differentiated on PORP-scaffolds using serum-free and xeno-free media to investigate the capability of such structures to be properly hosted by native tissues under a translational approach. Cell viability result stable up to 3 weeks, show successful osteo-differentiation of the stem cells in the scaffolds. This indicates the potential for minimizing the risk of prosthesis extrusion and minimizing revision surgery. We use Laser Doppler Vibrometry to assess performance of the prostheses in response to sound stimulation (2). PORPs are placed by an otologist on 4 human cadaveric temporal bones, in a frequency range between 100 Hz and 20 kHz. Stapes motion shows a good match against intact middle-ear outcomes with little inter-ear variability, especially at frequencies below 3 kHz. These results pave the way to a promising tissue engineering approach for ossicular replacement that can be used as a reliable long-term surgical alternative to the current standard of care.

In vitro models of the human gastrointestinal (GI) tract are often used for study in the food and pharmaceutical industries. A range of models for most organs of the GI tract have been developed. Current in vitro oesophagus models are often simplistic and do not simulate physiological conditions accurately 1. This project aims to develop a model of the human oesophagus that can be used to study the passage of orally administered medicines. In order to do this a material that mimics the surface of the oesophagus tissue needs to be developed. The innermost surface of the oesophagus has a thin basement membrane network of fibres 2. Electrospinning has been used to replicate this layer. Data was obtained on the mechanical and surface properties of porcine oesophagus, which is physiologically similar to that of humans. An electrospun polyurethane (PU) material was produced and combined with a gel phase (gelatin). The average fibre diameter of the electrospun PU was 128.1nm which, while higher that the reported average fibre diameter of the oesophageal basement membrane fibres (66nm), was within the reported acceptable range of 28-165nm 2. Mechanical testing of the electrospun PU showed that it had significantly different properties than the porcine oesophagus. However, when the electrospun PU is combined with a gelatin phase preliminary observations show a large change in the mechanical properties of the bulk material and results in a material which appears to share more textural and surface characteristics with porcine oesophagus tissue.

CONTROLLED ACTIVATION OF PREFABRICATED A-TRICALCIUM PHOSPHATE CEMENT PASTES STABILIZED BY SODIUM PYROPHOSPHATE

Calcium phosphate cements are frequently applied as bone substitutes due to their excellent biocompatibility. For successful clinical application, easy handling at the surgery is important. The mixing procedure can be effectively facilitated by the application of prefabricated cement pastes: Instead of mixing a liquid and a powder, a solution and a suspension are mixed, which can be assembled in one special syringe [1].

One prerequisite of this approach is the successful stabilization of a cement powder suspension in parts of the mixing liquid. In the present study, a suspension of reactive α-tricalcium phosphate powder in water was successfully stabilized up to 4 weeks at room temperature by sodium pyrophosphate (PP) in a concentration of 0.05 wt.%. Controlled activation of the hydration to calcium-deficient hydroxyapatite was accomplished by addition of a Na2HPO4/NaH2PO4 (Na2/Na) solution (weight ratio 4:1; overall concentration 30 wt.%). For systematic assessment of the activation mechanism, including the effect of the PP concentration and the amount of Na2/Na added, the hydration was studied by isothermal calorimetry, quantitative in-situ X-ray diffraction and Gillmore needle measurements at 37 °C.

Increasing the PP concentration lead to systematic retarding of the setting reaction at constant Na2/Na amount. An elevated quantity of Na2/Na addition at constant PP concentration resulted in acceleration of the hydration. These results indicate that the setting mechanism is adjustable for clinical needs by proper selection of the PP concentration and amount of Na2/Na added.

In developed countries, retinal degenerative diseases affecting Retinal Pigmented Epithelium (RPE), including Age-related Macular Dystrophy and inherited retinal diseases such as Retinitis Pigmentosa (RP), are the predominant causes of human blindness worldwide. So far, there is no cure for such diseases. We have developed a cell therapy medicinal product based on our expertise in tissue engineering and in the manipulation of pluripotent stem cells. This novel tissue engineered product (TEP) consists in RPE cells derived from clinical grade human embryonic stem cells disposed on a biocompatible substrate allowing the formation of a 3D functional sheet, suitable for transplantation. After functional validation in a rodent model of RP, we have tested the safety of the surgery and local tolerance in non-human primates (NHP).

A specific device was developed and non-human primates (NHP, n=6) were transplanted in one eye (right eye) with the TEP in the macular region. Retinal integrity and functionality were assessed at different time points (week 1, 2, 4, 6 and 7). Inflammation was also assessed. At the end of the experimental period, histological analysis was performed to evaluate the correct location and integration of the TEP within the host retina.

We have shown in NHP that our surgical method of implantation was safe and did not provoke any local inflammation or retinal deterioration. Morphologic and histologic studies indicated that RPE cells were integrated into the host retina and were able to interact with photoreceptors. These results allowed us the start of clinical trial in sept 2019 (NCT NCT03963154).

Most tissues in our body are fully vascularized which facilitates the gas and nutrient exchange from the blood circulation. Menisci, however, consist of a vascularized and non-vascularized region. In tissue engineering, mimicking the spatial distribution of vascular components is paramount. In fact, capillary ingrowth into non-vascularized tissues can lead to tissue matrix alterations and subsequent pathology. Three-dimensional (3D) bioprinting has the potential to reproduce tissues with anisotropic features. Nevertheless, recreating a construct with stable vascularized and non-vascularized regions has not been achieved to date.

Previously, it was shown that fibrin bioinks with type I collagen microfibers facilitate capillary and lumen formation of HUVECs (1). Here, we additionally developed cartilage matrix microfibers, normally involved in preserving the avascular nature of cartilage (2,3). We demonstrate that they successfully inhibited HUVEC capillary formation. Through supplementation of two fibrin-based bioinks with type I collagen or cartilage matrix microfibers, we 3D bioprinted complex structures with distinct regions that facilitate or inhibit vascularization. Constructs were 3D printed in a gellan gum microparticle-based suspension bath and showed a filament thickness of 350 micron. Four days after printing, the HUVECs showed network formation.

This study demonstrates the spatial-specific formation of capillaries in a 3D bioprinted construct. With this, we contribute to the development of biomimetic meniscal grafts. Moreover, this setup can serve as a platform for generating tissue constructs with vascularized and non-vascularized regions. These bioinks could be utilized for in vitro models for studying effects of new drugs, or mechanisms of vascularization.

INFLUENCE OF CU2+-DOPING IN B-TCP ON THE HYDRATION KINETICS OF BRUSHITE CEMENT

Karla Späth[P][1], Katrin Hurle[1], Friedlinde Goetz-Neunhoeffer[1]

[1] *Geozentrum Nordbayern, Mineralogy, Friedrich-Alexander University Erlangen-Nürnberg*

Corresponding author's email: karla.spaeth@fau.de

One example for brushite (CaHPO4·2 H2O) formation is the reaction of monocalcium phos-phate monohydrate (MCPM, Ca(H2PO4)2·H2O) and β-tricalcium phosphate (β-TCP, β-Ca3(PO4)2), which react with H2O according to (1). The use of Cu2+ as dopant for β-Ca3(PO4)2 leads to increased antibacterial activity, hence preventing inflammation [1] and has positive effects on angiogenesis and wound healing [2].

Ca(H2PO4)2·H2O + β-Ca3-xCux(PO4)2 + 7 H2O → 4 CaHPO4·2 H2O (1)

The effect of Cu2+ doping in β-TCP on the hydration was investigated by isothermal heatflow calorimetry, powder and in-situ XRD, ICP-MS measurements of the pore solution and 1H-NMR for determination of different proton mobility in free H2O and formed phases. β-TCP was mixed with MCPM with a molar ratio of β-TCP/MCPM = 1.63 and a water to solid ratio of 0.3 ml/g. Phytic acid (IP6, C6H6(OPO3H2)6) was used as a setting retarder. The measure-ments were conducted at 23 °C and selected mixtures were measured at 37 °C and 5 °C. β-TCP with Cu2+ contents between 0 and 5 mole-% were used. Heatflow calorimetry and in-situ XRD measurements showed an increasing retardation of the reaction with increasing amount of Cu2+ in β-TCP. Brushite and small amounts of monetite were detected as reaction products. The samples with Cu2+ show also a secondary phase with a strong preferred orientation, which is assumed to be a Cu2+ containing hydrate phase.

Organ-on-Chips (OoCs) are nowadays considered the nascent technology to replace animal models, in compliance with the principles of the 3Rs (Replacement, Reduction and Refinement) developed over 50 years ago [1]. Although that goal is still far off, their use might illuminate differences between animal models and humans, with important outcomes in drug screening, disease model and regenerative medicine [2]. In all these fields, vascularization is a key aspect and OoCs are particularly attractive to realize capillary vessels. Particularly in the brain, vascularization has exceptional features, which are represented in the blood-brain barrier (BBB). Using OoCs to develop a model of the human BBB is considered an interesting way to overcome the limitations of rodent models and transwell systems, by combining the handiness of an in vitro model with the complexity of a living organ, while reducing reagents consumption [3]. Our work is focused to develop a human BBB-on-chip model based on a continuously perfused microfluidic platform, recreating the exposure of the cells to different shear stresses, which can upregulate genes associated with junctional proteins and transporters, enhancing barrier integrity [4]. The chip design is based on a double-layer layout that puts in contact a fluidic compartment with endothelial cells ("blood side") to a static compartment with brain cells in a 3D matrix ("brain side") reproducing the three-dimensional environment of the brain parenchyma. In addition, our model allows the deposition of 3D brain cells by bioprinting technique for better controlling their spatial distribution.

For bone tissue engineering, the use of extracellular vesicles (EVs) are emerging as a promising acellular approach compared to cell-based therapies [1]. Despite their promise, the short half-life of these naturally-derived nanoparticles following systemic administration hinders their therapeutic potential. Therefore, this study aimed to develop an injectable chitosan-collagen composite hydrogel capable of controlling the release of osteoblast-derived EVs to promote bone regeneration.

Chitosan-collagen composites were fabricated at ratios of 100/0, 65/35, 25/75 and 0/100 wt%. The hydrogels gelation time, compressive modulus and pore size were characterised. Osteoblast-derived EVs were incorporated within the different composites and their release kinetics were determined using the CD63 ELISA. The size, morphology and concentration of released EVs were assessed via dynamic light scattering, nanoparticle tracking analysis and transmission electron microscopy. The osteogenic differentiation of human bone marrow stromal cells (hBMSCs) encapsulated within the EV-functionalised hydrogel was evaluated by qPCR, biochemistry and histological analysis.

The presence of collagen within the composite hydrogel significantly enhanced compressive modulus and reduced gelation times and pore size. EVs release kinetics was collagen dependent, where greater the proportion of chitosan in the composite, resulted in increased EV release. In monolayer, the functional activity of hydrogel released EVs was confirmed with enhanced hBMSCs proliferation and migration. Importantly, EV-functionalised composite hydrogels significantly promoted encapsulated hBMSCs osteogenic differentiation when compared to the EV-free gel during osteogenic culture.

These findings demonstrated the development of an injectable chitosan-collagen composite capable of controlling the release of osteoblast-derived EVs as a novel acellular tool to promote bone regeneration.

Bone bleeding is a common symptom in orthopedics. Development of biomedical materials for the intraoperative hemorrhage control and postoperative bone regeneration are crucial for the safety and recovery of patients. Injectable putty composed of a core-shell structured calcium sulfate-calcium polyphosphate granules and cellulose gel was developed to fill the bleeding site of bone and locally enhance bone regeneration. The former granule was prepared using calcium sulfate cement as templates, and the latter gel was prepared via mixing cellulose and water. Taking the advantages of calcium polyphosphate in being hydrolyzed by osteoblast released alkaline phosphatase to generate energy, phosphate ions, along with the fast resorption rate of calcium sulfate to provide calcium ions and space, the implanted granules after hemostasis can stimulate bone regeneration. This novel injectable putty is expected to be an alternative to bone wax for bleeding bone treatment.

The development of alternatives for autologous bone grafts is a major focus of bone tissue engineering. To produce living bone forming implants, skeletal stem and progenitor cells (SSPCs) are envisioned as key ingredients. SSPCs can be obtained from different tissues including bone marrow, adipose tissue, dental pulp and periosteum. Human periosteum-derived cells (hPDCs) exhibit a number of progenitor cell characteristics and have well-documented in vivo bone formation potency. Here, we have characterized and compared hPDCs derived from tibia with craniofacial hPDCs from maxilla and mandible, that could be a potential source for cell-based tissue engineered implants for craniofacial applications.

Maxilla- and mandible-derived hPDCs display similar growth curves as tibial hPDCs, with comparable trilineage differentiation in vitro potential towards chondrogenic, osteogenic and adipogenic cells. These craniofacial hPDCs are positive for the SSPC-markers CD73, CD164 and PDPN (1), and negative for hematopoietic and endothelial lineage markers. Bulk RNA-sequencing identified genes that are differentially expressed between the three sources of hPDCs. In particular, differential expression was found for genes of the HOX and DLX family, SOX9 and genes involved in skeletal system development. De novo in vivo bone formation after ectopic implantation in nude mice was observed in constructs seeded with tibial and mandibular hPDCs.

Taken together, we provide evidence that craniofacial hPDCs are potential sources for cell-based bone tissue engineering strategies. The mandible-derived hPDCs display - both in vitro and in vivo - chondrogenic and osteogenic differentiation potential, which supports their future testing and use for bone regeneration in craniofacial applications.

Extracellular vesicles (EVs) from human bone-marrow mesenchymal stem/stromal cells (BM-MSCs) are of much interest because they may exert therapeutic effects, such as modulating immune response at a site of injury. However, a reliable potency assay for evaluating immune-modulatory effects of EVs has yet to be established. Towards achieving this, here we isolated and characterised EVs from MSCs cultured under different conditions and assessed their immuno-regulatory properties, in term of influence on inflammatory cytokines release from CD4+ T-cells derived from peripheral blood mononuclear cells (PMBCs) of rheumatoid arthritis (RA) patients.

BM-MSCs were cultured in T175-flasks in media supplemented with either human platelet lysate (hPL) or EV-depleted FBS. After 48h, conditioned media was collected. EVs were isolated using PEG precipitation and characterised using nanoparticle tracking analysis (NTA), transmission electron microscopy (TEM), immunoblotting, and flow-imaging (Amnis ImageStream). Flow cytometry (LSRFortessa) analysed a panel of cytokines released from CD4+ T-cells exposed to the MSC-EVs.

NTA indicated significantly more EVs/particles released when MSCs were cultured with hPL-supplemented medium versus medium with EV-depleted FBS. TEM revealed spherical-shaped EVs, with both cultures. Immunoblots showed the presence of EV-associated proteins CD9, CD63, CD81 and Syntenin-1. Supporting these findings, flow-imaging showed increased numbers of CD9+, CD63+ and CD81+ positive sEVs when MSCs were cultured in hPL-medium. Preliminary data demonstrated that the MSC-EVs modulate (typically suppressing) the release of four cytokines that are associated with RA pathogenesis, i.e. TNFα, IL-22, GM-CSF and IL-2, highlighting their immune-regulatory potential. Further studies validating immune-modulatory effects of MSC-EVs on CD4+ T-cells are underway.

Skeletal myocytes play roles in a number of biological processes ranging from limb movement to the regulation of nutritional homeostasis, and are implicated in the pathophysiology of a variety of diseases involving muscle dysfunction. There is a pressing need for reliable models of mature human skeletal muscle to permit investigations into physiological and disease mechanisms, and to facilitate the generation of new therapeutics. While human induced pluripotent stem cells (hiPSCs) offer a promising starting material for skeletal muscle cells, their broad use has been hampered by difficult to reproduce, complex differentiation protocols. We have developed an optimised inducible system (opti-ox) that enables tightly controlled expression of transcription factors (TFs) improving cellular reprogramming approaches for the differentiation of hiPSCs. Through targeting of genomic safe harbour loci, we used opti-ox to achieve homogenous, inducible expression of the myogenic regulator MYOD1. MYOD1 induction leads to shutdown of the core pluripotency network, with myogenic factor activation. We demonstrate robust expression of myosin heavy chain, with the transition from immature (MYH3 and MYH8) to mature isoforms (MYH1) expression, in a time dependent manner. opti-ox reprogrammed skeletal myocytes express Desmin, Dystrophin and Titin, and form contractile, striated, multinucleated myotubes. Critically for metabolic studies, robust expression of the insulin-regulated glucose transporter GLUT4 is also detected. The scalability of opti-ox reprogramming provides a unique hiPSC based model of human skeletal myocytes, opening new avenues for high throughput screening and academic research applications, for consistent study of normal and pathological muscle biology.

Introduction: The study of tissue-engineered skeletal muscle has for decades been driven by a clinical need to treat neuromuscular diseases and volumetric muscle loss. The in vitro fabrication of muscle offers the opportunity to test drug and cell-based therapies, to study disease processes, and to perhaps one day serve as a muscle graft for reconstructive surgery. The aim of this study was to develop a biofabrication technique to engineer muscle for research and clinical applications.

Methods: A bioprinting protocol was established to deliver primary mouse myoblasts in a gelatin methacryloyl (GelMA) bioink. Molecular and functional analyses were performed on the bioprinted tissues over two weeks of differentiation. The tissue construct was implanted in an in vivo chamber, supplied by a surgically formed arteriovenous loop and transected nerve in male nude rats (two in both the experimental arm and control groups). After two weeks, the chamber contents were removed for histological analysis.

Results: This work demonstrated the importance of myoblast migration through the GelMA scaffold, with cells spontaneously forming fibres on the surface of the construct. This phenomenon enabled advanced maturation in vitro, and most critically, facilitated the connection between incoming vessels and nerve axons in vivo without the hindrance of a scaffold material. Our preliminary study yielded highly structured, regenerating and developmentally mature myofibres, with early innervation and vascularisation evident within the developing muscle pedicle.

Conclusions: This work developed a bioprinting technique for fabrication of functional skeletal muscle constructs, with applications for both disease modelling and regenerative medicine.

Lung adenocarcinoma (LUAD) growth depends on cell proliferation and migration which require interactions with extracellular matrix (ECM) components such as glycosaminoglycans (GAGs). How GAGs regulate cancer cell function is not fully comprehended. A suggested mechanism is it affects the interaction between cancer cells and various growth factors (GF) and cytokines. To better understand how the degree of sulfation (DS) of GAGs affects LUAD cells, sulfated alginates (AlgSulf) with varying degrees of sulfation (DS= 0.0,0.8,2.0,2.7) were synthesized to act as GAG mimics. Human and murine (H1792 and MDA-F471 respectively) LUAD cell lines were treated with AlgSulf of various DSs at two concentrations, 10 and 100 µg/mL. The anti-tumor properties were assessed using MTT, trypan blue exclusion, and wound healing assays for 2D models, while sphere formation assay was used to assess for the 3D model. MDA-F471 cell proliferation and viability decreased significantly at the concentration of 100 µg/mL as the DS of the biomimetic GAGs increased. Cell migration decreased as the DS of biomimetic GAGs increased ($p < 0.001$ for DS =2.0 and 2.7 compared to control) and decreased the diameter and number of spheres formed ($p < 0.001$). Finally, our study shows that GAG-mimetic AlgSulf with an increasing DS exhibits enhanced anti-proliferative and migratory properties and reduces the growth of KRAS-mutant LUAD spheres in vitro. The anti-tumor effects by the GAG-mimetic AlgSulf are possibly due to differential binding of GFs and consequential decreased cell stemness. AlgSulf may prove worthy in cancer therapy after further in vivo validation.

Bone defect is a significant health problem worldwide. Bone is also the second most transplanted tissue after blood. Myriad bone grafts are designed and applied in clinics. Limitations, however, from different aspects still exist, including limited supply, health complications, mechanical strength, and bioactivity. In this study, two synthetic proline-rich 'disorganized' peptides (P2 and P6) are incorporated into SmartBone® to manufacture a composite bioactive xeno hybrid bone graft named SmartBonePep®, with the aim to increase the bioactivity of the bone graft. The results, which include cytotoxicity, proliferation rate, confocal microscopy, gene expression and protein qualification, successfully prove that the SmartBonePep® has multi-modal biological effects on human mesenchymal stem cells from bone marrow. The successful physical entrapment of P6 into a composite xeno-hybrid bone graft, withstanding the manufacturing processes including exposure to strong organic solvents and ethylene oxide sterilization, increases the osteogenic potential of the stem cells as well as cell attachment and proliferation. P2 and P6 both show a strong biological potential and may be future candidates for enhancing the clinical performance of bone grafts.

CONTRAST-ENHANCED NANO-CT REVEALS DENTAL SOFT TISSUES AND CELLULAR STRUCTURES

Håvard haugen$_P$[1], Pia Titterud Sunde[1]

[1] *University of Oslo*

Corresponding author's email: h.j.haugen@odont.uio.no

nano-CT technologies offer 3D imaging methods, which allow high-resolution examination of bones and teeth, but soft tissue components have weak X-ray attenuation and are not easily visualized in CT images. We introduce a new methodology designed to simultaneously visualise dental ultrastructure including cellular and soft tissue components, by utilizing PTA in various concentrations and immersion time was tested and scanned with high resolution nano-CT. Three-dimensional nano-CT imaging of dental cementum and periodontium as well as interior components, such as odontoblasts and predentine, with high resolutions was made visible when using PTA staining. The optimal staining protocol differed in different segment of the tooth. The thickness of the cementum could be computed over the height of the tooth made possible by the PTA-enhanced contrast, and the attached soft tissue components of the interior of the tooth could be shown on the dentine-pulp interface in great detail. Three-dimensional illustrations allowed a histology-like visualization of the sections in all orientations with a single scan and easy sample preparation. Furthermore, the dentinal tubules, with the characteristic sigmoid curvature, could be visualized. The developed methodology show that it is possible to visualise hard tissue along with cellular structure and soft tissues using laboratory based nano-CT technique. The staining protocol depended on both tissue type and size. The methodology offers new possibilities for the visualisation of structures at the interphases between soft and hard dental tissue, particularly related to endodontic and periodontal research.

Hematopoietic stem cells (HSCs) have the ability to regenerate the entire blood and immune system [1], as such, they hold enormous clinical potential. In vivo they are supported by mesenchymal stromal cells (MSCs) and pericytes in a specialised microenvironment that provides physical and functional regulatory cues, termed the bone marrow (BM) niche. Once HSCs are removed from the niche their ability to self-renew is lost quickly, cells rapidly proliferate and spontaneously differentiate away from the long-term reconstituting (LT-HSC) phenotype in a matter of days rendering them clinically ineffective [2]. Here, we have developed a system to recapitulate properties of the BM niche microenvironment to support LT-HSCs in vitro. Using poly (ethyl acylate) (PEA) to promote material-driven unfolding of the extracellular matrix protein fibronectin (FN), we tether BM niche associated growth factors (GF) (e.g. BMP-2) to the exposed GF binding domain on FN [3]. Then by incorporating a collagen type I hydrogel in the stiffness range of the bone marrow (~0.1 kPa) [4], we were able to demonstrate maintenance of a niche-like phenotype in pericytes. This included expression of nestin, a key niche stromal marker [5], and production of HSC maintenance cytokines CXCL12 and SCF. Upon co-culture with HSCs, we found that this niche-like system is able to support LT-HSCs in culture. This material-based system offers a platform for investigation into fundamental mechanisms of stem cell regulation, as well as a more humanised model for genotoxicity screening of drugs, small molecules and cellular therapies.

We acknowledge support of EPSRC grant EP/P001114/1.

Objectives: To evaluate lateral ridge augmentation by guided bone regeneration (GBR) and prospects of space augmentation and maintenance in a chronic non-contained bone defect with the use of a non-resorbable TiO2-scaffold.
Materials and methods: Three buccal bone defects were created in each hemimandible of eight beagle dogs and allowed to heal for eight weeks. Then, treatment by GBR was assigned to following groups by block randomization: Test group: TiO2-scaffold and a collagen membrane, Positive control: Deproteinized bovine bone mineral (DBBM) and a collagen membrane, Negative control: Collagen membrane only. Each hemimandible was randomly allocated to 4 or 12-week healing time. Microcomputed tomography (microCT) was used to measure the width of alveolar bone, graft materials and new bone formation. Histological outcomes included descriptive analysis and histomorphometric measurements.
Results: MicroCT analysis demonstrated increasing new bone formation from four to twelve weeks of healing. The greatest width of mineralized bone was seen in the negative control group, albeit the test group showed the largest ridge volume. The positive control group demonstrated more mineralized bone in the grafted area than the test group, but small amounts were found in both groups. The negative control group presented a natural alveolar ridge shape when not contaminated with graft materials from adjacent sites.
Conclusion: The widest ridge following regeneration was found by the use of a collagen membrane and the non-resorbable TiO2-scaffold. This TiO2-scaffold maintained a larger space but demonstrated less mineralized bone formation than the negative control or the DBBM-graft at the timepoints investigated.

Congenital heart malformations are the leading cause of birth-defect related deaths [1] and occur during early morphogenesis, where the heart starts as a linear tube that bends and loops to transform into its final 4-chambered structure. To date, most of our understanding of heart malformations has been obtained from animal models, but differences in heart physiology and structure in animals when compared to humans limits the value of these models as surrogates for human heart development [2]. Thus, a tissue engineered model of early human heart formation, specifically the linear heart tube, could be tremendously valuable as a tool to expand our understanding of congenital defects. Here, we engineered a bioinspired model of the human heart tube using freeform reversible of embedding of suspended hydrogels (FRESH) 3D bioprinting. The 3D bioprinted heart tubes were cellularized using human stem cell-derived cardiomyocytes and cardiac fibroblasts and formed patent, perfusable constructs. Synchronous contractions were achieved 6 days after fabrication and were maintained for up to a month. Immunofluorescent staining confirmed large interconnected networks of sarcomeric alpha actinin-positive cardiomyocytes. Electrophysiology was assessed using calcium imaging and demonstrated anisotropic calcium wave propagation along the heart tube with a conduction velocity of ~1 cm/s. Contractility and function was demonstrated by tracking the movement of fluorescent beads within the lumen to estimate fluid displacement and force generation. In summary, we have 3D bioprinted a functional embryonic-stage human heart tube, which we plan to later use to model congenital heart defects.

Lymphedema is a chronic disease with great impact on the quality of life of patients and is caused by a non-functional lymphatic system. Surgical therapies for the treatment of lymphedema often rely on autologous transplantation of tissue, such as autologous lymph node (LN) transplantation. Despite their advantages compared to decongestion therapy, these techniques can be associated with severe side effects like donor site morbidities. Tissue engineered transplantable LN could help to reduce the need for transplanting autologous tissue as well as the associated side effects. Since LN anatomy is very complex, these organs are difficult to fabricate in vitro. It is therefore useful to mimic the organ's natural development processes in vivo in order to generate transplantable LNs. LN development is governed by the interaction of mesenchymal lymphoid tissue organizer (LTo) cells and hematopoietic lymphoid tissue inducer (LTi) cells. Adipose derived stem cells (ADSC) are similar to LTo in various aspects (morphology, cellular markers). By stimulating ADSC with cytokines involved in the natural development of LN, we tried to induce a LTo-like phenotype in the cells. The expression of CCL19, CCL21 and TRANCE which controls the population of the developing LN by lymphocytes was inducible by lymphotoxin α1β2 and/or TNF-α stimulation. Also the adhesion molecules ICAM1 and VCAM1 that provide adhesion motives for the lymphocytes could be upregulated this way. We demonstrate an in vitro cell culture approach for the conditioning of adult human cell populations by NF-κB activation, which could be applied for the tissue engineering of LN equivalents.

GET PEPTIDE NANOCOMPLEXES FOR ORAL BARRIER TRANSCYTOSIS AND INSULIN DELIVERY

Sahrish Rehmani[P][1], Kevin Shakesheff[1], James E Dixon[1]

[1] *University of Nottingham*

Corresponding author's email: sahrishrehmani36@gmail.com

Introduction: Oral-insulin-delivery would represent an overwhelming benefit to diabetic patients. Here, we report the use of novel multidomain-peptide system, based on cell-penetrating- peptides, termed Glycosaminoglycan-(GAG)-binding-enhanced-transduction (GET)-system1 as an efficacious transepithelial delivery-vector to promote insulin transcytosis, transduction, and intracellular uptake.

Methods: Fluorescently-labelled-insulin (Ins-F) was complexed with GET to form Ins-F-GET-nanocomplexes (Ins-F-GET-NCs). Caco-2 monolayers (human-colorectal- carcinoma cells) were employed as an in-vitro model for transepithelial delivery, assessing NC stability, and recycling using serial-dosing. NC size and surface-charge was characterised using dynamic-light-scattering (DLS). Insulin-reporter-iLite cells were employed to confirm the functional activity of NCs.

Results: GET-peptides generate NCs (size and charge; 140nm and +27.10mV) that greatly enhance insulin-transport across differentiated in-vitro models of intestinal-epithelium (>22-fold translocation over unmodified-insulin). GET-NCs exhibit continuous post-transfection release from monolayers (both apically and basally) linking uptake and insulin-recycling. Multiple-delivery results in intracellular accumulation, enabling cells to act as depots for sustained insulin-release without affecting cellular-viability and integrity. Importantly both the GET-peptides and Ins-GET-NCs were stable to proteolytic-degradation and stay intact after translocation intracellularly. Functional-assessments using transcription-reporter-assays activated by insulin-signalling revealed that Ins-GET-NCs retain biological activity and can induce pharmacological-response.

Conclusion: GET-NCs promote insulin transcytosis and absorption across in-vitro intestinal model and retain insulin's functional activity. These characteristics are needed for use as a tool for efficacious oral-insulin-delivery. Our system will serve as powerful tool for overcoming the barriers of low permeability of anti-diabetic peptides. Current focus is to improve insulin bio-availability which could allow GET-peptides to be a lead-technology in allowing effective oral-peptide therapeutics for diabetes and beyond.

Xenografts have the potential to be used as an alternative to human donor corneas but the human immune system hinders their use due to immediate danger sensing by innate immunity and adaptive antibody responses. Here we describe the potential of decellularization and gamma sterilization to reduce the inflammatory response of native porcine corneas (NPC) in human plasma and whole blood.

NPC were decellularized using 0.1% sodium dodecyl sulfate (SDS) and gamma irradiated(1). Collagen type I and antigens associated with acute xenograft rejection (α-Gal and NeuGc) were assessed by western blot (WB). Activation of the human complement system and cytokine release in contact with NPC, decellularized (DPC) and gamma irradiated (G-DPC) porcine corneas, were evaluated using an in vitro model system based on human plasma and blood. One-way ANOVA was used for statistical analysis.

Decellularization removed cellular components from NPC. WB confirmed the preservation of collagen type I ($p=0.1619$). The presence of α-Gal and NeuGc in DPC was significantly reduced compared to NPC ($p=0.0089$ and 0.0454, respectively). The complement activation products C3bc, C4bc, and sC5b-9 showed no significant differences between any of the groups. NPC, DPC and G-DPC induced IL-1β,IL-2,IL-6,IL-8,IL-1ra,MCP-1,MIP-1α,MIP-1β,TNF,G-CSF,INF-γ, and FGF-basic.

Our results confirm that SDS reduces the cellular components and presence of antigens of porcine corneas without altering the native extracellular matrix, which supports cellular regrowth. However, the induced cytokine release should be further investigated to manage its associated in vivo response to facilitate future clinical translation of G-DPC. Partially supported by Andalusian Regional Ministry of Health grant PIGE-0194-2019.

SHRINK-WRAPPING CARDIOMYOCYTES IN EXTRACELLULAR MATRIX TOWARDS IMPROVING REPAIR OF DAMAGED HEART MUSCLE

Jacqueline Bliley[P][1], Kristina Kim[1], Rachelle Palchesko[1], Madison Stiefbold[1], Adam Feinberg[1,2]

Heart disease and the associated pathologic changes in the myocardium are difficult to repair because cardiomyocytes, or heart muscle cells, have limited regenerative capacity [1]. This leads to a progressive decline in contractile function and in severe cases, heart failure. Direct injection of cardiomyocytes into the myocardium has been pursued to repair the damaged heart; however, current strategies face many challenges, including low cell engraftment and survival [2]. Here we report a strategy to encapsulate or "shrink-wrap" small clusters of cardiomyocytes within an extracellular matrix (ECM) nano-scaffold to enhance integration into heart muscle. To do this, we use a process we previously developed called surface-initiated assembly [3] to micropattern fibronectin ECM, to which the cardiomyocytes attach, on a sacrificial poly n-isopropyl acrylamide (PIPAAm) substrate. Following PIPAAm dissolution, small clusters of cardiomyocytes are released and the fibronectin ECM effectively shrink wraps around the cluster forming a conformal layer. Proof-of-concept studies performed with C2C12 myoblasts validated that cells could be shrink-wrapped, injected through a needle, and were able to stably integrate into engineered skeletal muscle tissues. Human embryonic stem cell-derived cardiomyocytes were also successfully shrink wrapped and displayed alpha-actinin sarcomeric striations as well as contractile behavior following the shrink-wrapping process. Future work will assess the ability of shrink-wrapped cardiomyocytes to repair damaged heart muscle.

SUSTAINED INTRAVITREAL ANTI-VEGF RELEASE FROM PEPTIDE NANOFIBER DELIVERY SYSTEMS

Seher Yaylacı[1]

[1] *Lokman Hekim University*

Corresponding author's email: seherustun@gmail.com

Ranibizumab is a recombinant VEGF-A antibody used in clinics for the treatment of wet form of age-related macular degeneration. It is intraviterally administered to ocular compartments and it needs frequent injections. However, intraviteral administration could cause side complications as well as patient discomfort. These necessitate alternative treatment strategies based on relatively noninvasive ranibizumab delivery that is more effective and sustainable in the eye vitreous than the current clinical regimen. Herein, we developed self-assembled peptide microgels from peptide amphiphile molecules to sustainably release ranibizumab from these microgels at high local dose. Peptide amphiphile molecules, which come together by themselves to form supramolecular filaments, can form gels only in the presence of electrolyte without the need for any agent and provide ease of use compared to polymeric materials. Another great advantage of such systems is that they can be found in free flowing solution as they have low molecular weight and can be easily injected into the targeted area and gel formation can be achieved. Therefore, toxic crosslinkers are not required for the gelation of peptide materials. At the same time, since the peptide materials are completely biodegradable, they do not need to be removed from the injected target when the drug they contain is completely consumed. In this study release profile of ranibizumab at different peptide concentrations was used to evaluate the release performance from the microgels for improved and modulated treatment of wet form of age-related macular degeneration.

Heart failure remains one of the leading causes of death worldwide; typically developing after a myocardial infarction.1 Over 15 years ago, the delivery of cell progenitors was first considered a pioneering strategy to overcome the limited regenerative capacity of the heart; yet to date, such bio-interventions have failed to gain approval for clinical use owing — in part — to poor cell retention and extremely low implantation efficiency.2 As such, there has been a real emergence of biomaterial-based cell delivery strategies for cardiac regeneration.3 In particular, self-assembling peptide hydrogels (SAPHs) offer fully-defined, injectable, biocompatible scaffolds with tuneable properties making them ideal for tissue engineering applications.

We demonstrate that SAPHs (FEFEFKFK) immediately recover following shear stress — using oscillatory rheology — and thereby, remained in the myocardium when injected in vivo. After 7 days, the SAPH (MCA-tagged), plus additional cargo (rhodamine particles), could still be observed within the myocardium. Moreover, SAPHs, both unmodified or modified with the 'RGD' cell-adhesion motif, supported the in vitro culture (3D 'sandwich' model) of cardiac progenitor cells (CPCs). In fact, CPCs recovered from both SAPHs demonstrated a significant propensity to differentiate toward cardiac lineages. Following in vivo delivery, CPCs were retained at the site of injury and observed to differentiate into cardiomyocytes (αSARC+). Injection of SAPH alone temporarily improved cardiac function post-injury but only SAPH + CPCs continued to show improvement beyond 4 days. This work highlights the suitability of SAPHs for cell-delivery and reinforces the need for a biomaterial-based approach for regenerative cardiac therapies.

Within regenerative medicine, the use of spheroids (3D aggregates) has increased in recent years due to their physiological relevance. To study the structure and function of these spheroids, microscopy is a vital tool, but their size/volume and biological variability can make microscopic imaging daunting. We developed several tools for automated acquisition and analysis, which we used to study how pancreatic spheroids comprising alpha and beta cells respond to local oxygen tension. In a static microwell system, we first used these tools to examine the cell response to oxidative stress. To study the role of local oxygen tension, we then cultured spheroids under flow conditions in a home-built microfluidic chip, in which an oxygen gradient was generated over a microwell array. Automated image acquisition allowed high-throughput detection of individual spheroids, followed by high resolution 3D imaging. During analysis, individual cells were automatically segmented, after which oxidative stress levels could be measured, and morphological data such as spheroid volume and cell distribution within the spheroid were also analysed.

We were able to show how individual cells within spheroids react to oxidative stress to various extent. Moreover, morphological changes within spheroids could be observed upon changes to local oxygen tension. In all, we show the merit of automated microscopy pipelines for both imaging and analysis to increase throughput, improve the reliability of data collected, and reveal new biological insight in cell spheroids.

Purpose: Scarcity of donor corneas is the main challenge driving the scientific community to find alternatives for corneal transplantation. Herein, we report the synthesis of a bioadhesive protein-based hydrogel (GELGYM) from grafting functional crosslinkable moieties on gelatin backbone to generate a corneal substitute.

Methods: To synthesize GELGYM with different functionalization degree (FD), a gelatin solution was mixed with different amounts of glycidyl methacrylate (GMA). The reaction mixtures were dialyzed and freeze-dried to obtain foam-like GELGYM precursors. These were dissolved in varying amounts of PBS to form different concentrations of GELGYM, and mixed with crosslinking solution (eosin Y, vinyl caprolactam, and triethanolamine). The resulting solution was carefully transferred to an appropriate mold or applied to the desired structure and light-crosslinked for various times (1-10 min). Chemical, mechanical, and optical properties, and biocompatibility, of the engineered hydrogel were analyzed.

Results: Chemical characterizations demonstrated the formation of GELGYM with different FD, depending on the reaction conditions. GELGYM can be stretched up to 4 times its initial length and can withstand high tensile stresses up to 1.95 MPa with compressive strains as high as 80% without breaking, as indicated by tensile and compression tests. GELGYM was highly transparent, adhesive and biocompatible, supporting cellular proliferation and migration in both 2 and 3-dimentional cell-cultures, without affecting corneal cell phenotypes.

Conclusions: GELGYM has tuneable structural and biodegradative characteristics, which can be controlled by varying FD, crosslinking time, and prepolymer concentration. These, along with its biocompatibility and adhesiveness suggest its application as corneal stromal substitute or filler.

3D bioprinting is a flourishing fabrication technology in regenerative medicine, whose potential large-scale implementation is hindered by technical hurdles such as printability and cell-survivability along with the time and resource-intensive in vitro screening experiments, employed for every new printing condition. We sought to provide the appropriate choice of a nozzle design base on shear stress, well-known as a crucial factor for cell-survivability in extrusion-based 3D bioprinting. Three widely used shear-thinning hydrogel materials in two different nozzle configurations were tested. Nozzle design parameters were tested in the range relevant to practical application, using Latin hypercube sampling (LHS). Computational fluid dynamics (CFD) simulations were performed to quantify the flow profile and the resulting shear stresses. The outcome of CFD from the different combinations was fitted into a machine learning method, 'Gaussian process' (GP). The relationship of each nozzle design parameter and its relative importance on the response was obtained from the GP. This suggested that both material properties (power-law index) and the lower nozzle length and exit radius are the most important parameters for blunted nozzles, whereas the middle radius of the conical nozzle is an additional crucial factor influencing shear stress. The importance of the current approach lies in eliminating non-influential variables and providing a quantitative description of influential ones using a broad range screening that would be almost impossible using conventional in vitro experiments. In summary, we demonstrate the efficacy of in silico modelling as the feasible alternative to lower the burden of costly experimental trial-and-error and aid future development.

Introduction; Most artificial organs with scaffolds have some limitations, such as inflexibility in design, lack of cytocompatibility, toxic effects, and post-transplant degradation. The present study sought to generate scaffold-free trachea and esophagus-like structures using several types of human cells by a bio-three-dimensional (3D) printing system. The rationale of the present study was to generate a scaffold-free trachea esophageal-like structure using bio-three-dimensional (bio-3D) printing technology and to assess circumferential replacement using the structure. Methods; human cartilage cells (NHACs), human fibroblasts (NHDFs), human umbilical vein endothelial cells (HUVECs), human esophageal smooth muscle cell (hESMCs) and human mesenchymal stem cells from bone marrow (MSCs) were used. By using bio-3D printer "Regenova®", structures with different combinations of cells were made for trachea and esophagus. The structures were transplanted into F344 rats with immunosuppressant. Results; We transplanted the structures of ladder shape for trachea and simple structure for esophagus. We replaced the trachea by the structure circumferentially and for esophagus performed end to side anastomosis to abdominal esophagus and stomach. The rats survived one month and more after surgery. The structures were matured in vivo with epithelial cells extended from native trachea and esophagus and with micro vessels and blood cell. Conclusions; we will show the possibility of artificial organs made by bio-3D printer.

THE INTERNATIONAL SPACE STATION NATIONAL LAB – STEM CELLS AND BIOFABRICATION

Marc Giulianotti[1], Michael Roberts[1]
[1] *Center for the Advancement of Science in Space*
Corresponding author's email: mgiulianotti@issnationallab.org

The International Space Station (ISS) U.S. National Laboratory is enabling a new era of research in space aimed at improving life on Earth. The ISS National Lab accomplishes this by promoting and brokering a diverse range of research in life sciences, physical sciences, remote sensing, technology development, and education.

The ISS National Lab has a strong record of supporting stem cell research and biofabrication in space. These efforts have been enabled through the use of direct solicitations, partnerships with other government agencies, and collaborations between commercial companies and foundations. The talk will outline some of the projects and programs developed through these efforts and highlight some of the key findings from the studies. Additionally, we will overview current opportunities for the research community.

As we enter the third decade of continuous human occupancy of the ISS we continue to expand the use of the ISS National Lab. One area of expansion comes in developing public-private partnerships aimed at enabling in space biomanufacturing. While the focus of the ISS National Lab is to encourage these partnerships for the development of technologies that directly impact humans on Earth there are clear overlaps for exploration efforts. The talk will conclude with a summary of where these efforts currently stand and overview some of the planned next steps.

CONTROL OF STAPHYLOCOCCAL-MEDIATED PROTEASE ACTIVITY USING CELLULOSE-COLLAGEN WOUND DRESSINGS IN A DIABETIC FOOT MODEL

Rahaf Issa$_P$[1], Kate Thompson[1], Bianca Price[1]

[1] *Department of Pharmacy and Optometry, The University of Manchester, Manchester, UK.*

Corresponding author's email: rahaf.issa@manchester.ac.uk

Chronic wounds, such as diabetic foot ulcers, are maintained in a state of constant inflammation, characterised by abundant levels of proteases, which can delay wound healing. Selecting a dressing capable of controlling such factors can have a significant impact on the healing of chronic wounds. In this study, we developed an in vitro complex chronic wound model, consisting of fibroblasts and keratinocytes in a collagen matrix, to assess the effects of two oxidised regenerated cellulose (ORC)/collagen dressings, Promogran® and Promogran Prisma®. Models were wounded using a biopsy punch. Cells and models were maintained in a persistent state of inflammation using 5-10% Staphylococcal supernatant. In keratinocyte scratch assays, exposure to Staphylococcal supernatant increased protease production by 6.3-fold and delayed cell migration without affecting cell viability; leaving the scratch area 60% open after 48hrs. In the models, unstimulated wounds showed signs of healing within 6 days of wounding, and resembled unwounded skin by day 10. However, stimulation with Staphylococcal supernatant delayed wound healing, with no evidence of infiltrating fibroblasts or keratinocytes at day 6. Both dressings reduced protease levels in stimulated models within two days of treatment. Protease levels returned to baseline within 10 days of treatment with Promogran®, and 6 days of treatment with Promogran Prisma®. Stimulated wounds, that previously did not show any signs of healing, fully healed within 6 days of treatment with the dressings. In summary, ORC/collagen dressings mitigate the negative effects of Staphylococcal-mediated protease activity on wound healing in our in vitro model.

Skin is a highly complex, hierarchical, and dynamic organ that consists of an epidermal barrier layer and dermal matrix, containing hair follicles, glands, blood vessels, and nerves. The current 3D organotypic co-cultures are simplistic models that fail to capture many of the key biological functions of human skin and are limited in their ability to model normal tissue function and disease processes. This project aims to develop next-generation in vitro models of human skin using 3D bioprinting to mimic the tissue's essential structural and cellular complexity.

To establish an appropriate bioink to be used in the human skin equivalent model, we have purified decellularised ECM (dECM) from porcine skin. Western blot and Mass Spectometry analyses demonstrated the success of the dECM protocol by indicating the presence of major ECM molecules including, collagen I and fibrillin. Rheological analyses demonstrated the shear thinning properties of dECM hydrogels, indicating its suitability as a bioink. When used as a dermal matrix for 3D skin equivalent models, dECM hydrogels supported epidermal stratification with expression of terminal differentiation markers and the presence of a defined cornified layer. Finally, the dECM was compatible with advanced fabrication methods, including the use of sacrificial materials and printing within a gelatin support bath, thereby demonstrating its flexibility as a bioink.

Thus, the dECM hydrogel developed here represents a promising biomaterial for 3D bioprinting, and future studies will apply this bioink to the development of next-generation skin equivalent models.

IN VIVO MODULATION OF MSC-DIRECTED HOST IMMUNE RESPONSE BY SI-HPMC HYDROGEL

Noelle MATHIEU$_P$[1]

[1] *IRSN*

Corresponding author's email: noelle.mathieu@irsn.fr

MSC therapy is considered as promising option to treat various disorders. Based on hundreds of clinical trials the safety of MSC therapy seems clear. However, they do not confer expected beneficial effect, suggesting a real need to accelerate research towards the successful clinical application. We previously showed that embedding MSC from rat in a hydrogel, namely Silanized HPMC, increased the number of engrafted cells and MSC can be detected until 21 days in irradiated rat colonic mucosa [1-2]. However, biomaterials, according to their composition influence the biocompatibility with the host organism and the inflammatory and immune reaction. In the present study, we analysed in vivo the MSC-directed host immune response when embedded in Si-HPMC hydrogel.

We demonstrated that Si-HPMC hydrogel and Si-HPMC embedded hu-MSC injections do not induce statistical increase of innate immune infiltrate. Adaptive immune response has also been evaluated by measuring (i) serum antibodies directed specifically against hu-MSC and (ii) apoptosis of hu-MSC induced by cytotoxic lymphocytes. We demonstrated that the level of anti-huMSC antibodies and hu-MSC apoptosis induced by lymphocytes are statistically reduced when the cells are embedded in Si-HPMC compare with cells resuspended in PBS1x.

Altogether these data demonstrated that embedding MSC in Si-HPMC decrease the specific immune response directed against xenogenic MSC and favour MSC survival in the inflamed tissue that could explain the increase their therapeutic benefit. This also open perspectives for allogenic clinical use.

Introduction

Single cell technologies in cancer research are recently strongly developing since these enhance the molecular understanding. Biomolecules such as lipids are known to play a major role in cancer biology. Being able to visualize their distribution on a single cell level will open up new molecular information on the development, growth and heterogeneous composition of cancer cells. We present a single-cell imaging mass spectrometry method as powerful tool to map biomolecule distribution.

Material & Methods

Breast cancer cell lines were cultured, plated onto coated ITO slides and incubated overnight. Washing and drying steps were applied. Prior to imaging, norhamane matrix was sublimed onto the cell containing slide. Single cell chemical profiling was achieved using 5 µm spatial resolution MALDI imaging coupled to high mass resolution detectors (FTICR & TimsTOF). SCiLS Lab software (Bruker) was used for visualization and statistical analysis.

Results

The full chemical composition of breast cancer cell lines, including lipids identification, is generated on a single cell level. Thanks to the applied imaging technique, lipid distributions within a single cell are visualized. Based on statistical analysis of the single cell profiles, we generated a model that is able to distinguish different cell types.

Conclusion

Our direct identification and visualization method of biomolecules on a single cell level opens new possibilities in breast cancer research. Cellular differences can be detected, possibly leading to the identification of specific molecular pathways and biomarkers. Moreover, visualization of compound distributions within a single cell is a major step in understanding intracellular pathways.

Parkinson's disease (PD) is an age-related neurodegenerative disorder, characterized by a selective loss of dopamine (DA) neurons causing motor dysfunctions1. The exact mechanism behind dopaminergic cell death is still unknown, being therefore a challenge the development of reliable disease models that can truly recapitulate the features of the disease. Recent advances have prompted the development of human brain organoid systems, that mimic the organization and function of brain regions2, which in turn can be used as platforms for studying the neuroprotective effects of newly therapeutic tools, like the secretome of mesenchymal stem cells (MSCs). Thus, the first objective of this work was to modulate neuronal degeneration in human midbrain organoids (hMOs), to foster dopaminergic repair, using the secretome of bone marrow-derived MSCs. For that, two different in vitro PD models were used: hMOS treated with 6-OHDA to induce DA neurons degeneration, and hMOS carrying DJ-1 mutation (known to cause autosomal recessive PD). The hMOS generation was based in the protocol developed by Monzel et al.2, and in both models the cultures were exposed to MSCs secretome. Through high-content image analysis we observed that treated hMOS had more TH-positive cells and less fragmented neurons when compared to the untreated cultures, in both models. Considering these results, we are currently developing a combined PD mice model, using DJ-1 KO animals exposed to 6-OHDA. A combined may provide new insights from the point of view of the dual-hit hypothesis, representing a more robust model to study the therapeutic effects of MSCs secretome.

The repair of traumatic and degenerative ruptures of deep flexor tendons remains one of the most intriguing topics in hand surgery. Current treatment methods fail in efficient repair of the injured tendon, and are mainly challenged in attaining sufficient mechanical strength and in limiting adhesion and inflammation issues. This research aims at developing a more potent solution for deep flexor tendon repair by combining a mechanical (improved mechanical properties) and biological approach (incorporation of bio-active compounds). A reinforced, multi-layered electrospun tubular construct is developed, composed of three layers: an inner electrospun layer containing an anti-inflammatory component (Naproxen), a middle layer of braided monofilament as reinforcement and an outer electrospun layer containing an anti-adhesion component (hyaluronic acid, HA).

In a first step, a novel acrylate endcapped urethane-based precursor (AUP) is developed and characterized by measuring molar mass, acrylate content and thermo-stability. The AUP material is benchmarked against commercially available poly(ε-caprolactone) (PCL). Next, the materials are processed into multi-layered, tubular constructs with bio-active components (Naproxen and HA) using electrospinning. In vitro assays using human fibroblasts show that incorporation of the bio-active components is successful and not-cytotoxic. Moreover, tensile testing using ex vivo sheep tendons prove that the developed multi-layered constructs fulfill the required strength for tendon repair (i.e. 2.79 - 3.98 MPa) [1], with an ultimate strength of 8.56 ± 1.92 MPa. In conclusion, by combining a mechanical approach with the incorporation of bio-active compounds (biological approach), this solution shows its potential for application in deep flexor tendon repair.

Nonalcoholic fatty liver disease (NAFLD) is considered a leading cause of chronic liver disease worldwide and it encompasses the simple steatosis to the more severe steatohepatitis, including cirrhosis and hepatocellular carcinoma[1-2]. Although no effective treatments are available, hydroxytyrosol (HT) has been shown to contrast the development of hepatic steatosis through its lipid-lowering, antioxidant and anti-inflammatory activities. However, the efficient delivery of this molecule to hepatocytes remains a crucial aspect: we propose the design of smart traceable nanogels as a promising tool to promote the intracellular HT release, avoiding metabolic alterations and the loss of the active molecule in the extracellular environment. Nanogels are composed by polyethylene glycol and rhodamine-labeled polyethyleneimine[3], and their performance was evaluated in an in vitro model of hepatic steatosis characterized by a fat overload induced through a mix of free fatty acids (FFA)[4]. The obtained results show a substantial decrease in the intracellular triglyceride accumulation only when HT was delivered by the nanovectors, improving the efficacy with regard to the current administration of HT in its free form. Moreover, oxidative stress levels were not detected in the treated cells and the reduced cell viability associated to FFA overload was significantly mitigated using the nanogel-delivered HT, restoring to a healthy liver condition. Hence, these formulated nanogels may represent a more effective strategy compared to common drug administration routes for protecting liver cells from the development of hepatic steatosis.

SYNTHETIC EXTRACELLULAR MATRICES BASED ON SUPRAMOLECULAR MATERIALS

Patricia Dankers$_P$[1]

[1] *Eindhoven University of Technology*

Corresponding author's email: p.y.w.dankers@tue.nl

The extracellular matrix (ECM) is a complex assembly of various molecules held together via both covalent and noncovalent interactions. In order to make materials with comparable properties it is proposed that supramolecular materials based on hydrogen bonding units are eminently suitable. Synthetic supramolecular materials can be made that are composed of supramolecular monomers polymerized via similar interactions. This results in dynamic materials. An important challenge in the synthesis and formulation of synthetic extracellular matrices, is besides the balance between dynamics and robustness, the introduction of complexity. This complexity can exist of bioactive molecules that are either supramolecularly or covalently attached to the materials, or might originate from the assembly of the supramolecular monomers into various (hierarchical) structures. Both parameters will heavily influence the function of the materials synthesized when brought into contact with cells and tissues. The bioactivity we have introduced into our supramolecular systems is based on small synthetic peptides, large ECM proteins, carbohydrates or decellularized ECM. In this way we studied the complexity of the bioactive signals displayed to the cells. Interestingly, small synthetic peptides can outperform mixtures of a large amount of different bioactive compounds, highlighting the importance of simple synthetic systems.

Pericytes, brain microvascular endothelial cells (BMECs), astrocytes, and neurons form the neurovascular unit (NVU). NVU dysfunction is commonly seen in vascular dementia and Alzheimer's disease (1). Pericytes have been shown to contract capillaries and thus reduce cerebral blood flow, in a downstream response to amyloid-β, a hallmark protein of Alzheimer's disease (2). However, the full role of pericytes in health and disease remain poorly understood, partially due to a lack of adequate models that can recapitulate the complexity of the multi-cellular NVU. The aim of this study is to incorporate pericytes into a 3D in vitro model to study the function, and dysfunction, of the NVU and the pericytes within it. Brain pericyte-like cells and BMECs were differentiated from human induced pluripotent stem cells (iPSCs) (3, 4) and co-cultured in a transwell-type NVU model. Integrity of the endothelial barrier function was evaluated by transendothelial electrical resistance (TEER) measurements. Hydrogel encapsulation was used as a contraction indicator. Brain pericyte-like cells stained positively for pericyte markers NG2, PDGFR-β, CD13, and CD146. Co-culture of pericyte-like cells with BMECs resulted in a significantly increased TEER compared with mono-cultured BMECs. Furthermore, these brain pericyte-like cells significantly decreased the hydrogel surface area by 40% showing their potential ability to contract. These results suggest that functional brain pericyte-like cells were obtained and can be incorporated into a NVU model. We will build on these findings to develop a robust model to study pericytes within the NVU to investigate their function and dysfunction in health and disease.

Microtia is a congenital deformity of the external ear that ranges from complex craniofacial deformities where ears are virtually absent, to ones that are correctly formed but smaller than usual[1]. This condition affects 1 in 6,000 infants born in the UK annually[1]. Currently, microtia patents are limited in their therapeutic options. Typically, bone marrow mesenchymal stromal cells (MSCs) have been investigated as a cell source for generation of cartilaginous grafts[2]. Standard induction of chondrogenesis uses high density culture (HDC) and chondrogenic media (CM). CM typically contains a cocktail of dexamethasone and transforming growth factor-beta 1 (TGFb1). However, dexamethasone is also a major component of osteogenic media[3]. Leading to off-target effects such as the proclivity of MSCs to undergo hypertrophic differentiation[4]. Here, we demonstrate isolation of a novel cell source; CD146+ pericytes from microtia biopsies vasculature (ear pericytes; EPs) and culture in a chondrogenic-targeting microenvironment. Using poly (ethyl acylate) (PEA) to promote material-driven unfolding of the extracellular matrix protein fibronectin (FN), we tether TGFb1 to the exposed GF binding domain on FN[5]. The PEA system permits targeted delivery of nano-doses of GFs to cells, potentially reducing off-target effects associated with complex CM formulations[5]. We demonstrate that recapitulating aspects of the native niche microenvironment using the EPs seeded in HDC onto the PEA system leads to chondrogenesis that does not exhibit the hallmarks of hypertrophy. As PEA can coat 3D structures, it's use is easily envisioned this technology could be used on complex human ear shaped scaffolds.

INTRODUCTION: Biomaterials have been used to create micro-scaffolds, allowing the generation of active biophysical signals for directing stem cell fate. The Nichoid, has been reported to maintain the stemness capacity in cells of different origins [1]. The aim of this study was to investigate: i) the proliferation, differentiation and stemness properties of neural precursor cells expanded inside the Nichoid (NIC-NPCs); ii) the therapeutic potential of NIC-NPCs in preclinical experimental model of Parkinson's Disease (PD) [2,3]. METHODS: Nichoids were fabricated by two-photon laser polymerization using an organic-inorganic photoresist. NPCs expanded inside the Nichoid were counted and analyzed through RNA-seq, Real Time PCR, western blot and immunofluorescence. Parkinsonism was induced by the administration of MPTP in C57/black[3] and the recovery of function was investigated with behavioral tests. RESULTS: 7 days after plating, the NIC-NPCs show a significantly higher proliferation and viability than in standard floating conditions and NIC-NPCs show an increase in pluripotency. Moreover, NIC-NPCs showed a potentiation in their therapeutic features by counteracting neurodegeneration and promoting recovery of function in vivo. These evidences are supported by histological analysis of specific molecular markers. Moreover, NIC-NPCs downregulated gliosis. CONCLUSIONS: Here we provide evidences that NIC-NPCs both favors their pluripotency and potentiates their efficacy showing great promise in the field of regenerative medicine.ACKNOWLEDGEMENTS: Financial support was received from "Neurogel-en-Marche" Foundation; Fondazione "Romeo and Enrica Invernizzi"; ERC grant NICHOID, G.A. 646990 and NICHOIDS, G.A. 754467.

Mesenchymal stromal cells (MSC) derived from the umbilical cord connective tissue, the so-called Wharton's Jelly (WJ) have a promising regenerative potential, which is mainly attributed to the cells' secretome including extracellular vesicles (EV). EV carry functional microRNAs (miRNAs), which are delivered to target cells.

We hypothesize that WJ-MSC-derived EV contain miRNAs, that interfere with signaling pathways involved in brain injury of premature infants. Thus, we aimed to characterize and quantify the miRNA content of WJ-MSC-derived EV.

EV were retrieved from WJ-MSC culture supernatants by serial highspeed and ultracentrifugation. A genome-wide profiling of paired WJ-MSC and WJ-MSC-derived EV from the same individuals (n=6) was done by preparing small RNA libraries, and Illumina NextSeq Sequencing. KEGG pathway enrichment analysis was done by DIANA-miRPath v.3.

In EV, 850 miRNAs were expressed (mean normalized counts > 1). Thereof 213 were significantly upregulated in WJ-MSC-derived EV compared to their donor cells, while 120 were downregulated. KEGG pathway enrichment analysis showed that the miRNA present in WJ-MSC-derived EV targeted genes having key roles in pathways related to apoptosis, neuroinflammation and the maturation of the oligodendrocyte lineage.

Our data strongly suggest that several miRNAs found in WJ-MSC-derived EV have key functions in neuroregeneration, substantiating their therapeutic potential in premature brain injury.

Background: Knee osteoarthritis (OA) is a degenerative joint disease affecting the articular cartilage and its surrounding tissues. OA development is often associated with cartilage damage earlier in life and appears to be increasing in the younger population. Sufficient treatment of osteochondral defects and early detection of OA are crucial for possible cartilage regeneration and postponement of OA development. In this work we studied the lipid signature of Hoffa's fat pad (HFP) of patients with OA or a cartilage defect (CD) using Matrix-assisted laser desorption/ionization mass spectrometry imaging (MALDI-MSI), in order to characterize novel biomarkers for OA and cartilage regeneration.

Methods: Snap-frozen HFP of three OA and three CD patients were cryosectioned at 15 µm and sublimed with Norharmane matrix before being analyzed using MALDI-MSI (negative and positive ion modes) on a RapifleX Tissuetyper at 50 µm lateral resolution. In addition, lipid identifications were obtained in consecutive slides on an Orbitrap Elite™ Hybrid Ion Trap-Orbitrap Mass Spectrometer in data dependent acquisition mode. Data were analyzed using MATLAB and Lipostar software.

Results: Principal component and discriminant analysis showed that different lipid species were responsible for the discrimination between OA and CD patients. Phosphocholines and sphingomyelins were more abundant in the OA group, whereas phosphoethanolamines and phosphoserines were more common in the CD group. Furthermore, molecular intra-tissue heterogeneity was found for adipose-, connective- and synovial tissue.

Conclusions: Our results suggest that lipid analysis in HFP using MALDI-MSI could be a useful source for biomarker detection in predicting cartilage regeneration and OA development.

CADHERIN-11 AND CADHERIN-2 REGULATE MESENCHYMAL STEM CELLS DIFFERENTIATION DIFFERENTLY IN MONOLAYER CULTURE COMPARED TO AGGREGATE CULTURE

Fiona Passanha[P][1]

[1] *Maastricht University*

Corresponding author's email: f.passanha@maastrichtuniversity.nl

The acquisition of specific cell fate is one of the core aims of tissue engineering and regenerative medicine. The influence of the cell–material interface on cell fate has been an area of significant research, but comparatively little is currently known about cell–cell interaction. Furthermore, while there is significant evidence that cells cultured as aggregates positively influence fate decisions, the mechanisms underlying this are not known. Human mesenchymal stem cells (hMSCs) from bone marrow have the ability to differentiate into three lineages in vitro and are an example of a cell type that has been shown to differentiate more effectively as aggregates. Here we study aggregates of hMSCs in vitro, in which we study cadherin expression, an important class of proteins involved in cell adhesion and signaling during proliferation and differentiation into different lineages. We make a comparison to cells cultured as a monolayer. We observe that proliferating hMSCs cultured as a monolayer expressed lower levels of cadherin-2 and increased cadherin-11 expression at cell–cell contact sites over time, which was not evident in the aggregate cultures. Furthermore, the importance of the cadherins in regulating the differentiation of hMSCs is evident by their knockdown. Knocking down the cadherins impeded hMSC differentiation towards the adipogenic lineage, but cells continued to differentiate to the osteogenic lineage.

Abstract **#1173**

CADHERIN-11 REGULATES EXTRACELLULAR MATRIX PRODUCTION IN MESENCHYMAL STEM CELL

Fiona Passanha[P][1]

[1] *Maastricht University*

Corresponding author's email: f.passanha@maastrichtuniversity.nl

For regenerative medicine, directing stem cell fate is one of the key aims. Human mesenchymal stem cells (hMSCs) are versatile adult stem cells that have been proposed for several clinical applications, therefore directing their fate is of utmost importance. For most clinical applications, their differentiation towards the adipogenic lineage is an undesired effect. Cadherin-11, a cell adhesion molecule expressed by the hMSCs, is required for their commitment towards the adipogenic lineage. To investigate the mechanisms through which cadherin-11 regulates adipogenic differentiation, we studied the hMSCs and its knockdown. We observed that hMSCs lacking cadherin-11 had decreased expression of type VI collagen and fibronectin. In our study, we provide evidence of increased TGFb1 and the subsequent translocation of phosphorylated SMAD 2/3 into the nucleus by cells that lack cadherin-11, which could be attributed to the changes in extracellular matrix composition. Taken together, our study implicates cadherin-11 in regulating extracellular matrix production.

Human Adipose-Derived Stem Cells (hADSCs) represent a promising source for cell therapies because their availability is less invasive compared to the one from other organs or tissue. In the body, SCs reside in a specialized microenvironment, characterized by a unique combination of biophysical and biochemical properties. Recently, biomaterials have been used to create 3D micro-scaffolds, which mimic the biomechanical characteristics of SC niches. In this context, the micro-niche "Nichoid" has shown the ability to induce pluripotency in SCs thanks to the isotropic mechanical stimuli(1,2). The aim of this study was to investigate the proliferation and stemness properties of hADSCs expanded inside these engineered niches with a cubic-pore configuration.

Nichoids were fabricated by two-photon polymerization using a biocompatible photoresist(3). hADSCs were isolated from lipoaspiarate adipose tissue obtained by liposuction performed in voluntary subjects. Cells expanded inside the cubic Nichoid have been characterized by viability assay, Real Time PCR and immunofluorescence analysis. Furthermore, neural differentiation was also investigated.

The expansion inside the cubic 3D micro-scaffold permits the potentiation of stemness features by upregulating the expression of pluripotency genes. Furthermore, cells expanded could be easily collected in order to be transplanted.

Our findings represent a great promise for the Nichoid's application in the field of regenerative medicine, in particular in neurodegenerative diseases as Parkinson's disease and Spinal Cord Injury.

The development of suitable models that better recapitulate tumor microenvironment is essential to understand cancer biology and to develop effective treatments [1]. Multiple myeloma (MM) is a hematological neoplasia in which bone marrow (BM) niche depicts a key role in disease progression and drug resistance. MM cells maintenance in vitro, and the reproduction of the in vivo occurring drug resistance (DR), remains still challenging for tissue engineering approaches. The use of microspheres as 3D substrate in in vitro tissue modeling has increased prevalence in past years. In this work, a biomimetic substrate has been generated by using extracellular matrix (ECM)-coated microspheres kept in suspension (microgels) with MM cells. Polymeric microspheres have been obtained by emulsion polymerization method from acrylates and acrylic acid and functionalized with ECM molecules (fibronectin, hyaluronic acid). Suspension cultures of MM cells in the platform have been exposed to dexamethasone. The generated 3D culture system significantly increased cell proliferation in comparison with conventional 2D cultures and corroborated the development of resistance to dexamethasone under BM biomimetic conditions.These studies imply the development of an innovative 3D versatile cell culture platform, in which the impact of specific ECM formulations in MM cells proliferation and DR can be studied.Acknowledgements: PROMETEO/2016/063 project is acknowledged. This work was also supported by the Spanish Ministry of Science, Innovation and Universities trough Sandra Clara-Trujillo FPU17/05810 grant.

Nonviral systems involve the complexation of nucleic acids with positively charged gene carriers (mostly cationic polymers or lipids) to promote their cell uptake. Despite their biosafety as compared with their viral counterparts, nonviral carriers exhibit some obstacles including their fast degradation, aggregation tendency and lower transfection efficiency [1]. Among nonviral carriers, niosomes have emerged as potential candidates for gene delivery applications providing higher stability and lower toxicity compared with classical liposomes [2]. The aim of this work was to produce different niosomes formulations in order to achieve an effective transfection of human mesenchymal stem cells (hMSCs), a potential population for applications in regenerative medicine [3]. Niosomes with various helper lipids and surfactants were prepared by a reverse phase evaporation technique. Niosomes and their nioplexes with a reporter DNA lacZ plasmid (placZ) were characterized by different methodologies including agarose retardation and SYBR Green-I dye exclusion assays. Likewise, both size and charge from systems were evaluated by DLS and ELS, respectively. Results showed that niosomes formulated at 1:10 placZ /cationic lipid ratio (w/w) provided the higher transfection efficiency of hMSCs monolayers.

Ageing is a multifactorial and tissue-specific process associated with a decline of protein, cell, and organ function [1]. Ageing in the cardiovascular system is seen by researchers as the beginning of human ageing [2]; however, our understanding is relative scarce. As cardiac extracellular matrix (ECM) provides structural support for cardiac cells and regulates many cellular homeostasis and intracellular signaling processes, the aim of this work was to identify and validate cardiac ECM proteins involved in physiological and pathological ageing (premature ageing). To accomplish this goal, we have performed proteomic analyses of cardiac tissue lysates and decellularized cardiac tissue ECM from old and young mice or human cardiac tissues. The impact of pathological ageing was investigated using FFPE cardiac tissue from double mutant mice for LMNA gene (progeroid mice) and patients diagnosed with Hutchinson-Gilford progeria syndrome. We have identified physiological and pathological ageing signatures in ECM proteome in both species. Decellularized ECM allowed us to show a higher number of ECM proteins differentially regulated in physiological ageing and identify a commonly interesting hit protein inter-species which have been studied in vitro to disclose its role in cardiovascular ageing biology. The current study is the first to show the impact of ageing (physiological and pathological ageing) in cardiac ECM proteome in human and mouse. Ongoing studies will dissect the role of the ageing-affected protein in cardiovascular ageing biology and identification of new therapeutic targets. The authors would like to acknowledge the financial support through the FCT PhD Studentship (PD/BD/106051/2015) and project entitled "An iPSC-derived vascular model of Progeria to identify mediators for smooth muscle loss" (Ref:029229), and trough the ERA Chair entitled "ERA atUC: Enhancing Research in Ageing at the University of Coimbra" (Ref:669088). We further acknowledge the funding from the European Union's Horizon 2020 research and innovation programme under grant agreement No 952266.

TRACHEAL TISSUE ENGINEERING: IS THERE ANY PROGRESS?

Seong Keun Kwon[P][1,2]

[1] *Seoul National University Hospital*

2 Seoul National University College of Medicine

Corresponding author's email: kwon.seongkeun@gmail.com

There are no effective solutions for the treatment of advanced structural disorders of the large airways. Although tracheal resection and end to end anastomosis is the primary treatment of choice, it is technically challenging and is not applicable to long tracheal stenosis. Allo-transplantation is associated with significant long-term mortality due to infection and immunosuppression, especially in the respiratory system. There is also a paucity of donors for transplantation.

In the past decade, tissue-engineered tracheal structures re-populated with cells or stem cells have been tried. The potential clinical advantages of autologous stem-cell-derived transplants are that patients who receive them would not need immunosuppression and that the transplants are hypothesized to be remodeled by local stroma to simulate native tissue. However, most of the studies failed clinical translation due to restenosis at the anastomotic site. Thus, there is a significant unmet need for novel methods of replacing and regenerating human tracheal tissue.

The ideal endpoints for tracheal replacement are normal airway and lung function, appropriate growth, high quality of life, and the elimination of the need for repeated surgical interventions.

Here I would like to describe the series of my studies on the tracheal regeneration focusing on reducing the restenosis while enhancing angiogenesis using various stem cells, spheroid culture, 3D printed scaffold, bioreactors, bioactive drug eluting scaffolds to modulate the fibrosis pathway, and modification of transplantation technique using pedicled flap.

ENGINEERING OSTEOARTHRITIC CARTILAGE MODEL THROUGH DIFFERENTIATING SENESCENT HUMAN MESENCHYMAL STEM CELLS FOR TESTING DISEASE-MODIFYING DRUGS

Hang Lin[P][1], Ning Wang[1]

[1] *University of Pittsburgh*

Corresponding author's email: hal46@pitt.edu

Significant cellular senescence has been observed in cartilage harvested from patients with osteoarthritis (OA). Preclinical studies further suggest that selectively removing senescent cells attenuates the development of post-traumatic OA. However, the mechanism underlying senescence-associated cartilage degeneration has not been fully demonstrated. In this study, we aim to develop a senescence-relevant OA cartilage model to study the pathogenesis of OA and develop disease-modifying OA drugs (DMOADs). Specifically, human bone marrow-derived mesenchymal stem cells (MSCs) were expanded in vitro up to passage 10 (P10-MSCs). Following their senescent phenotype formation, P10-MSCs were subjected to pellet culture in chondrogenic medium. Results from qRT-PCR, histology and immunostaining indicated that cartilage generated from P10-MSCs displayed both senescent and OA-like phenotypes without using other OA inducing agents, when compared to that from normal passage 4 (P4)-MSCs. Interestingly, the same genetic expression differences observed between P4-MSCs and P10-MSC-derived cartilage tissues were also observed between the preserved and damaged OA cartilage regions taken from human samples, as demonstrated by RNA Sequencing data and other analysis methods. Lastly, the utility of this senescence-initiated OA cartilage model in drug development was assessed by testing several potential DMOADs and senolytics, including naproxen, SM04690, FGF18, ABT-263, as well as a senolytic cocktail: dasatinib (D)/quercetin(Q). The results suggest that pre-existing cellular senescence can induce the generation of OA-like changes in cartilage. The P4- and P10-MSCs derived cartilage models also represent a novel platform for predicting the efficacy and toxicity of potential DMOADs on both preserved and damaged cartilage in humans.

Non-coding RNA (ncRNAs) are a large class of molecules able to promote bone regeneration and to control bone homeostasis. It includes small (e.g. microRNAs) and long [lncRNAs (e.g. lincRNA)] transcripts that do not translate into proteins but can modulate cellular differentiation, proliferation, or extracellular matrix (ECM) composition. This study aims to explore the role of miR-29c, and the related lncRNAs, in the ECM secreted by human primary mesenchymal/stromal cells (hMSCs) and osteoblasts.

To achieve this goal, hMSCs were isolated from the bone marrow of osteoporotic patients that underwent total hip arthroplasty following a fragility fracture. miR-29c overexpression in hMSCs led to a decrease in the expression of several ECM components including COL1A1, COL1A2 and COL3A1, whereas miR-29c inhibition had the opposite effect. Mineralization was increased in miR-29c-overexpressing hMSC, while osteogenic marker ALP was not changed by this miRNA under osteogenic-inducing conditions. This suggests a role of miR-29c in mineralization rather than in early stages of osteogenic differentiation. Next, ENCORI platform was used to identify lncRNAs predicted to interact with miR-29c. In vitro assays showed that increased miR-29c levels negatively impacted lncRNA H19 expression. On the other hand, miR-29c silencing promoted H19 expression. Importantly, silencing of H19 led to impaired expression of collagens.

In conclusion, expression of ECM components can be potentially programmed by engineering the miR-29c/H19 axis.

This work was funded and supported by FCT - in the framework of the project POCI-01-0145-FEDER-031402 - R2Bone, under the PORTUGAL 2020 Partnership Agreement, through ERDF.

Adverse effects of inhaled pollutants on human health are largely accepted however investigation methods are challenged by European regulations and the promotion of animal welfare. In response, various alternative in vitro methods are developed. Among all, body-on-a-chip systems reveal to be interesting microtools shown to better mimic physiological conditions and enable potential specific inter-tissue interaction studies.

The purpose of this project is to connect a bronchial tissue with a metabolically functional liver biochip to assess any potential toxicological interactions between both compartments during inhalation-type exposures.

The in vitro lung/liver-on-a-chip model was validated through referenced hepatotoxic exposures of acetaminophen (APAP) by monitoring various cell parameters such as viability, bronchial tissue integrity, mucin detection on the tissue surface and hepatic metabolism after 72-hour exposures. In spite of xenobiotic exposures, Calu-3 bronchial tissues and HepG2/C3A biochips show strong viability and differentiation: E-cadherin and Claudin-1 expressions and elevated transepithelial electrical resistance (TEER) values indicate cohesive bronchial tissues, MUC5A production by bronchial tissue is seemingly maintained and hepatic and pulmonary metabolisms remain active. Presence of secondary metabolites highlight successful passage and transit of APAP through the closed circuited system.

Hepatotoxic exposures through the pulmonary tissue result in observable adverse effects in both compartments, translating an active inter-compartmental communication and a sensitivity of the device to xenobiotic exposure. Characterization of the developed lung-liver-on-a-chip is promising and opens the way to new physiologically relevant applications for toxicological research such as pesticide investigation.

GCN5 is a histone acetyltransferase with a role in adipogenesis. Arrhythmogenic Cardiomyopathy (ACM) is a genetic disease associated with sudden cardiac death and cardiac fibro-fatty replacement. Human primary cardiac stromal cells (CStCs) are known to contribute to adipogenesis in the heart of ACM patients. This study aims to evaluate whether GCN5 plays a role in intracellular lipid accumulation of ACM CStCs. CStCs are obtained from right ventricle biopsies of ACM patients and from samples of healthy cadaveric donors (CTR). Western Blot analysis reveals higher GCN5 levels in ACM CStCs compared to CTR CStCs in growth medium (ACM=1.017±0.08003, CTR=0.6187±0.09208; p<0.0044). After the exposure to Adipogenic Medium (AM) for 7 days in presence of 200 µmol/L MB-3, a specific GCN5 inhibitor, ACM CStCs show a reduction of lipid accumulation (ACM AM=1236±119.6, ACM AM+MB-3=234.3±42.19; p=5.5x10-17). Lipid accumulation is also significantly decreased in ACM CStCs after GCN5 silencing (Untrasduced=777.4±154.6, Scramble=678.4±107.4, shRNA GCN5=95.34±18.81; Untransduced vs shRNA GCN5 p=4.6x10-10; Scramble vs shRNA GCN5 p=2.04x10-23). To investigate the mechanisms involved, a transcriptomic analysis has been performed: in presence of MB-3, pathways related to metabolic processes are downregulated, while pathways related to redox balance are upregulated. In agreement, MB-3 administration is also able to reduce the mitochondrial Reactive Oxygen Species (ROS) concentration (ACM AM=4120±309.2, ACM AM+MB-3=2571±207.8; p=3.0x10-8), while the treatment of ACM CStCs with the mitochondrial ROS scavenger, MitoTempo (500 nM), significantly reduces lipid accumulation (ACM AM=1764±149.9, ACM AM+MitoTempo=1132±131.3; p=4.4x10-6). Our findings suggest that GCN5 inhibition might reduce fat accumulation of ACM CStCs, possibly by modulating redox processes.

Anterior cruciate ligament (ACL) rupture accounts for 40% of knee injuries [1], requiring 400,000 reconstructions annually worldwide [2] Decellularised porcine superflexor tendon (pSFT) provides an off-the-shelf, cost-efficient option for ACL reconstruction (ACLR). During decellularisation, phosphate buffered saline (PBS) is used for washing out cytotoxic solutes and reagents, whilst maintaining tissue hydration. It has been shown to increase water content in tendon, swelling the tissue [3]. This has proven to reduce the mechanical properties of tendon [4, 5]

In this study, end stage PBS washes in the standard protocol were substituted with 0.9% physiological saline to determine if tissue swelling could be reduced without negatively affecting its mechanical properties, while achieving the same degree of cellular removal. pSFTs decellularised using the modified protocol were compared to pSFTs decellularised using the standard protocol and native tendons.

Geometrical measurements and weight exposed no significant differences in tissue swelling between decellularised groups, yet less percent increase in width and thickness for the modified group. Histological evaluation showed efficient decellularisation in both groups, with no observational differences in histoarchitecture. Stress relaxation testing resulted in reduced relaxation moduli for both decellularised groups. The mechanical properties obtained from strength testing were not significantly different compared to native pSFTs or between them. However, the toe region modulus of the modified group was significantly different to both native pSFTs and standard group. Decellularised pSFTs using the standard or modified process have suitable mechanical properties to act as a viable graft for ACLR.

A METHOD TO GENERATE PERFUSABLE PHYSIOLOGIC-LIKE VASCULAR CHANNELS WITHIN ORGANS-ON-CHIP

Erika Ferrari[P][1], Roberta Visone[1], Paola Occhetta[1], Marco Rasponi[1]

The recapitulation of 3-dimensional (3D) architecture of native organs, including their vasculature, is paramount for the generation of functional in vitro models. Advanced Organs-on-Chip (OoC) platforms have been recently developed, able to provide physical stimulations to enhance tissue-specific functionality. However, these models present either separating membranes[1] or scaffolds[2] between tissues and endothelial cells, introducing physical barriers not present in the native milieu. Moreover, they fail to recapitulate the intrinsic circularity of vascular channels, which is known to promote barrier functionality and cytoskeletal alignment of endothelial cells[3]. We here developed a method to generate on-chip a perfusable circular endothelial channel embedded in a 3D construct without any physical separation. The device comprises a 720µm central culture chamber, flanked by two lateral channels for medium replenishment, separated by rows of hanging posts. We implemented the method in a novel Liver-on-Chip platform: hepatocytes (HepaRG) were embedded in a fibrin gel, generating a 3D construct surrounding an inner vascular channel, lined by endothelial cells (HUVECs). Liver functionality was assessed through albumin, enzymatic assays and immunofluorescence staining of peculiar hepatic biomarkers. Electrodes were added to assess the generated hepatic-endothelial barrier through transendothelial electrical resistance (TEER) measurements. The 3D vascularized liver model, suitable for drug screening applications, is also amenable to study the behavior of the immune component flowing in the vasculature in phato-physiological conditions. The proposed technology is compatible with the uBeat® technology[4], providing microtissues with a controlled mechanical stimulation thus resulting suitable with other applications (e.g. heart, gut) in the OoC field.

Aqueous microgels exhibit unique properties like high chemical functionality, reversible deformability, surface activity, and stimuli-responsiveness. Functional microgels can be used as building blocks for the preparation of well-ordered nanostructured biomaterials of different dimensions and complexity.

This contribution will focus on stimuli-responsive microgels exhibiting non-covalent dynamic crosslinks based on host-guest complexes, ionic bonds or hydrogen bonds. The development of new synthesis methods that allow controlled integration of supramolecular functionalities into microgels opens new ways to generate functional polymer materials and systems with unique functions like stimuli-responsiveness, re-shaping, and triggered disassembly.

Monodisperse colloidally stable microgels with a high amount (> 30 mol-%) of zwitterionic groups were synthesized using W/O miniemulsion approach. High contents of zwitterionic groups in microgels led to the formation of dynamic reversible ionic crosslinks along with permanent covalent crosslinks generated by bisacrylamide. Obtained microgels exhibit temperature-triggered swelling/deswelling behavior and co-existance of UCST- and LCST-type transitions in aqueous solutions.

A new synthesis method to obtain aqueous supramolecular temperature-responsive microgels using polyphenols as multifunctional physical cross-linker was developed recently. The precipitation polymerization of N-vinylcaprolactam in the presence of tannic acid leads to the formation of well-defined stimuli-responsive microgels cross-linked by hydrogen bonds formed between the tannic acid and carbonyl groups of the polymer chains. We demonstrate that obtained microgels exhibit reversible temperature-triggered swelling/deswelling and undergo pH-triggered degradation and re-shaping in aqueous solutions.

Extracellular vesicles (EVs) derived from mineralising osteoblasts have demonstrated their potential as osteoinductive acellular therapies bypassing the limitations associated with cell-based approaches. Nevertheless, the clinical translation of EVs is still obstructed by issues associated with their purity, homogeneity and scalability. In this study, the formulation of osteogenic proteoliposomes was investigated to develop an EV-biomimetic artificial model based on the characterization of naturally-derived osteogenic extracellular vesicles. EVs were isolated from mineralising osteoblasts over a 2-week period and their size, morphology and concentration were subsequently characterised along with the validation of EVs tetraspanin markers. The EVs pro-osteogenic capacity on promoting human mesenchymal stem cells (hMSCs) osteogenic differentiation were assessed via quantifying alkaline phosphatase activity and calcium deposition. Lipidomics and proteomics analysis were conducted to determine EV composition which guided the formulation of biomimetic proteoliposomes using the thin-film hydration method followed by extrusion. EVs proteomics analysis highlighted that several proteins such as annexins were enriched in EVs derived from mineralising osteoblasts. The proteoliposomes did not significantly affect hMSCs viability when compared to the use of naturally derived EVs. Importantly, the biomimetic synthetic vesicle membrane harboring annexin V and tissue non-specific alkaline phosphatase (TNAP) were found to be functional with the validation of the mediation of Ca2+-influx by annexin V into the nanoparticles and TNAP enzymatic activity. Taken together, these findings demonstrate the potential of proteoliposomes as a suitable candidate for the clinical translation of synthetic extracellular vesicles-based therapy for bone regeneration.

Adipose-derived stem cells (ADSC) are considered as the active substance of medicinal products dedicated to numerous diseases. However, despite promising outcomes from clinical trials, the effectiveness of ADSC-based therapies remains limited. According to the current state-of-the-art, the ADSC-based products are prepared under conditions of atmospheric oxygen concentration – dramatically higher when compared to conditions present in their niche. High oxygen concentration in cell culture is related to reactive oxygen species emergence increasing cell death occurrence.

The main objective of this study was to determine the effect of physiological oxygen concentration on ADSC in cell culture, as compared to ambient conditions (5%O2 vs. 20%O2, v/v). Serum-free, GMP-grade medium was used to provide resemblance to manufacturing of medicinal product. The following aspects were examined in cells cultured under both conditions in 3 time points up to day 21: proliferation (PrestoBlue Assay), selected gene expression (qPCR), DNA-damage (Immunocytochemistry), senescence markers (Flow Cytometry) and ROS presence (Immunocytochemistry).

Our findings demonstrate that oxygen concentration closer to physiological provides more suitable environment for stem cells, resulting in higher proliferation ratio, significantly slower acquisition of senescence (measured by β-galactosidase activity), 2-fold lower incidence of double stranded DNA breaks on late passages (measured by phosphorylation of histone H2A.X variant) along with higher expression of genes encoding proteins crucial in wound healing – VEGF and Collagen I. Therefore, we speculate that tailoring oxygen concentration to specific stem cells needs might ensure better outcomes of clinical applications by improving cells condition and survival ratio.

[2] *Lehigh Unievrsity*

Corresponding author's email: anr320@lehigh.edu

Restoring homeostasis of elastic matrix in the aorta wall through regeneration and repair is critical to reversing abdominal aortic aneurysms (AAAs), rupture-prone localized aortal expansions. This is challenged by poor tropoelastin mRNA synthesis by adult and diseased vascular smooth muscle cells (SMCs). We showed that bone marrow mesenchymal stem cells (BM-MSCs) and SMCs of specific phenotypes derived therefrom (cBM-SMCs) exhibit significant elastogenic and anti-proteolytic properties in 2-D and 3-D culture systems to provide significant paracrine pro-elastogenic and anti-proteolytic stimuli to aneurysmal SMCs. While these findings encourage prospects for use of these cells for therapeutic in situ elastic matrix repair in AAAs, there are uncertainties in their biodistribution and safety, AAA homing potential and mechanisms, and long term regenerative and anti-proteolytic/inflammatory effects in the AAA wall. We investigated the effects of single and multiple dosing of the two cell types in an elastase injury rat AAA model. From assessments based on MRI based AAA sizing, histology, cytokine arrays, ELISA, and western blot analyses, we determined that cBM-SMCs exhibit the injury homing properties of BM-MSCs, can home into the AAA wall and show better retention within. Our results indicated the potential of the cells to improve elastic matrix structure, attenuate inflammatory cytokines implicated in elastic matrix breakdown and to regress aneurysm growth. These outcomes were enhanced with repeat cell dosing. The results indicate promise of a cBM-SMC-based cell therapy for AAAs though the long-term dosing regimen must be optimized and cell delivery to the AAA wall improved for better therapeutic outcomes.

Regenerative repair of the elastic matrix is a challenge to reversing pathophysiology of proteolytic disorders including Abdominal Aortic Aneurysms (AAAs). Extracellular Vesicles (EVs) are cellular components that can facilitate intracellular communications and signaling. We have demonstrated the pro-elastogenic and anti-proteolytic benefits of adult bone marrow mesenchymal stem cells (BM-MSCs), which support a regenerative cell therapy for AAAs. We thus investigated the role of EVs in elastic matrix regenerative repair effects of human BM-MSCs. EVs isolated from BM-MSCs were characterized for their bio-physical properties, and their regenerative and anti-proteolytic effects were evaluated on cytokine-injured rat aneurysmal SMCs (EaRASMCs).

EVs sourced from MSCs displayed average particle sizes of 100 nm and TEM showed negatively stained EVs to exhibit a characteristic bilayer membrane structure and a typical size range. Western blot and exosome antibody array analysis established the presence of EV surface markers TSG101 and tetraspanins (CD63, CD9), along with the presence of mesenchymal specific cell marker, Vimentin. EVs treated EaRASMC cultures exhibited anti-proteolytic effect, by inhibiting expression of key enzymes responsible for AAA progression. EV treatment was also beneficial in upregulating the expression of Lysl oxidase(LOX), a key enzyme responsible for crosslinking of elastin precursor molecules into mature fibers, and also in increasing the deposition of total cellular elastin.

Our studies showed that EVs derived from BM-MSC source provide significant anti-proteolytic and pro-elastogenic stimuli to aneurysmal SMCs, and have potential for application as a cell-free approach to aortic aneurysm wall repair.

Despite its limitations, an autograft is the gold standard for the treatment of large peripheral nerve injuries (PNIs). We aimed to prepare an off-the-shelf advanced nerve guidance conduit (NGC) with capacity to regenerate PNIs as effectively, but overcoming the autograft's limitations.

Advanced NGCs were composed of an outer collagen type I (Coll) tubular shell and Coll and chondroitin-6-sulphate (CS) internal matrix that was enriched by adding extracellular matrix molecules (Coll/CS/ECM). NGCs with Coll/CS and Coll/CS/ECM were tested in vitro for their immunomodulatory and neurotrophic potential and compared with autografts in vivo in a rat critical-sized nerve defect model.

In vitro analysis showed that in comparison to Coll/CS conduits, Coll/CS/ECM significantly decreased secretion of inflammatory markers and significantly increased production of nerve growth factor, vascular endothelial growth factor and interleukin-6.

In vivo analysis showed that the response of the two NGCs to electrical stimulation was similar to the autograft group and no differences were seen in electrophysiological recordings either. Consistently, no significant differences in muscle weight loss were observed between either NGC and autograft group. Importantly, total neurofilament positive area and the number of myelinated axons within both NGCs was similar to autografts. In agreement with in vitro results, Coll/CS/ECM significantly increased vascularisation when compared to Coll/CS and autograft.

Collectively, our results demonstrated that enrichment of a NGC with ECM derived molecules resulted in a biomaterial capable of modulating immune response and increasing secretion of pro-repair molecules that ultimately resulted in bridging large PNIs to a level equivalent to an autograft.

Adipose tissue is distributed throughout most parts of the human body, fulfilling a variety of important functions such as energy storage, hormone secretion, protection of inner organs and heat isolation. It is a lose-bound connective tissue with a heterogenous cell population next to the fat-filled adipocytes. It is known for all tissues, that extra cellular matrix (ECM) shows great influence on cell recruitment, development and maturation. Therefore, ECM is a promising candidate to create an in vivo-like surrounding for cells and gaining meaningful results with test models in vitro.

In our approach we compared different 3D models to achieve in vivo-like cell behavior regarding the phenotype in combination with characteristic adipocyte functions. Models of interest were spheroids in suspension culture and a 3D cell suspension hydrogel with a prior developed matrix. Latest, comprising the polysaccharide gellan gum blended with decellularized adipose tissue to mimic native ECM. Hydrogel set up took place via bioprinting a porous grid structure and spheroid creation by liquid-overlay-technique. In all approaches adipose derived stem cells (ASCs) were used and differentiated to adipocytes for 14 days.

The results showed a successful lipid accumulation, expression of perilipin A and peroxisome proliferator-activated receptor-γ as well as a secretion of the characteristic adipokines adiponectin and leptin for both models. For each model a superior behavior could be observed: due to the hydrogel-matrix, a spontaneous differentiation of ASCs and within spheroid culture, a higher differentiation capacity.

Further, hydrogel-matrix optimization and bioprinting of spheroids, with and without additional hydrogel-matrix, is striven.

Lower back pain predominantly that related with intervertebral disk degeneration (IDD) has significant impact on nearly 80% humans. The primary cause of IDD is the increasing loading of annulus fibrosus arising from the gradual loss of mechanical properties of degenerated nucleus pulposus (NP). Injectable hydrogel as a synthetic hydrated matrix exhibits significant application potential in the regeneration of NP due to its characteristic viscoelasticity, controllable mechanical properties and availability in minimally invasive operation. Although numerous viscoelastic materials has been developed to study the role of matrix stiffness on the differentiation of NPC phenotype, rare studies conducted in isolation of biological activity only focus on effects of matrix stiffness on nucleus pulposus cells (NPC) and nucleus pulposus tissue (NPT). In present investigation, an injectable viscoelastic PVA-based hydrogel has been exploited to study the influence of matrix stiffness on NPC and degenerated NPT. By variation of the PVA content, thermoplastic hydrogel which not only bear superior injectable performance but also different stiffness is achieved. By the approach of encapsulation of NPC with PVA-based hydrogel, the proliferative and differential capacity of NPC in the hydrogel matrix was systematically studied. Furthermore, it can be established that the low stiffness matrix can play a positive role in the regeneration of NPT compared with high stiffness matrix through minimally invasive injection therapy on the degenerated NP.

The intestinal epithelium is characterized by a complex microscale topography formed by finger-like protrusions called villi and invaginations called crypts. This organized three-dimensional (3D) architecture together with the soft mechanical properties of the intestinal tissue are essential for cell behavior and tissue function. However, the experimental in vitro modeling of the delicate intestinal architecture is limited due to the difficulty in microfabricating soft materials with complex 3D geometries, high aspect ratio and curvature using efficient and simple methods. In this work, we fabricated soft hydrogel scaffolds that accurately mimic the villus and crypt morphologies of the intestinal epithelium using a simple and moldless approach (1).

We used mixtures of polyethylene glycol diacrylate (PEGDA) and acrylic acid (AA), or PEGDA and gelatin methacryloyl (GelMA) to fabricate 3D hydrogels by a single-step photolithography process. Different photomasks were used for the fabrication of the micropillars mimicking the intestinal villi and the crypt-like invaginations. The dimensions of the villi and crypts were easily fine-tuned just by changing the energy dose. The scaffolds were directly microfabricated onto permeable membranes, enabling their assembly into cell culture inserts. Intestinal epithelial cells lines or organoid-derived primary cells covered the biomimetic scaffolds and form polarized monolayers with proper barrier properties. The use of PEGDA-GelMA blends also allowed the fabrication of cell-laden scaffolds that mimic the intestinal stromal compartment.

Through these results, we demonstrated that this microfabrication technology is a promising tool to faithfully replicate the intestinal mucosa topography with improved performance, while keeping compatibility with standard cell culture techniques.

Skin wound healing is a complex and dynamic process that aims to restore skin integrity. Mesenchymal stem cells (MSCs) and cold plasma (APCP) are two innovative and safe therapies that have been demonstrated to accelerate and improve the healing of wounded skin [1, 2]. Herein, we describe the application of allogeneic MSCs combined with APCP in a sheep experimental model.

Two lesions were surgically induced on the back of three sheep: one was treated with MSCs and APCP, and one with PBS (placebo). APCP was applied daily. Clinical observations with histopathological and molecular analysis were used to assess the healing process at 7, 14, 21 and 42 days.

Clinically, both groups presented similar trends in wound contraction and re-epithelialization. Treated wounds showed a higher proliferation (Ki67+) and a quicker maturation of the granulation tissue than the placebo at 14 days, probably supported by the increased gene expression of VEGF. The gene expression of collagen type I and III further confirmed these findings. At 42 days, treated wounds showed a proper distribution of skin appendages resembling unwounded skin. No signs of flogosis were detected. On the contrary, in the placebo, a less amount of skin adnexa with a hyperplastic epithelium and dermal fibrosis were observed.

The combined application of MSCs and APCP led to an appropriate development of the granulation tissue and skin adnexa, thus leading to a better quality (i.e. restitutio ad integrum) of the repaired skin respect the placebo.

Many epithelial tissues have complex three-dimensional (3D) topographies that are inherently curved. Recent advances in microfabrication techniques have allowed the development of sophisticated in vitro models that replicate this complex architecture of the native tissues. In particular, engineered intestinal tissues often use hydrogels to mimic villi structures (1). These finger-like protrusions of a few hundred microns in height have a well-defined topography and curvature. However, the characterization of these large tissue engineered constructs at single-cell resolution is technically challenging. Confocal microscopy imaging is limited by the sample thickness, whereas routine histological procedures are not suitable for high water content samples such as hydrogels. We developed a novel embedding method that allows for the histological processing of these delicate hydrogel structures (2). Using low molecular weight poly(ethylene glycol) diacrylate (PEGDA) as embedding media, we obtained a block that could be further sectioned with vibrating microtome or cryotome faithfully preserving the villi-like structures of the scaffold. We then examined the cell morphological response to the villus-like microstructures by high-resolution imaging of the cross-sections. We analyzed, in a spatially resolved manner, the cellular and nuclear morphology along the villi. We observed that cell morphological response was highly influenced by the microstructures showing significant differences in cell height and shape at different regions of the villi that presented distinguished curvatures. These findings, which are in good agreement with the data reported for in vivo experiments on the intestinal native tissue, highlight the impact of the micron-scale topography and curvature on epithelial cell behavior.

Silanization is a low cost reproducible technique to modify a material surface. We have previously reported that the addition of 11-Aminoundecyltriethoxysilane to glass substrates significantly increased neurite outgrowth length, from primary neurons, and supported primary Schwann cell adhesion compared to plain glass substrates and those coated with 3-aminopropyl triethoxysilane. We have also shown that by changing the silane chain length, the deposition of amine groups can be controlled, affect cell responses at the submicron scale. Our previous work showed the potential of 11-Aminoundecyltriethoxysilane as a coating of biomaterials in peripheral nerve repair applications. We therefore, modified Polycaprolactone (PCL) films, and electrospun fibres, with 11-Aminoundecyltriethoxysilane. Scaffolds were characterised by water contact angle, SEM, AFM and XPS. NG108-15 neuronal cells, rat primary Schwann cells and dissociated chick dorsal root ganglia were cultured on scaffolds for 7 days. Cell viability was confirmed using live/dead assay and cells labelled with β III tubulin and for S100β to confirm phenotype and perform quantitative assays.

Scaffold characterisation confirmed the addition of 11-Aminoundecyltriethoxysilane to PCL. The addition of 11-Aminoundecyltriethoxysilane to PCL scaffolds increased cellular activity and increased number of live cells could be visualised on modified PCL scaffolds. The highest average neurite lengths were found on primary neurons, and NG108-18 neuronal cells, cultured on 11-Aminoundecyltriethoxysilane modified PCL scaffolds.

PCL scaffolds can be surface modified, using 11-Aminoundecyltriethoxysilane, to improve neuronal cell responses in vitro. Future work will involve applying this treatment to PCL scaffolds to use with synthetic nerve guide conduits for investigations in vivo.

Liver sinusoidal endothelial cells (LSECs) are highly specialized endothelial cells at the interface between blood and hepatocytes, forming a permeable barrier thanks to many pores called fenestrae on their membrane, to the lack of basal membrane and to their high endocytic activity. LSECs are exposed to different mechanical constraints, namely a very weak stiffness from the subendothelial space of Disse and shear stress due to blood flow.

In various liver pathologies, LSECs undergo important phenotypic changes such as loss of fenestrae, development of a basal membrane and appearance of specific markers. Similarly, these changes occur in isolated LSECs within 48 hours of in vitro culture.

This project's goal is to identify the experimental parameters needed to ensure the long-term maintenance of fenestrae.

UV-crosslinked chemically modified gelatin-based hydrogels (Gelatin Methacryloyl or GelMA) were synthesized, characterized and used as cell culture support mimicking both healthy and pathologic space of Disse by tuning the mechanical properties of the hydrogel.

Sk-Hep1 (human LSEC line) cells were successfully cultured on GelMA hydrogels. The impact of various biological factors (VEGF, latrunculin, hepatocyte-conditioned culture media, BMP-9) on the cell phenotype was investigated in terms of adhesion, spreading, proliferation, viability and presence of fenestrae (assessed by scanning electron microscopy).

The co-culture of functional LSECs with hepatocytes will be a pivotal step for liver tissue engineering. It will also enable more relevant liver on chip models that could be used as drug screening platforms in order to assess human hepatotoxicity in the early stages of drug development.

Cases of liver disease have been increasing for several decades, and are now responsible for 2 million deaths globally per year 1. Demand for transplants far exceeds supply which only satisfies 10% of cases on the waiting list1. New methods for the production of in-vitro liver tissue models will help unlock potential treatments that can reduce the need for transplantation. Here we investigate further the incorporation of human liver extracellular matrix (hLECM) into 3D electrospun scaffolds, elucidating a little understood factor: donor-donor variation2. Human liver samples from five different donors have been decellularised by SDS perfusion to provide ECM . The ECM has then been lyophilised and milled to a powder before incorporating into a solution of PCL. The solutions were then electrospun into scaffolds that can support HepG2 cells. The ECM and scaffold contents were analysed using FT-IR and immunohistochemical methods. HepG2 cells were cultured on the scaffolds and tests were conducted including: cell viability, DNA quantitation, immunohistochemistry staining, albumin excretion and gene expression of key functional markers. This study shows that our method successfully obtains scaffolds containing different human liver ECM samples and allows for comparison between the different donors.

Introduction:

Metallic meshes filled with different bone grafts are one of the common treatments for maxillary bone defects. Due to their mechanical properties, they can maintain the stability of the graft during the regeneration process. Nevertheless, a second surgery is needed to remove the mesh, with all the side effects that entails. Also, when autologous bone graft is used, the possibility of side effects associated to bone harvest like pain and morbidity increase. The main objective of this industrial project is to develop patient specific bioactive and biodegradable implants to substitute current techniques.

Methods:

Different bioactive calcium phosphate-based glass microparticles (MPs) were dispersed into polycaprolactone (PCL). Then, the mixtures obtained were 3D printed by fused deposition. Scaffolds were tested with human mesenchymal stem cells (hMSCs) and human gingival fibroblasts (hGFIB). Moreover, production of proteins such us alkaline phosphatase and vascular endothelial growth factor have also been quantified.

Results:

Parallel patterned scaffolds with interconnected macro porosity and homogeneous MPs dispersion were obtained. No cytotoxicity was detected by LDH assay. High biocompatibility was achieved regarding metabolic activity for both cell types. Printability of clinical cases with complex geometries have been achieved. Printed implants prototypes show a proper structure stability.

Discussion & Conclusions:

This platform holds a promising potential to develop safe bioactive and biodegradable patient specific implants, with good biocompatible properties and response to hGFib preventing future implant exposure.

Acknowledgements:

This industrial project is being developed in collaboration with AVINENT Implant System and supported by “Doctorat Industrial” grant (2017DI076) from AGAUR.

In research fields as cancer and drug/biomaterial testing, intravital microscopy is fundamental to study the evolution and the dynamics of physiological phenomena at the microscale, as the subcutaneous foreign body response in terms of cell behavior and neovascularization rate. We developed a miniaturized imaging window, the Microatlas, that implanted subcute guides cell migration and neovascularization into synthetic micro-scaffolds incorporated in the device. Those scaffolds were two-photon polymerized[1] on glass coverslips (Ø12mm), with a biocompatible resist. Micrometric reference structures allowed the microscope field-of-view repositioning at different time-points during experiments. The device implanted in living chicken embryos was inspected by fluorescence microscopy. Confocal and two-photon fluorescence observations at implantation sites demonstrated tissue growth inside the scaffolds and neovascularization with a capillary density six-time greater than untreated tissue; Second harmonic generation signal showed an oriented layer of collagen-I. In conclusion, the Microatlas guided in vivo a quantifiable localized reaction inside its scaffolds, in terms of cell repopulation, collagen and capillary formation. Thus, our device can be used as a reliable imaging window for intravital quantifications.

The objective of this study is to preliminary evaluate the potential of decellularized extracellular matrix (dECM) from equine tendon as injectable hydrogels and bioink materials. Superficial flexor digital tendon of horses, dead from unrelated causes were aseptically harvested, chopped in slices and stored at -80oC. For decellularization, the slices were freeze-thawed prior to Triton X100 incubation, followed by lyophilization and milling (1; 2). Hydrogels were produced by first digesting the dECM powder with HCl and pepsin for 48 hours, followed by its cold neutralization with NaOH 0.2 M. Different concentration of dECM (1 and 2 wt.%) stabilized by transglutaminase (1 wt.%) crosslinking were used to produce the hydrogels (3). The microstructure was evaluated with confocal and scanning electron microscopy (SEM). The injectability and printability using 25G needle were macroscopically evaluated and hydrogels rheological behavior were characterized. Hydrogel fibrillation was confirmed by confocal and SEM, showing porous structure with well-defined nanoscale fibrils. However, while 2 wt.% hydrogels showed good integrity and permitted easy manipulation, 1 wt.% hydrogels were fragile. These characteristics were also reflected on their rheological properties, which showed higher viscosity and storage modulus for the 2% dECM, that can be tuned by transglutaminase crosslinking. Moreover, combined with 3D printing techniques in agarose-based support bath, these injectable hydrogels derived from equine tendon dECM allow to print 3D structures with good resolution. Altogether, these results suggest that equine dECM might be a promising biomaterial to be used as cell carrier in injectable formulation or bioinks.

In Age-related Macular Degeneration (AMD) and Retinitis Pigmentosa (RP), photoreceptors (PRs) are susceptible to degeneration due to their malfunction or because of a primary dysfunction of the retinal pigment epithelium (RPE). This cell loss is irreversible and leads ultimately to blindness. Cell therapy, which consists in the replacement of dead cells by other cells generated in vitro, is a promising therapeutic option. We recently developed a RPE therapy that could target a small part of the RP population (5%). The next step is to obtain a functional bio-engineered retina containing both RPE and PRs that could be suitable to treat the majority of RP patients and late stage AMD patients.

To generate this complex retinal tissue, we developed a protocol to produce PRs from human pluripotent stem cells (hPSCs) compatible with a clinical application. Using a combinatorial screening approach, we obtained a pure population of retinal progenitor cells co-expressing the genes PAX6 and VSX2 after 2 weeks of differentiation. This co-expression was evaluated by immunofluorescence assays. A transcriptomic analysis confirmed the retinal fate specification of differentiated hPSCs. After 7 weeks of differentiation, we also obtained immature PRs expressing Crx and Recoverin. We are pursuing this combinatorial screening strategy to obtain pure and functional PR cultures.

To assemble RPE and PR cells, we developed a micro-structured polymeric scaffold composed of regularly spaced holes where PRs could develop outer segments. Once established, this complex retinal tissue will be transplanted into blind rodent models of inherited degeneration to evaluate its therapeutic activity.

Bioprinting is an emerging technique for the fabrication of biological constructs that can be used in regenerative medicine and in vitro drug testing1. However, until today, extrusion-based bioprinting processes are limited to resolutions of hundreds of micrometers, which hampers the reproduction of intrinsic functions and morphologies of living tissues2,3. This study describes an electrohydrodynamic process, named cell electrowriting (CEW), that relies on the generation of cell-laden fibers with diameters between 5- 40 µm based on an electrical field to fabricate organized three-dimensional (3D) structures. Versatility of the CEW process is demonstrated by the use of two photoresponsive hydrogel bioinks, i.e., based on gelatin and silk fibroin, which display different gelation chemistries. The rapid photo-mediated crosslinking mechanisms, electrical conductivity and viscosity of these two engineered bioinks allow the fabrication of 3D ordered fiber constructs with pores down to 100 µm with different geometries (e.g. hexagons and curved-patterns) of relevant thicknesses (up to 200 µm). Importantly, the biocompatibility of the gelatin- and silk fibroin-based bioinks enable the fabrication of cell-laden constructs, while maintaining high cell viability post-printing. Taken together, CEW opens up fascinating opportunities to manufacture microstructure scaffolds that can better resemble cellular microenvironments for regenerative medicine and organ-on-a chip models.

Human brains differ remarkably in size and cellular composition from rodent models used in pre-clinical research. For example, human cortical neurons have larger dendritic trees, distinct electrophysical properties and express different protein isoforms. For neuronal indications, less than 10% of findings derived from animal models can be translated to the clinic. A robust source of human iPSC-derived neurons would offer an attractive in vitro model for basic research and high content drug screens, which could reduce costs, improve screen specificity, and accelerate drug development. However, conventional iPSC differentiation protocols are often complex inconsistent, and difficult to scale. To overcome these problems, we developed a proprietary gene-targeting strategy (opti-ox) that enables highly controlled expression of transcription factors to rapidly reprogram human iPSCs (hiPSCs) into pure somatic cell types. We have manufactured consistent and homogenous cultures of glutamatergic neurons (>80% VGLUT1/2) and GABAergic neurons (>95% VGAT1, GAD2), which show homogenous molecular phenotype at single cell transcriptomics resolution. Reprogramming is highly consistent and synchronised, yielding fully functional neurons in less than 14 days. Our technology opens up novel avenues for the development of in vitro models to support research and healthcare innovations.

Extracellular vesicles (EVs), heterogenous lipid bilayer-enclosed structures released from a broad range of cell types, are stable carriers of small molecules. Despite promising results in the use of EVs to stimulate cardiac regeneration and protection, a better understanding of endogenous EV biogenesis and their release remains crucial when translating these therapies into the clinic. Here, we established a novel way to visualize and study EVs in the myocardium by using a Cre-loxP recombination system. Endothelial cells (ECs) were infected with an adenovirus (ADV CMV-LoxP-DsRed-LoxP-GFP) and became red (reporter+). Transducing these reporter+ cells with a second ADV (CMV-CRE), confirmed that recombination at the loxP sites induces a colour shift, from red to green. We also transduced neonatal rat cardiomyocytes (NRCMs) with an adeno-associated virus 6 (AAV6 cTNT-CFP-CRE) and verified that after 24h, >90% of the cells became CFP+. When co-culturing both cells, we observed that CFP+ NRCMs, in the upper compartment, released Cre-enriched vesicles that were taken up by endothelial reporter+ cells in the lower compartment, inducing a color switch from red to green. These data demonstrate that not only CMs can secrete Cre-containing vesicles, but also that these EVs have a functional role in the recipient (endothelial) cells. These are the first steps towards a more complex in vivo system to trace cardiac endogenous EVs in reporter mice, allowing for tracking of vesicle biogenesis, trafficking, biodistribution and timing in the heart.

Corresponding author's email: hz357@cam.ac.uk

Heart attacks cause irreversible damage to myocardium. There are very few treatment options available to fully restore cardiac function, except heart transplantation. However, cardiac patches have been under intense research in recent years as a potential route to repair tissue. By design, scaffolds should ideally be similar to the extracellular matrix (ECM) of myocardium. This presentation focuses on work undertaken to develop and characterize three-dimensional collagen heart patches that have comparable architectural and mechanical properties to the natural tissue.

A liquid nitrogen freeze-drying technique was used to produce collagen scaffolds with aligned porosity, offering the potential to fabricate more complicated structures for personalized heart patches and improving histological integration. X-ray microtomography suggested that by controlling the temperature profile during the freezing stage, anisotropic scaffolds with pore sizes from 65-249 micrometre could be made using this method, providing flexibilities in choosing cell types and also allowing for vascular network penetration. Chemical crosslinking was applied, and the elastic modulus was characterized by compression tests in water to simulate in vivo situation. The modulus of non-crosslinked scaffolds was within 1.4-3.8 kPa, and crosslinking was found to improve the modulus up to 6 kPa. Surprisingly, pore size had negligible effects on modulus within the range of 76-140 micrometre. Moreover, the pore alignment orientation was found to affect measured modulus, showing mechanical anisotropy, which is also observed in natural tissue.

By understanding how to manipulate scaffold structures and tune mechanical properties, we offer the possibility of replicating myocardium ECM for cardiac patch development.

Hutchinson-Gilford Progeria syndrome (Progeria) is a rare premature aging disease that leads to early death. Smooth muscle cells (SMCs) are the most affected cells in Progeria patients, although the reason for such sensitivity remains poorly understood. We developed an in vitro mono-culture cell system to study the susceptibility of Progeria SMCs to arterial flow shear stress using a microfluidic device. Progeria SMCs derived from iPSCs could recapitulate the most important aspect of the disease, i.e., Progeria SMCs loss under flow shear stress. Microarray analysis comparing Progeria SMCs cultured in static conditions and under slow conditions reveals that Progeria SMCs have significant changes in extracellular matrix secretion, specifically an enzyme, MMP13. Moreover, Progeria SMC detachment is prevented by the inhibition of this enzyme. Importantly, double mutant LmnaG609G/G609GMmp13-/- mice or LmnaG609G/G609GMmp13+/+ mice treated with a MMP inhibitor showed lower SMC loss in the aortic arch than controls. Our results offer a new platform for developing treatments for HGPS individuals that may complement previous pre-clinical and clinical treatments. To the best of our knowledge, this is the first study documenting part of the mechanism underlining the sensitivity of HGPS SMCs to arterial flow shear stress.

DNA-INSPIRED NANO-MATRIX FOR BIOFABRICATION IN SPACE AND ON EARTH

Yupeng Chen[P][1], Anne Yau[1], Ian Sands[1]

[1] *University of Connecticut*

Corresponding author's email: yupeng.chen@uconn.edu

Articular cartilage has limited regenerative ability, composing a minimal number of chondrocytes and components of dense extracellular matrices (ECM). The absence of biomechanical loading caused by joint immobilization on Earth or microgravity in space can damage chondrocyte functions and degrade cartilage tissue. Scientists have investigated various types of biomaterials along with stem cells and biological factors to fabricate engineered cartilage. However, it is still challenging to maintain long-term homeostasis of the engineered cartilage tissue. The key question is how to promote stem cells chondrogenic differentiation in the early stage and then inhibit their hypertrophy after differentiated.

Relying on DNA nanotechnology, our lab has developed a library of Nano-Matrices, composed of Janus-based nanotubes (JBNTs) and ECM proteins to create a biomimetic microenvironment for stem cell growth and functions. In this study, the JBNTs, mimic collagen fibers, can self-assemble with Matrilin (MATN), creating an optimal microenvironment selectively for chondrogenic differentiation and chondro-lineage cell growth. Moreover, our nanomaterials can deliver a mechano-sensitive miRNA to overcome the absence of biomechanical loading in space or on Earth. Therefore, it would enhance chondrogenesis while inhibiting hypertrophy to achieve long-term homeostasis of a cartilage tissue construct.

Furthermore, the Janus base Nano-Matrices are injectable scaffold which can be easily applied to the “difficult-to-reach” locations such as deep tissue injuries and the microchannels of tissue chips. A further goal of our research is to biofabricate an engineered cartilage tissue constructs to mimic native tissues in tissue chips for a variety of applications both in space and on Earth.

3D printing of hydrogels is a method that is applied with increasing frequency in the field of regenerative medicine. Unfortunately, many of the hydrogels that are used traditionally for 3D cultures like collagen and fibrin are only poorly suitable for printing 3D structures. To overcome this problem, we established a blend of methyl cellulose and gelatine (Gel-MC) that can be applied as a 3D-printable sacrificial gel. By studying the rheological properties of different blends of Gel-MC we were able to optimize the printing condition for the gel and to use it, to 3D print sacrificial moulds fitting for our in vivo model of choice – the arteriovenous loop model of the rat. By loading the moulds with collagen or fibrinogen-solutions and dissolving the Gel-MC in cell culture medium, we were able to fabricate cell-laden negatives of the printed moulds. Tetrazolium-salt assays demonstrated that the Gel-MC blend is not harmful for various primary cell types. By culturing the constructs with cells in vitro, we assessed the stability and the uniformity of the fabricated fibrin and collagen constructs. Finally, we created a hydrogel implant for the arteriovenous loop model consisting of multiple functionalized parts, made from different types of hydrogel with different properties. Histological staining of the explants demonstrated tissue ingrowth as well as superior degradation properties when compared to implants made in one piece. We were able to show that printable sacrificial hydrogels for the fabrication of 3D fibrin or collagen constructs are a promising alternative to directly printed hydrogel structures.

A number of bioinspired, synthetic, tissue adhesives have been created by incorporating 3,4-dihydroxy-L-phenylalanine (L-dopa), a modified amino acid that produces chemical bonding, in marine adhesives [1]. We present evidence that strong, biocompatible, wet field adhesives can be created by combining a phosphorylated amino acid that is highly enriched in marine bioadhesives, phosphoserine, with calcium phosphate cements [2]. Phosphoserine modified cements (PMCs) strongly adhere to a wide range of tissues, including bone and biomaterials (i.e. metals, polymers), and remodel in vitro, and in vivo [3, 4].

PMCs are tacky, viscous, pastes that strongly bond calcified tissues and biomaterials (2-5 MPa shear) during the setting reaction, and cure as hard, strong ceramics (50-100 MPa compression). The wet bond strength is stronger than the shear strength of human cancellous bone in many regions of the body. In fractured rodent femurs PMC stimulated robust healing, tissue remodeling (in vivo), and strong adhesion (pull-out, compared to fibrin glue, ex vivo), with failure occurring in cancellous bone and not PMC. NMR and SEM analyses suggested that the adhesive effect arose, partially, from the unique, amorphous microstructure, which included a nanoscale mineral surface layer that readily wets most surfaces. Using targeted manipulation of reactive chemical moieties (e.g. ortho/ para substitution) the adhesive strength could be finely tuned, suggesting that successive iterations of PMC with stronger calcified tissue adhesive strength can be created by via rational design of chemical reactivity.

Background: Pathologic hypertrophy induces the release of anti-angiogenic factors from cardiomyocytes (CM) to endothelial cells (ECs), leading to impaired angiogenesis and ultimately to the development of heart failure (HF). Intercellular communication via extracellular vesicles (EVs) allows the exchange of small molecules, such as microRNAs. These non-coding RNAs control gene expression and are powerful regulators of several biological processes such as angiogenesis. The study of EV-mediated microRNA transfer that occurs during cardiac hypertrophy will help identify new therapeutic targets for HF.

Aim: Understand the role of miR-30d-3p in the angiogenic processes that occur during pathological hypertrophy towards HF.

Methods and Results: By performing a qPCR-based screening we observed that under stress conditions, CMs are able to release EVs that are enriched in miR-30d-3p. Functional assays to evaluate endothelial angiogenic capacity upon gain-of-function, using precursor molecules, or loss-of-function, using LNA inhibitors, of miR-30d-3p revealed that upregulation of miR-30d inhibits endothelial cell migration and tube formation. The potential targets and mechanism of action of miR-30d-3p were investigated by RNA-seq on HUVECs after miR-30d-3p modulation. Results suggest that miR-30d exerts its function by targeting cytoskeleton-related genes. In fact, a proliferation functional screening, using a siRNA library directed against potential targets of miR-30d, resulted in significant decrease of EC proliferative capacity.

Conclusion: Hypertrophic CMs-derived EVs carry microRNAs that induce deleterious effects on ECs and cardiac angiogenesis, miR-30d-3p being one of them. Modulation of vesicle content and/or specific microRNAs on the recipient cells might constitute a novel therapeutic strategy for the treatment of HF.

Electrically conductive poly(ε-caprolactone) (PCL)-polyaniline (PANI) blend electrospun scaffolds have been previously described for their potential use in neural tissue engineering applications (1). Further processing enabled the production of coaxial fibers (951±465 nm), which are both electroconductive (0.063±0.029 S cm-1), soft (1.3 MPa) and biodegradable. The versatility of this biomaterial platform, which can be produced as aligned fiber meshes with tunable fiber diameters, conductivities, mechanical properties and degradability rates is also interesting for growth and regeneration of muscle tissue. In this work, we have studied the ability of PCL-PANI electrospun fiber scaffolds to mimic the microenvironment of native muscle tissue in order to support adhesion and growth of myoblasts and maturation into multinucleated, contractile myofibers (2, 3). Preliminary results showed high biocompatibility of mouse primary myoblasts with the biomaterial substrate promoting cell growth over the maturation timeline. After 3 days of differentiation, the formation of aligned small myotubes was observed, some already exhibiting striations at cytoskeleton level. Further experiments based on fluorescence microscopy are currently ongoing to evaluate the structural maturity of the muscle tissue culture, setting the basis to study the effects of additional external stimuli (e.g. electrical stimulation) on the artificial muscle tissue fabrication.

The authors thank Fundação para a Ciência e Tecnologia for funding through iBB (UID/BIO/04565/2019), Stimuli2BioScaffold (PTDC/EME-SIS/032554/2017), Neuron (PTDC/CTM-CTM/30237/2017), CardioWheel (PTDC/EQU-EQU/29653/2017), scholarships (PD/BD/114045/2015) and PORL2020 through PRECISE(16394). This project was also in part funded by European Commission H2020 FET Open project MyoChip.

Magnetic levitational bioassembly of three-dimensional (3D) tissue constructs represents a rapidly emerging scaffold- and label-free approach and alternative conceptual advance in tissue engineering. The magnetic bioassembler has been designed, developed, and certified for life space research. To the best of our knowledge, 3D tissue constructs have been biofabricated for the first time in space under microgravity from tissue spheroids consisting of human chondrocytes. Bioassembly and sequential tissue spheroid fusion presented a good agreement with developed predictive mathematical models and computer simulations. Tissue constructs demonstrated good viability and advanced stages of tissue spheroid fusion process. Thus, our data strongly suggest that scaffold-free formative biofabrication using magnetic fields is a feasible alternative to traditional scaffold-based approaches, hinting a new perspective avenue of research that could significantly advance tissue engineering. Magnetic levitational bioassembly in space can also advance space life science and space regenerative medicine.

Heart failure is an epidemic of the 21st century and occurs in 33% of the population above 55 years, with a 30-days-mortality of >11%. Heart transplantation is gold standard for end-stage heart insufficiency, but donor hearts cover only <0.5% of the demand. Alternatives are mechanical heart assist systems (e.g. ventricular assist devices, LVADs) during the drug-supported regeneration phase of the patient's heart.

However, LVADs struggle with device-induced thrombus formation due to inadequate blood flow dynamics of the blood pump rotor, leading to the definition of the 4DbloodROT project. Focus is the R&D on stereolithography-based additive manufacturing, novel hemocompatible materials and surface functionalization, all-together strongly extending the freedom for blood-flow-compatible design of rotors with novel exceptional biomimetic complexity (in 3D-shape & stiffness (=4D)). Final result is an in vitro optimized rotor design as basis for extended in vivo and clinical testing.

MANIPULATING THE MATRIX: USING NATURE'S TOOLKIT TO INSTRUCT CELL RESPONSES FOR PERCUTANEOUS DEVICES

Nicholas G Fischer$_P$[1], David A De Jong[1], Conrado Aparicio[1]

[1] *University of Minnesota*

Corresponding author's email: Fisc0456@umn.edu

Native extracellular matrixes act as signaling repositories to regulate cell behavior and function. Installation of medical devices disrupts these matrices and interactions of resident cells with microenvironmental cues. As a result, percutaneous devices, medical device with a skin penetrating element such as catheters and dental implants, have suffered high failures rates and infection since 2,500 BCE. Here, we present a new, broadly-applicable physicochemical strategy to leverage matrix for instructing epithelial cell behavior toward extending the lifespans of percutaneous devices.

We first synthesized a series of photopolymerizable polymers with catechol and structurally-similar moieties, easily coated on percutaneous device surfaces, with systematically varied physicochemical properties but similar mechanical properties. Tuning surface charge and polarity enabled us to control keratinocyte hemidesmosome formation, adhesive structures that anchor cells to matrix, formation and downstream signaling. A series of inhibitor and knock-down experiments demonstrated the bioinstructive effect of our materials on elaborated matrix, laminin332 in particular, in an integrin-dependent manner. Finally, we challenged our engineered materials in a course of experiments, including ex vivo, meant to reflect the harsh environment experienced during clinical therapeutic use and showed our materials retain their mechanical and bioinstructive properties. We propose our biostructure polymers direct cell responses via modulation of laminin332's structure in the pericellular matrix. Our strategy leverages the secreted matrix, via material properties, for control of matrix-mediated signals toward enhancing biological responses critical for long-term stability of percutaneous medical devices.

We developed a 3D in vitro model for mesenchymal stem cells (MSCs) differentiation based on the Nichoid scaffold, a synthetic microniche with a precise geometry, which emulates the tensional states of the native niche. The hypothesis is that the Nichoid shapes cell morphology thus varying the nuclear pore permeability to transcription factors [1]. In this work, fluorescence microscopy and multimodal label-free microscopy [2] were applied to investigate MSCs response to differentiation media inside 3D Nichoids.MSCs were cultured with adipogenic and chondrogenic culture media for 21 days inside Nichoids and investigated with fluorescence microscopy and label-free multi-photon microscopy at different time points. Results showed that MSCs expanded in the 3D environment and conditioned towards the chondrogenic lineage produced smaller collagen-I deposits with respect to flat substrates. Fibrils were more evident in scaffolds corridors than inside the pores. Contrarily, adipogenesis was enhanced inside Nichoids with respect to controls. The use of multimodal label-free microscopy allowed to chemically identify and spatially localize collagen and lipids in 3D.Our results suggest that the Nichoid stiffness significantly promote adipogenic differentiation, while limiting chondrogenesis.This work received founding from the European Research Council (ERC projects NICHOID, No. 646990, NICHOIDS, No. 754467, MOAB, No. 825159); European Commission (FET-OPEN project IN2SIGHT, G.A. 964481); European Space Agency (ESA project NICHOID-ET, G.A. 4000133244/20/NL/GLC); National Centre for the Replacement, Refinement and Reduction of Animals in Research (NC3Rs projects MOAB, G.A. Introduction: Dental implants have become a well-accepted treatment modality for the replacement of missing teeth with high success rates. However, complications such as peri-implantitis still affect a significant number of patients. As peri-implantitis is biofilm-related, microbiological profiles of subjects may be indicative of future potential for development of this complication and help to develop personalised, surface modifications.

Aim: To perform a clinical study to establish potential similarities and differences in the microbial profiles and antibody-mediated immune response profiles of patients with 'healthy' implants and those affected by peri-implantitis.

Methods: Patients with dental implants were separated into 2 groups: patients with 'healthy' implants and patients with peri-implantitis. Along with clinical data, the following samples were collected: whole blood, saliva, supragingival plaque, and subgingival plaque around implants. Blood plasma was subsequently processed for Mimotope Variation Analysis (MVA) used for immunoprofiling of antibody immune response, while polymerase chain reaction (PCR) method was used for detection and quantification of 10 periodontopathogen DNAs from saliva, supragingival and subgingival plaque.

Results: Statistically significant differences between bacterial loads were only observed in subgingival samples. MVA immunoprofiling revealed differential immune response to mimicking epitopes of Actinomyces and Porphyromonas antigens specifically in subjects with peri-implantitis. When combined, microbial and immunoprofiles identified differences in immune response among subjects with dental implants.

Conclusions: Correlative patterns observed between microbial and immunoprofiles might be further used to highlight the specific immunologic features of host immune response pre-implantation as well as for personalized risk assessment for complication development and mitigation with specific surface modifications.

ASSOCIATION OF VNTR RS33966823 POLYMORPHISM IN 3-UTR REGION OF FGFRL1 GENE WITH THE RISK OF COLORECTAL CANCER

Ali fatahian-kelishadrokhi[P][1], Parisa mohammadinejad[1]

[1] *Biotechnology Research Center, Shahrekord Branch, Islamic Azad University, Shahrekord, Iran*

Corresponding author's email: fatahian1993@gmail.com

Introduction: One of the most common cancers in the world is colon cancer. One of the factors that affect colon cancer is inflammation due to increased cryoprotein protein function, the gene encoding this protein in human FGFRL1. If this gene is damaged, it will increase the performance of cryoprotein protein, and this increase in performance will in turn produce cytokines called IL-1β and inflammation. Regarding the important role of FGFRL1 gene in colon cancer, in this study, VNTR polymorphism was evaluated in healthy and colon cancer patients.

Methods: In this study, 98 patients with colon cancer and 104 healthy subjects selected for VNTR polymorphism of the CIAS1 gene with PCR and gel electrophoresis were studied. Data were analyzed by SPSS 21 software, 2 nd test and logistic regression test.

Results: The results showed that 15 different genotypes and 7 types of alleles were found in the VNTR polymorphism of the FGFRL1 gene. The individuals with the 12-unit repeat allele had the highest and lowest values for those without this allele. The results showed that the genotype lacking a 12-repeat allele compared to the genotype of people with a 12-repeat allele reduced the risk of colon cancer.

Discussion: The results were consistent with the studies (P = 0.01) and the VNTR polymorphism of the FGFRL1 gene can be used as a biomarker for diagnosis of colon cancer, and it regulates various processes related to inflammatory response and colon protection from injury.

Keywords

EVALUATION OF A TISSUE-ENGINEERED NERVE CONDUIT FOR PERIPHERAL NERVE REGENERATION OF A RAT SCIATIC NERVE DEFECT

Alexane Thibodeau[P][1,2], Todd Galbraith[1], Chantal Fauvel[1], Hélène Khuong[1,2], François Berthod[1,2]

Introduction

Treatments for peripheral nerve transections remain a challenge. Nerve damage can lead to severe loss of sensibility and motor functions with important impact on patient's quality of life. Our goal is to produce a scaffold-free nerve tube (NT) prepared exclusively from the patient's own cells. A viable conduit pre-seeded with endothelial (ECs) and Schwann cells (SCs) could allow a faster recovery for patients with major peripheral nerve transections.

Methods

NT's are made of human fibroblast sheets seeded with both EC and SC's and rolled to form a compact tubular structure. NT's were implanted in rats for 22 weeks to repair a 15 mm sciatic nerve defect. Graft innervation was observed by immunofluorescence and toluidine blue staining. The gastrocnemius muscle weight was used as a reliable measurement of reinnervation status. The horizontal ladder rung test was used to determine functional outcome assessment. The sciatic functional index (SFI) was determined from treadmill walking.

Results

The NT enhanced nerve fiber migration. Toluidine blue staining revealed mature myelinated fibers after 22 weeks. Equivalent muscle mass was observed in grafted NT's vs gold standard control autograft. After 22 weeks, a partial motor function recovery was observed in rats with similar efficiency in both NT and autograft ($p>0.05$).

Conclusions

A pre-vascularized NT with autologous cells increases nutrients and oxygen supply through the rapid establishment of a capillary network. Primary SC's may release nerve regeneration factors. In a long-gap model, it has been shown that pre-vascularized and pre-seeded NT's allows for a better motor function recovery.

The use of 3D printing has enabled the production of custom made scaffolds for tissue regeneration. The success of the technology is based on the meticulous design of inks that offer tunable reactions for the precise printing of scaffolds. In this study, a printable sol-gel silica-based hybrid ink for bone regeneration was developed by combining tetraethyl orthosilicate (TEOS) and gelatin, crosslinked with (3-Glycidyloxypropyl)trimethoxysilane (GPTMS), which was incorporated to reduce the brittleness of the silica and to enhance degradation rates. The sol-gel reaction speed was controlled by using different pHs and reagent ratios to obtain a proper printing window at 35ºC, which would allow the incorporation of bioactive molecules. Moreover, the silica-based ink has to maintain the shape once dried. Therefore, different aging times and drying methods were evaluated to determine the most adequate approach. Preliminary results show that, out of all of the assessed combinations, four have an acceptable printability and shape fidelity. These inks were characterized in terms of printing diffusion rate, collapse area factor, contraction caused by the drying step, and the physicochemical properties. Cell cultures demonstrated that aging time had an effect on cell viability, being cytotoxic for short aging times. To improve the cell behavior, a gelatin coating was applied to the printed scaffolds with the purpose of blocking the unreacted crosslinker and, consequently, reducing its cytotoxicity and improving cell adhesion and proliferation. Therefore, this sol-gel silica-gelatin hybrid ink can be a potential material for the 3D bioprinting of custom made scaffolds for bone regeneration.

Models adequately mimicking skeletal muscle injuries and diseases are important tools to understand and study mechanisms underlying initiation and progression of diseases as well as tissue regeneration and remodeling after injuries [1]. While a small number of 3D systems for investigating myogenic diseases are already published, there is still a lack of models for myogenic injuries.

Herein, we present how an established tissue engineering approach to create biomimetic skeletal muscle-like tissue can be used to model injuries. Healthy tissue constructs were created through mechanical stimulation of murine myoblasts with a bioreactor [2] and subsequently subjected to different types of stress (e.g. mechanical overstimulation with high frequency or high tensile stress or complete deprivation of mechanical stimulation). Mechanical overstimulation resulted in an immediate stress response as well as prolonged signaling effects (a.o. activation of p38 and ERK 1/2 after 15 minutes, FAK after 6 hours, AKT and S6 after 3 days of stress). Furthermore, high frequency overstimulation led to increased mRNA expression of markers of proliferation (e.g. CCND1) and early- and mid-stage myogenesis (e.g. MyoD, MyoG), and changed morphology of myotubes (random orientation with a hypertrophic phenotype). Deprivation of mechanical stimulation for seven days led to severely impaired integrity of myotubes on a morphological level, but also to downregulation of signaling pathways involved in stress response and myogenic development. Thus, we conclude that the first steps towards the establishment of a biomimetic tissue-engineered skeletal muscle injury model were successful despite further refinement and investigation of the mechanisms involved are still needed.

Fibrin hydrogels have proven highly suitable scaffold materials for skeletal muscle tissue engineering (SMTE) approaches in the past. Certain parameters of those types of scaffolds, however, greatly affect cellular mechanobiology and therefore the myogenic outcome [1]–[3]. The aim of this study was to identify the influence of scaffold stiffness and architecture on myoblasts and evaluate if those effects differ between murine and human cells. Therefore, myoblasts were cultured on fibrin-coated well-plates (“2D”) or embedded in fibrin hydrogels (“3D”) with different rigidities.

Firstly, we established an almost linear correlation between hydrogels´ fibrinogen concentrations and Young´s moduli in the range of 7.5 mg/ml to 30 mg/mL fibrinogen (corresponds to a range of 7.7 kPa to 30.9 kPa). The effects of substrate stiffness on myoblast proliferation changed depending on hydrogel architecture with an inhibitory effect of higher fibrinogen concentrations in 3D gels and vice versa in 2D. The opposite effect was evident in differentiating myoblasts as shown by expression analysis of myogenesis marker genes and changed myotube morphology. Furthermore, cultivation in a 3D environment slowed down proliferation compared to 2D, with a significantly more pronounced effect in human myoblasts. Differentiation potential was also substantially impaired upon incorporation into 3D gels in human, but not in murine, myoblasts.

With this study, we gained further insight in how scaffold stiffness and architecture affect cellular behavior and myogenic outcome of SMTE approaches. Furthermore, the results highlight the need to adapt parameters of 3D cultivation set-ups established for murine cells when applied for human cells.

KERATICNOCYTE-SPECIFIC ADHESION PEPTIDE COATINGS: A NON-ANTIMICROBIAL STRATEGY TO PREVENT INFECTION OF PERCUTANEOUS DEVICES

Conrado Aparicio[P][1], Nicholas G. Fischer[1], Alexandra C. Kobe[1], John Pizarek[1], Jiahe He[1], David A. De Jong[1]

Percutaneous devices are widely used medical devices, yet infections lead to a multi-billion dollar healthcare burden(1). The tooth, a Nature's successful percutaneous organ, displays marked longevity/lack of infection because of a unique basement membrane surrounding it that mediates a durable soft tissue attachment to the tooth that prevents access of bacteria and thus, prevent biofilm formation(2). Resident keratinocytes form hemidesmosomes (HDs) that anchor cells to the tooth surface and secures the peri-organ seal(3). However, fibroblast, which cannot form HDs and thus a sound peri-implant seal, can colonize device surfaces contributing to device failure. Coatings of keratinocyte adhesion peptides (KAPs) capable of inducing HD formation and favor proliferation of keratinocytes vs fibroblasts may serve as one strategy for enhanced lifespans of infection-prone percutaneous devices.

Four KAPs curated from basement membrane biomolecules(4) were immobilized using click chemistry and physiochemically characterized. Keratinocyte proliferation, HD formation and downstream formation, and cytokine production were characterized. Two KAPs showed a marked ability to upregulate HD formation and downstream signaling and produce a broader array of wound-repair cytokines compared to other KAPs and controls. Further experiments were carried with these two leading KAPs. Fibroblast proliferation and a fibroblast/keratinocyte co-culture were used to demonstrate cell-specificity and significantly increased expression of proteins related to tooth longevity. Finally, the KAP coatings' durability under simulated use was assessed. Our KAPs coatings represent an alternative to antimicrobials toward enhancing the hosts' ability to prevent infection through sound and durable soft tissue attachment to percutaneous devices.

Total skin loss is a common skin complication affecting millions of people worldwide, mainly in chronic disease. A slight delay in wound management resulted in loosing skin stability and integrity that could lead to chronic wounds or even death. Biomaterial is the main core element in tissue engineering triad to develop a related product such as skin tissue engineering. The ovine collagen type I (OCT-I) was a natural-based biomaterial produced from raw tendon through an acid-based extraction method to obtain high-yield collagen content. Recently, the OCT-I has been proven and tested tremendously since 2011 until now covering the in vitro, in vivo, safety evaluation and pre-clinical model [1-5]. The findings of these evaluations demonstrated positive and promising output to further explore OCT-I as a potential rapid treatment for future use in skin wound management. The next challenging stage is currently faced up covering the up-scaling, quality control and sustainability of OCT-I from laboratory scale to larger production. It requires a lot of time due to involve various parties including government, industrial partner and related regulatory body to make it happened. The Medical Device Authority (MDA), Ministry of Health, Malaysia is a regulatory body responsible to register any medical devices in Malaysia. Specific requirements should be followed through prior to registering different types of medical devices (Class A-D). Therefore, the future driven of successfully commercialized tissue engineering products are depending on the mutual collaboration of academicians, scientists, industrial partners and regulatory bodies in a particular country.

INTRODUCTION: Damage to the corneal epithelium triggers important changes in the composition of the extracellular matrix to which the basal human corneal epithelial cells (hCECs) attach. These changes are perceived by integrins and lead to re-epithelialization of the injured epithelium. Among the intermediates downstream of integrin signalling, WNK1 is the kinase whose activity is the most strongly increased during corneal wound healing. The goal of the present study was to determine the contribution of WNK1 to corneal wound healing and to identify the mechanisms and proteins through which WNK1 mediates its influence on that process. METHODS: A scratch wound assay conducted on hCECs grown as monolayers and a wound healing protocol performed on tissue-engineered human corneas (hTECs) were both used as in vitro models to study the impact of a WNK1 pharmacological inhibitor, WNK463, on corneal wound healing process. Gene profiling and transcription factors microarray analyses were also conducted either in the presence or absence of WNK463. RESULTS: Inhibition of WNK1 significantly reduced the rate of corneal wound closure in monolayer and in our 3D model. It also prevented the activation of its downstream target proteins SPAK and OSR1. In addition, WNK1 inhibition also modified the gene expression pattern in hCECs and considerably reduced the activity and expression of a number of key transcription factors in vitro. CONCLUSION: These results will validate a new function for the WNK1 kinase in corneal wound healing and might lead to the identification of a new therapeutic target in the field of corneal wounds.

Invasive electrodes implanted in peripheral nerves are neural prosthetic devices that can be harnessed to control neuroprostheses in human amputees(1). The Foreign Body Reaction (FBR) is a nonspecific inflammatory response of the host immune system to the implanted material, which represents one of the main challenges to overcome in chronic implants(2). This process is characterized by 3 phases, ending in device encapsulation, due to collagen deposition around the implant, which forms a fibrotic capsule that can ultimately isolate the electrode surface from the surrounding tissue leading to its progressive loss of functionality(2,3).

In this in vitro work, we tested the biocompatibility and ultra-low fouling features of the organic polymeric coating – zwitterionic sulfated poly(sulfobetaine methacrylate) (SBMA) hydrogel – compared to the synthetic coating – poly(ethylene glycol) (PEG) – to reduce plasma protein adsorption and cell adhesion to polyimide surfaces, which are early hallmarks of the FBR(2).

After its synthesis, the SBMA hydrogel was preliminarily characterized through the measurement of the Young's modulus and water contact angle. Cytotoxicity analysis of the zwitterionic hydrogel showed its biocompatibility. In vitro assays with human myofibroblasts and macrophages on PEG- and SBMA hydrogel-coated surfaces were performed to evaluate their adhesion and viability. Because of the high hydration, biocompatibility and swelling capacity, low stiffness, and ultra-low fouling characteristics of the hydrogel, this polymer showed lower cell adhesion, activation and different cell morphology compared to adherent controls.

Overall, our soft SBMA hydrogel could outperform PEG coatings as more suitable dressing of intraneural electrodes for reducing the FBR.

[1] *Department of Biomaterials, Institute of Clinical Dentistry, University of Oslo, 0317 Oslo, Norway*

Corresponding author's email: maryam.rahmati@odont.uio.no

Surface modification of implant surfaces has been a promising solution to avoid the failure of biomaterials after implantation. Although researchers suggest several strategies for surface functionalization of titanium-based implants, only a few studies have compared the osteoimmunomodulatory effects of ionic nanostructures and biofunctionalization in the same biological model. Although enamel matrix derivate (EMD) is known for its positive influences on bone cell responses; its in vivo osteomodulatory responses should be evaluated. In this study, we functionalized the titanium–zirconium implant surface with EMD using an electrochemical cathodic polarization method. Afterward, we evaluated the immune and bone tissue responses to the EMD coated titanium–zirconium implants in the tibia of eight Gray Bastard Chinchilla rabbits. EMD stimulated higher ALP activity and lower cytotoxicity in wound fluid, as well as a lower expression of inflammatory markers after 8 weeks indicating its osteoimmunomodulatory effects after implantation. Overall, the results suggested that implant surface biofunctionalization using EMD could be useful in regulating the immune responses to implant.

Introduction: Pancreatic ductal adenocarcinoma (PDAC) is the 95% of cancers of the exocrine pancreas and is often associated with a poor prognosis. In addition to therapeutic failures, like chemotherapy, attributed to the PDAC microenvironment, the Epithelial-mesenchymal transition (EMT), is implicated in carcinogenesis and confers metastatic properties on cancer cells improving mobility and invasion. This phenomenon is very important and a new in vitro 3D model is needed in which it can be studied.

Aim: recreate an in vitro 3D model with PDAC primary cells to study the EMT phenomenon and cancer cell migration.

Methods: We fabricated and optimized spongy scaffolds made of PVA/Gelatin (G) (70/30 w/w) via emulsion with G, followed by 1 freezing cycle, and lyophilization. Primary PDAC cells were isolated from patient's specimens, characterized and seeded at 1×106 cells/scaffold. These constructs were cultured for 15 days and assayed at 2, 5, 8, 15 day time-points (n = 3). Along culture time, the AlamarBlue metabolic assay was performed. At each time-point, the constructs were processed for histology: cell morphology was investigated via hematoxylin and eosin staining, proteins involved in the EMT (i.e., EGFR, PAN-CK, TGF-β, MMP-9, actin and desmin) were evaluated via immunohistochemistry (IHC)

Results: IHC results show that the scaffold/cell system resembles the EMT process well, in particular TGF-β protein modulation, that from literature seems to be an important stimulus.

Conclusion/Significance: The PVA/G sponges mimicking well the pancreatic tissue environment, in this way it is possible study the metastatic mechanisms of PDAC through EMT.

Many nnovations are introduced in the macro- and micro-geometry of both the implant necks, abutments, and prosthetic connections, with the aim to promote the maintenance of adequate mucosal height and thickness during healing, minimizing the marginal peri-implant bone loss (1, 2).
Recently, a new implant design has been introduced (Prama, Sweden & Martina, Italy), which is inspired to the biologically oriented preparation technique (BOPT) described for natural teethRecent non-controlled clinical studies, reported favorable results in terms of marginal bone stability and Pink Esthetic Score (PES), at 18 and 36 months, after adopting this implant design in the esthetic area of the upper maxilla (3).
However, a comparative analysis is lacking, both at the clinical and preclinical level, which validates the features of this implant and provides evidence for its efficacy in maintaining stable peri-implant tissues.
The aim of this randomized, controlled, experimental trial was to inquire through a comparative histometric analysis, whether the adoption of the Prama implant design (test), compared to a conventional bone level implant provided with a cilindrical, machined surface abutment (control), could affect the height and thickness of the peri-implant tissues, as well as the position of the free gingival margin (FGM) and of the first bone to implant contact (B).

In bottom-up tissue engineering, spheroids are used as building blocks for the fabrication of large tissue structures. During culture, the spheroid size can serve as a quality attribute while their fusion rate is a crucial parameter in biofabrication. Therefore, monitoring technologies with potential for integration and upscaling have to be investigated. In this study, a lens-free imaging (LFI) device was evaluated for automatically monitoring the abovementioned characteristics. Human periosteum derived cells (hPDCs) were seeded onto agarose microwells and cultured up to 1 week in chondrogenic media to form µTissues. After 24 hours, spheroids were captured with bright-field (BF) microscopy and LFI. The spheroids were manually segmented and their area, major axis length and roundness were extracted for validation of the LFI set-up. After 1 week of maturation, a fusion assay was performed in the presence (20 µM) and absence of ROCK-inhibitor for both set-ups. The morphological changes were captured over 24 hours with a 10-minute time interval. For the LFI images, a random forest classifier was trained to segment the doublets and features such as their area and roundness were extracted. The BF images were processed using a thresholding approach. For the LFI set-up, the relative errors on the area, major axis length and roundness were 5.8 ± 4.9%, 4.7 ± 2.5% and 4.7 ± 3.1%, respectively. The classifier obtained a sensitivity, precision and F1-score of respectively 0.959, 0.952 and 0.956. Preliminary analysis of the roundness indicated slower fusion in the absence of ROCK-inhibitor, with consistent results for both set-ups.

Novel biomaterials are constantly being developed to facilitate regeneration of lost bone tissue resulting from trauma or degenerative diseases. Hydrogel composites are of particular interest in this field due to their therapeutic efficacy and reasonable mechanical strength. We have previously developed a non-biodegradable Laponite® crosslinked pNIPAM-co-DMAc hydrogel which promotes osteogenic differentiation of human mesenchymal stem cells (hMSCs) when loaded with hydroxyapatite nanoparticles1. However, for load-bearing bone defects such hydrogel composites are not adequate mechanically. This study explores the suitability of the Laponite®-pNIPAM-co-DMAc hydrogel incorporated in a bioactive scaffold for bone tissue regeneration. This investigation reports the effects associated with incorporation of the hydrogel on the degradation rate of bioactive scaffolds fabricated via foam replication. This investigation also explores the application of the hydrogel as a means to deliver and maintain hMSCs. The XRD data confirmed in vitro apatite mineralisation after 14 days of aging in PBS for scaffolds with and without hydrogel. Using SEM and EDX, it was shown that the cells' shape and composition were maintained in the hydrogel-glass ceramic system and calcium-rich extracellular matrices were deposited on the cells after 21 days. We are currently evaluating cell viability using a series of histological and immunohistochemical characterisations. We speculate that the hydrogel provides a suitable environment for the cells to survive whilst the bioglass scaffold degrades and promotes cell adhesion and differentiation. We further hypothesise that the non-biodegradable nature of the hydrogel will provide long-term mechanical support whilst the bioactive ceramic network degrades, and a new tissue is generated.

Collagen scaffolds, one of the most used biomaterials in corneal tissue engineering, are usually crosslinked to improve mechanical properties, enzyme tolerance capacity, and thermal stability. More biocompatible crosslinkers, such as 1-ethyl-3-(3-dimethylaminopropyl)carbodiimide hydrochloride (EDC), provide lower crosslinking density and reduced mechanical properties. Conversely, those that generate mechanically more robust scaffolds, such as glutaraldehyde (GTA), tend to induce greater toxicity. Herein, we evaluate the capability of sodium metabisulfite (SM) and sodium borohydride (SB) to restore biocompatibility after crosslinking.

EDC-crosslinked collagen scaffolds were treated with different concentrations of GTA. To mask the free aldehyde group produced through the GTA crosslinking, scaffolds were then treated with SM or SB. Mechanical and functional properties were evaluated. Cell viability was studied using different cultured corneal cell types. The effect of each scaffold treatment on human monocyte differentiation was evaluated. One-way ANOVA was used for statistical analysis.

EDC-GTA double crosslinking significantly improved the mechanical properties and enzymatic stability of the collagen scaffold. GTA decreased cell biocompatibility, but this was reversed by treatment with SB or SM. SB or SM did not reduce or affect mechanical properties, enzymatic stability, or transparency of the double crosslinked scaffold. Differentiation of monocytes to activated macrophages was not initiated in contact with any scaffold.

Our result demonstrated that GTA improves mechanical properties of the EDC crosslinked scaffolds in a dose dependent manner, and that subsequent treatment with SB or SM restores biocompatibility. This novel manufacturing approach would facilitate the translation of collagen-based artificial corneas to the clinical setting.

Organs-on-chip (OoCs) are catching on as a promising and valuable alternative to animal models, in line with the 3Rs principle. OoCs enable the creation of 3D tissue microenvironments with pathophysiological relevance at unparalleled precision and complexity, offering new opportunities to model human diseases in vitro and to test the potential therapeutic effect of novel drugs, while overcoming the limited predictive accuracy of conventional 2D culture systems (1,2,3). Here, we present a liver-on-a-chip platform to investigate the effects of two plant-derived polyphenols, namely Quercetin and Hydroxytyrosol, on nonalcoholic fatty liver disease (NAFLD) using a high-content analysis readout methodology (4,5). NAFLD is currently the most common cause of chronic liver disease worldwide; however, its complex and multifactorial pathogenesis is still far from being clear, and a definitive treatment has not yet been established (6,7). In our experiments, we observed that both polyphenols seem to hamper the progression of the free fatty acid-induced hepatocellular steatosis, showing a cytoprotective effect due to their antioxidant and lipid-lowering properties (8). In conclusion, the findings of the present work could provide novel therapeutic strategies to contrast the onset and progression of NAFLD.

Ischemic heart diseases are the leading cause of death worldwide. Novel approaches have been focusing on restoring cardiac function by mainly targeting cardiac repair, however in vivo studies promoting both contractile and electrical functional recovery are scarce. Piezoelectric materials are capable of generating electric current upon mechanical deformation. Since the heart exhibits robust cyclic movements, implantation of these materials on the myocardium holds great potential for designing biomaterials with self-sustained electrical stimulation, harnessing the contractile proficiency of healthy regions of the ventricle to stimulate damaged ones. In this work, piezoelectric patches implanted on ex vivo rat Langendorff-perfused working hearts and cardiac slices did not preclude tissue function and had the ability to slightly improve its contractility, comparing with control electrically inert PCL patches. Following one month of in vivo heart implantation on a mouse model of myocardial infarction, piezoelectric patches caused improvement of the cardiac function, mainly on heart electrical integrity. Despite no notable alteration in histological parameters, the transcriptome of piezoelectric patch-implanted hearts was altered specifically on the more contractile/proficient portion of the left ventricle, showing a downregulation of genes associated with matrix remodeling and heart failure when compared with the PCL control, suggesting a more efficient functional recovery from the infarction by the piezoelectric group. The current work is the first therapeutic cell-free biomaterial-based patch with piezoelectric properties that can be directly applied to the healthy myocardium without compromising its function, while causing an improvement on the overall function of the mouse infarcted heart.

In the past few decades, many attempts have been made to manufacture an ideal tissue-engineered graft for intricate tissue of bone; however, inconsistencies between in vitro and in vivo experiments still exist due to negligence towards the immune system/implant interactions. Regarding the immunomodulation as a new critical factor in bone tissue engineering (BTE), amniotic membrane (AM)-derived products with its immunomodulatory effects have recently shown promising applications in ocular or cutaneous treatments and have paved the way for other applications such as BTE. Herein, we hypothesized that AM scaffold or a combination of AM, chitosan, and alginate scaffold could enhance osteogenic activity and induce angiogenesis in in vivo studies. We aimed to exploit human AM matrix to fabricate a 3D porous scaffold allowing cellular infiltration, proliferation, osteogenic differentiation, and in vivo angiogenesis. We reported mechanical and structural properties of the scaffolds and assessed cell viability regarding these groups. As they demonstrated increased cell proliferation, we investigated the osteogenic differentiation and mineral deposition of adipose-derived mesenchymal stem cells within scaffolds in the presence and absence of osteogenic supplements. We further analyzed the Balb/c subcutaneous implants of the scaffolds for inflammatory reaction, implant/immune cell interactions, and angiogenesis. Incorporation of amniotic membrane ECM bone biomimetic scaffolds promoted osteogenesis even in the absence of osteogenic factors and induced angiogenesis while reducing chronic inflammation at the site of implantation. Collectively, our data on AM derived composite porous scaffolds stands on being appropriate as bone graft substitutes.

Hard tissue disorders such as osteoporosis, maxillofacial and cranial defects, oral defects affecting enamel, dentine, and periodontal tissues affect more than half of the world population [1, 2]. Here we report an integrated approach combining additive manufacturing with supramolecular chemistry to develop acellular hierarchically mineralizing scaffolds for hard tissue regeneration. Our approach uses the interplay between protein's order and disorder to generate a supramolecular framework capable of triggering hierarchical apatite growth within 3D printed scaffolds guiding mineralization from the nanoscale up to complex macroscopic structures. Polymeric scaffolds of desired structural parameters such as porosity, pore size, and pore connectivity were 3D printed using computer-controlled rapid prototyping technology. Scaffolds were coated with elastin-like protein (ELP) to form a uniform layer of ~10 µm thickness throughout. The mineralized scaffolds were acid-resistant and exhibited high stiffness and hardness of up to 33.0 and 1.1 GPa, respectively [3]. Furthermore, the scaffolds supported adhesion and proliferation of human bone marrow cells (hBMCs) and stimulated the expression of alkaline phosphatase (ALP) as compared to naïve scaffolds. Overall, this approach integrates advantages of supramolecular chemistry, tunable organic-inorganic interactions, additive manufacturing, and commemorates ease of design and fabrication of a novel platform to enhance osteoinductivity and osteoconductivity in bone regeneration. We envisage that this approach can have important implications for the design of smart biomaterials which not only can acellularly self-mineralize by drawing ions from the implant site but also exhibit the capacity to infiltrate and integrate with the underlying native tissues.

DEVELOPMENT OF CARTILAGE DECELLULARIZED EXTRACELLULAR MATRIX INK

Katie Hogan[P][1], Mollie Smoak[1], Antonios Mikos[1]

[1] *Rice University*

Corresponding author's email: kh48@rice.edu

Decellularized extracellular matrix (dECM) has become an attractive material for applications in regenerative medicine and tissue engineering due to its retention of native biochemical cues to promote cell growth, proliferation, and differentiation. Extrusion 3D printing represents a versatile fabrication platform for dECM hydrogel scaffolds due to its precise control over internal microarchitecture and bulk geometry. However, cartilage dECM inks often lack the rheological and mechanical properties for traditional extrusion printing and often require synthetic copolymers or scaffolding. Previously, gelatin-based sacrificial baths (FRESH) have enabled printing of soft hydrogels but demonstrate opposite gelation kinetics compared to dECM. Here, the objective of our work is to develop and characterize a cartilage dECM ink for extrusion printing without the need for additional polymer incorporation using a Pluronic-based sacrificial bath, which demonstrates LCST gelation behavior, and dual-gelation via riboflavin photo-crosslinking.

Harvested hyaline cartilage was decellularized using physical, chemical, and enzymatic means, and biochemical characterization performed to quantify sulfated glycosaminoglycans, collagen, total protein, and DNA content. Rheological and mechanical characterization were performed to evaluate viscosity, shear thinning behavior, temperature sweep, photo-crosslinking, and compressive modulus. Following 3D printing, constructs were evaluated for print resolution via fiber diameter and pore circularity. Additionally, long-term stability and degradation of the constructs were evaluated in collagenase. In addition to enabling cartilage dECM printing without co-polymers or scaffolding, this printing system may be adapted for broader use for dECM and LCST polymer inks which have not traditionally been compatible with extrusion 3D printing.

Selected antimicrobial peptides (AMPs) can self-assemble into supramolecular structures (1), which has been overlooked as causative of their antimicrobial activity as well as a potential tool for developing potent multifunctional antimicrobial biomaterials. Moreover, the higher antimicrobial potency of D-enantiomers compared to L-enantiomers of AMPs cannot always be attributed to their different resistance to protease degradation and enables the development of more effective biomaterials(2). We have vastly studied these effects and the structure-function correlations of a designer AMP, GL13K, derived from the parotid secretory protein(3). We have also developed potent antimicrobial GL13K coatings on medical devices and tissues to protect them against infection for their use in dentistry and orthopedics(4,5).

Here, we tested and compared all L- and D-amino acid versions of GL13K and its negative randomized amino acid peptide versions, GL13K-R. We assessed (a) structural links between the AMP secondary structure, supramolecular self-assembly dynamics, and antimicrobial activity, (b) differences in structural interactions with model bacterial membranes and components of the bacterial outer envelope, and (c) governing surface physicochemical properties to build effective AMP coatings. We demonstrated that (a) the ability of and faster dynamics for supramolecular assembly of D- GL13K compared to L-GL13K was correlated with higher AMP activity, (b) specific and strong interactions between D-GL13K and bacteria-wall proteoglycans was suggestive of higher potency against Gram-positive bacteria, and (c) surface polarity of AMP-coated substrates was the dominant factor governing AMP/substrate interactions. Our findings can instruct the universal design of efficient self-assembled AMP coatings on biomaterials, biomedical devices and/or natural tissues.

In this study, the injectable sodium alginate and gelatin hydrogels were synthesized and modified by using silane coupling agents and calcium chloride to improve physicochemical and mechanical, the behavior of hydrogels. The morphology of the hydrogels displayed a homogeneous structure for all samples. The chemical structure of the raw materials and the hydrogels confirmed the possible cross-linking reaction. High level of absorption capacity and resistance to rapid degradation demonstrated suitable stability of the gels with the highest concentration of polymers and lowest (3-glycidyloxypropyl) trimethoxysilane (GPTMS): polymer ratio (0.5:1 w/w). Bioactivity evaluation confirmed the formation of hydroxyapatite layers that can improve the effectiveness and durability of the hydrogels. The rheological properties of the hydrogels indicated the higher stability of the storage modulus and viscosity when the higher concentration of polymers and the lower concentration of cross-linker were applied. Consequently, hydrogels (10 %W/V gelatin, 8.5 %W/V sodium alginate, and GPTMS: polymer ratio (0.5:1 w/w)) can be useful for further in vivo and pre-clinical evaluation for urinary incontinence treatment.

In this study, the possibility of binding of alcoholic extract of aloe vera to the electrospun gelatin was investigated. After producing the gelatin fibers, they were immersed in the aloe vera extract solution to allow the extract to be infiltrated into the fibers. Scanning electron microscopy (SEM) and optical microscopy revealed that the fibers were well oriented on the aligned nanofibers. The 3D cavities between the fibers might be suitable sites for cell migration and loading the antibiotic drugs or plant extracts that release the drug into the nanofibers compared to the films due to a better surface area to the volume of nanofibers. The NIH-3T3 fibroblasts cells were cultured and the cytotoxicity was evaluated. The results of the MTT assay showed cell viability and proliferation of the scaffolds and the aloe vera extract. Gelatin plays an important role in the cell adhesion. To improve the mechanical and thermal properties of gelatin, glutaraldehyde has been used as a cross-linker. The results showed that as the concentration of glutaraldehyde increases, the number of cavities decreases which confirms the enhancing of the scaffold strength. These nanofibers scaffolds might be a good candidate as a dressing material for wound healing applications.

Calcium phosphate-based scaffolds with porous structures similar to natural bone are frequently used in bone tissue engineering. The current challenge to further improve their performance is focusing on the optimization of their 3D structure with additive manufacturing allowing to produce scaffolds with a high degree of local control on the internal pore architecture. This allows to balance the biological requirements with the biomechanical ones, such as is the case for gradient porous scaffolds (GPS) which are porous structures where the porosity changes in space with a specific gradient. To properly test the effectiveness of scaffold architecture on drawing in cells and guiding neotissue formation in vitro, an environment similar to the physiological conditions is needed. In spite of ample studies showing the importance of pore gradient in conventional in vitro models, much less research has been done on the performance of GPS biomaterials in a dynamic 3D culture environment.

Therefore, this study investigated the influence of pore architecture on cell proliferation and matrix deposition. Immortalized bone marrow mesenchymal stem cells were seeded on additive manufactured CaP scaffolds and cultured for up to 21 days in 3D perfusion bioreactor. Live/Dead staining of the construct was performed to show the presence of live cells. Contrast-enhanced nanoCT imaging was used to visualize the neotissue (cells + extracellular matrix) formed inside the scaffold.

This study provides a quantitative insight into the spatial gradient of scaffold's pore architecture and confirms the influence of perfusion bioreactor system for the in vitro development of 3D cell–carrier constructs.

MICROCARRIERS WITH COMPLEX ARCHITECTURES MANUFACTURED BY TWO-PHOTON LITHOGRAPHY FOR MECHANOBIOLOGICAL MANIPULATION AND EXPANSION OF MESENCHYMAL STEM CELLS

Jason Hutchinson[P][1], Felicity Rose[1], Cameron Alexander[1], Ricky Wildman[1]

[1] *University of Nottingham*

Corresponding author's email: jason.hutchinson@nottingham.ac.uk

Mesenchymal stem cells (MSCs) have been widely utilised for tissue repair, however for effective treatment large numbers of cells are needed due to low retention in defect sites [1]. Stem cell populations can be expanded through culture on microcarriers. Current strategies struggle to meet population sizes required as the availability of surface area is not the only factor to be considered when promoting cell growth. Complex architectures exhibiting specific biophysical cues can increase MSC expansion capacity and control differentiation [2]. The production of bio-instructive microcarriers using biophysical cues have the potential for in vitro cell expansion that surpasses currently available technologies as well as the capability for in vivo utilisation as a multifunctional tissue modulator through particle-based scaffolds.

Two photon lithography creates highly accurate microscale structures with feature sizes down to 100nm. This technology was employed to create microparticles with varying designs for culture with MSCs. A variety of microcarrier designs were created and fabricated with optimisation of materials, fabrication procedures and post processing strategies. Initial experimentation has provided insight into cellular infiltration, proliferation and migration across microparticle designs highlighting several promising architectures. Useful methodology for directing cells to geometries through pHEMA coated 2PL fabrication has been established and holds much promise for further experimentation. Current work focuses on examination of cell expansion yield for identified designs leading to phenotypic differentiation analysis of MSCs over the expansion period. Finally, novel µSLA technology will be explored to meet clinically relevant scales and compare effectiveness of bio-instructive microcarriers to currently available technologies.

Keywords

Microcarriers; Mesenchymal stem cell; Two photon lithography

Introduction: Vascular network development in volumetric tissue defects remains a challenge in tissue engineering. We propose that scaffold architecture which dictates cell proliferation and tissue morphogenesis, also controls stromal-vessel interactions. We evaluate interaction between mesenchymal stem cells (MSCs) and microvascular fragments (MVFs) within hydroxyapatite (HA) scaffolds of various pore sizes containing fibrin hydrogels. Additionally, a computational model validates the architectural effects on vascularization observed in vitro.Methods: Sintered HA scaffolds were synthesized by template coating at 3 pore sizes (450, 340 and 250 µm). Primary bone marrow MSCs were seeded first at 1x105/scaffold. Fibrin gels were constituted at 2:5 fibrinogen:thrombin at 20 mg/mL. MVFs isolated from rat fat pads were seeded at 20,000 MVFs/mL. The MVF-fibrin filled MSC seeded-HA scaffolds were then cultured for 3, 7, 14 and 21 days in vitro. Decalcified samples imaged (lectin staining) or RNA extracted for sequencing. µCT scans were used to create finite element models of scaffolds for each pore size and AngioFE (FEBio) was used to simulate capillary development over a period of 7 days.Results and conclusions: Lectin staining showed continued vessel growth and branching. Highly porous interconnected scaffolds influence the development of capillary networks: fibrin gels offer limited resistance to capillary morphogenesis, 450 µm pores showed capillary loops within pores, 340 µm pores showed a mix and the 250 µm pores showed vessels bridging across pores. Computational modeling with appropriate inputs showed promise in matching biological experimental findings which can be leveraged for improved porous biomaterials scaffold design.

Objective: This study was designed to investigate the regeneration of patella tendon/ligament using a scaffold-free biofabricated 3D construct of autologous adipose tissue-derived mesenchymal stem cells (AT-MSCs) in rabbits.
Design: A columnar construct (inner diameter of 2.5 mm, height of 3 mm) was fabricated by using bio-3D printer (Regenova; Cyfuse Biomedical K.K., Tokyo, Japan), and it was consisted of 320 spheroids each containing 2.0 × 10^4 AT-MSCs. After the construct was matured following to fusion of the spheroids, it was cut to patch shape (length of 8 mm, width of 3 mm). And then, it was autologously implanted into a defect at the right patella tendon/ligament in each of eighteen adult Japanese white rabbits (kbt-JW; Biotech Co., Ltd, Tosu, Japan; 2.5-3.5 kg; 27-37 weeks old). The contralateral (left patella tendon/ligament) defect was untreated as a control. The eighteen rabbits were divided into three groups (6, 12, and 24 weeks post-implantation groups), and those patella tendons/ligaments were eventually evaluated histopathologically.
Results & Conclusion: Currently, a difference between the implanted site and the control site was observed in tendon/ligament thickness. For the future, differences between the both sites will be examined in orientation of collagen fibers and network of existing cells. These results will probably suggest that autologous implantation of a scaffold-free biofabricated 3D construct of AT-MSCs into a tendon/ligament defect could regenerate the original structure of tendon/ligament for post-operative 6 months.

Understanding of kinetics on aggregate behaviors of human induced pluripotent stem cells (hiPSCs) is important knowledge for developing stable mass culture process. Here we found critical factors inhibiting growth of hiPSCs in suspension culture through analysis of aggregate size distributions and kinetic parameters when culturing two types of cell lines (253G1 and 201B7 lines) in static suspension and rotating flow cultures, which were realized by multi-dimple plate and rotating wall vessel, respectively. In the case of 253G1 line in rotating flow culture, aggregate number decreased and size increased drastically during culture time, t = 0 - 24 h due to coalescence between cell aggregates. The apparent specific growth rate decreased after t = 24 h although cell number and aggregate size gradually increased in static suspension culture. On the other hand, in the case of 201B7 line in rotating flow culture, cell and aggregate number, and aggregate size kept constant levels during t = 24 - 72 h due to collapse of cell aggregates by stripping of single cells from aggregate, suggesting that specific death rate increased after t = 24 h despite constant levels of apparent specific growth rate and aggregate number in static suspension culture. Distributions of E-cadherin and extracellular matrices in aggregates, which critically affects coalescence and collapse, respectively, were also quite different between cell lines. Our kinetic analysis concluded that excessive increase of aggregate size due to coalescence and stripping of single cells due to collapse critically affected growth of hiPSCs in suspension culture.

Introduction: The inner lining of the upper airway includes ciliated epithelium and lamina propria essential for barrier function. This layer is disrupted upon injury and results in inflammation and fibrotic scarring[1]. We developed a model to study the impact of basement architectural cues on the epithelial-fibroblast interaction at air-liquid interface by using randomly-oriented and aligned polycaprolactone (PCL) fibers. Materials and Methods: Plasma treated randomly oriented and aligned PCL electrospun fibers were placed in transwell chambers and were seeded with human tracheal fibroblasts (HTFs) for 7 days and then human bronchial epithelial cells (HBEs) were introduced above the HTF layer. An air-liquid interface was established on day 14 to promote HBE differentiation. Permeability, cell proliferation, and expression of fibroblast (fibronectin and S100A4) and epithelial (MUC5A) markers were evaluated using ELISA and immunofluorescence (IHC) imaging (n=6). Quantitative data were compared using one-way Analysis of Variance (ANOVA) followed by Tukey's test for post hoc determination of significant differences at $p<0.05$.Results and Discussion: Fiber alignment resulted in higher expression of fibroblast markers during the first 7 days while randomly oriented fibers generally caused higher (27%) cell proliferation over time. In addition, IHC images revealed homogenous HBE growth above the HTFs layer with significant laminin-rich matrix deposited at the interface and dispersed spheroidal epithelial clusters observed in both groups. Larger epithelial spheres were observed in coculture on randomly oriented fibers with rudimentary ciliated structures.Conclusions: A successful epithelial-fibroblast coculture system with pro-fibrotic behavior was achieved by controlling architectural cues introduced during initial fibroblast-epithelial interactions.

The expression of H19 long non-coding RNA (lncRNA) is known to steeply diminish during the development of the cardiovascular system. While H19 knockdown has been shown to hinder endothelial cell proliferation and their capacity to form capillary-like structures, approaches aimed at restoring H19 expression have demonstrated controversial results. Here, we used extracellular vesicles (EVs), known to be involved in vascular development, growth and maturation, and modulate their content with H19 in order to analyze their effect on therapeutic angiogenesis. For that purpose, we overexpressed the mouse H19 gene in human mesenchymal stem cells (WJ-MSC) for 48 h, after which we collected and characterized the EVs. Our results showed that H19-transfected WJ-MSCs secreted EVs enriched in H19 without changing the physical-chemical profiles of scramble-transfected EVs. Furthermore, H19-EVs were internalized by mouse aortic endothelial cells (MAECs), which resulted in a >2-fold increase in H19 expression compared to control. Treatment of MAECs with H19-EVs significantly ($p<0.05$) accelerated their angiogenic response, resulting in a >10% increase in the total tube length and in a >20% increase total number of junctions, compared to control. In a wound closure assay, both H19-EVs and vector-EVs elicited a strong enough response to match that of the positive control (bFGF). In this case, all treatments significantly ($p<0.05$) decreased wound area relative to untreated MAECs, regardless of the presence of H19. This study demonstrates that H19 modulates angiogenesis in cardiac endothelial cells, encouraging its exploitation in cardiac applications. Furthermore, it portrays EVs as an effective delivery agent for lncRNAs. EFFECTS OF TOPOGRAPHICAL CUES ON HEMOCOMPATIBILITY OF POLYVINYL ALCOHOL HYDROGELS AND ENDOTHELIAL CELL RESPONSES

Yuan Yao[P][1], Evelyn Yim[1]

[1] *University of Waterloo*

Corresponding author's email: yuan.yao@uwaterloo.ca

Introduction: Topographical patterning of hydrogels has attracted broad attention due to its potential to affect cell behaviors and functions. In this study, we fabricated various topographies on polyvinyl alcohol (PVA) hydrogels to investigate the effects of topographical cues on hemocompatibility of the material and endothelial cell behaviors.
Materials and Methods: PVA hydrogels with different topographies were manufactured as described previously [1]. Topographies including micro-gratings, 2 µm pillars and 1.8 µm concave and convex lenses were studied. Fucoidan was conjugated on all PVA hydrogels to improve endothelial cell adhesion on PVA. Endothelial cells (ECs) were studied by immunofluorescence staining of F-actin, VE-cadherin, PECAM-1 and focal adhesion. Functional differences of ECs were assessed by monocyte adhesion assay and tube formation. Platelet adhesion and activation as well as thrombin generation on different topographies were tested to evaluate the effects of topographies on hemocompatibility.
Results: ECs formed monolayers on all types of patterned surfaces, and no significant differences on VE-cadherin expression were observed. Cells on all grating structures had significantly lower circularity and higher alignment compared other patterns. Monocyte adhesion on ECs and tube formation were affected by topographies. However, no significant differences were seen in thrombin generation on different topographical patterns. All surfaces had low platelet adhesion and activation, but no significant differences were observed among various topographies.
Conclusion: Topographies on hydrogel samples have an effect on EC functions, and grating structures induced more cell alignment. However, the hemocompatibility of patterned surfaces was not significantly different from PVA and ePTFE.

INFLUENCE OF 3D AGGREGATE CULTURE ON EPIGENETIC MEMORY AND PLURIPOTENCY MAINTENANCE IN HUMAN INDUCED PLURIPOTENT STEM CELLS

Naruchit Thanuthanakhun[P][1], Mee-Hae Kim[1], Masahiro Kino-oka[1]

Although three-dimensional (3D) suspension culture is widely recognized as a promising approach for human induced pluripotent stem cell (hiPSC) manufacturing, an intracellular mechanism regulating cell pluripotency under this culture environment is still unclear. In this study, we investigated effect of 3D aggregate culture condition on cell behavioral and epigenetic alteration in association with the pluripotent state of hiPSCs. Compared with cells in two-dimensional (2D) monolayers, cells in 3D aggregates showed differential regulation of cell adhesion and Rho/Rac proteins during growth processes. In response to 3D culture, Rho was upregulated, while Rac was constantly maintained at low level. Additionally, cells in 3D culture substantially downregulated myosin phosphorylation, a key mediator of actin cytoskeletal contractility, compared with cells in 2D culture. Quantitative measurement of global histone methylation demonstrated that cells in 3D culture earlier increased the active H3K4me3 mark and persisted the repressive H3K27me3 mark throughout culture period, moreover, cells in 3D culture noticeably presented naïve pluripotent marker expression. These findings significantly extend our understandings of epigenetic and pluripotency regulation through mechanotransduction mechanism that might be taken into consideration in the design and improvement of culture environments for stem cell production.

DUAL SCALE POROUS SCAFFOLDS BY MELT EXTRUSION

Phong Tran[P][1]

[1] *Queensland University of Technology*

Corresponding author's email: phong.tran@qut.edu.au

We combined 3D printing with porogen leaching to develop scaffolds with dual macro-micro scale porosity. By extruding a mixture of molten polycaprolactone polymer and microscale porogen particles, scaffolds with pre-determined macro-architecture were prepared, that were then leached to reveal microscale porous networks. The scaffolds had interconnected macroscale porosity of about 60% with an average pore size of 700 µm and intra-strut microscale pores with a porosity of nearly 40% and average pore size of 20–70 µm. We showed that the microscale porosity resulted in higher scaffold surface area, increased protein adsorption, faster degradation and enhanced blood clotting in vitro. We also demonstrated the use of this new type of scaffolds in regenerating bone in a rat calvarial defect and in local drug delivery for infection or cancer treatment.

Uniformed distribution of the seeded cells on to the culture surface at seeding cells are quite important for cell proliferation. Therefore, the important culture process is currently carried out by skilled workers. In order for regenerative medicine to develop in the future, mechanization of cell culture is indispensable, but there are many details are remain uncleared for developing automated cell culture systems. Therefore, we focused on cell seeding and conducted experiments on the effects of ejection shape and shaking on cell dispersion. In this report, we created a new giant liposome to visualize the dispersed state, and examined the visualization of the cell dispersion at cell seeding. We will present the results of the experiment.

OXYGEN NANOBUBBLES FOR THE DELIVERY OF THERAPEUTICS AND THE REVERSAL OF HYPOXIA

Jonghoon Choi[P][1]

[1] *Chung-Ang University*

Corresponding author's email: nanomed@cau.ac.kr

Hypoxia is a key concern during the treatment of tumors, and hypoxia-inducible factor 1 alpha (HIF-1α) has been associated with increased tumor resistance to therapeutic modalities. In this study, doxorubicin-loaded oxygen nanobubbles (Dox/ONBs) were synthesized, and the effectiveness of drug delivery to MDA-MB-231 breast cancer and HeLa cells was evaluated. Dox/ONBs were characterized using optical and fluorescence microscopy, and size measurements were performed through nanoparticle tracking analysis (NTA). The working mechanism of Dox was evaluated using reactive oxygen species (ROS) assays, and cellular penetration was assessed with confocal microscopy. Hypoxic conditions were established to assess the effect of Dox/ONBs under hypoxic conditions compared with normoxic conditions. Our results indicate that Dox/ONBs are effective for drug delivery, enhancing oxygen levels, and ROS generation in tumor-derived cell lines.

The generation of a hierarchical and functional vascular network is one of the major challenges in cardiac tissue engineering. We investigated how to 3D bioprint vascularized human heart tissues by using vascularized cardiac spheroids (VCSs) in permissive hydrogels. First, VCSs were generated by co-culturing human cardiac myocytes, fibroblasts and endothelial cells in hanging drop cultures. Then, 3D bioprinted heart tissues (3DHTs) were generated by extruding VCSs mixed in alginate/gelatin-based hydrogels with optimal printability and durability. Vascular endothelial growth factor (VEGF) was applied to 3DHTs to further promote vascular network formation. Our study showed that bioprinted VCSs are viable for at least 30 days after printing and synchronously contract when electrically paced. Paired VCSs within 3DHTs fuse and generate tissues with defined geometries. VEGF promoted both angiogenic branching from VCSs into the surrounding hydrogel and spheroid fusion. Our 3D rendering analysis of 3DHTs stained with CD31 antibodies showed a branched lumenized vascular network. Altogether, our findings indicate that VCSs can be used as building blocks to 3D bioprint vascularized human heart tissues. Given their unique features in better recapitulating the vasculature typical of the human heart microenvironment, 3DHTs have the potential to be used to both prevent and treat cardiovascular disease.

3D bioprinting attempts to fabricate engineered cartilage simulating the architectural and biological characteristics of the native cartilage. Main constraint of current approach is limited understanding of the role of bioink on molecular signaling pathways during in vitro chondrogenesis. In depth study was conducted to assess cartilage-specific molecular signaling pathways in human mesenchymal stromal cells (hMSCs) laden 3D bioprinted silk-gelatin (SF-G) constructs. Detailed proteomics analyses performed by us helped to deduce the modulation of the anabolic and catabolic chondrogenic pathways by hMSCs encapsulated in 3D bioprinted SF-G constructs. The interaction between SF-G bioink and hMSCs contributed to expression of in vivo like chondrogenic signaling pathways: Wnt/β-catenin, Wnt/PCP, HIF-1, and Notch since day 1 of chondrogenic differentiation. Additionally, we tried to elucidate the contentious role of TGF-β signaling in vitro, by evaluating the differential protein expression by hMSCs laden bioprinted constructs cultured in the presence and absence of TGF-β3. Our results demonstrated the activation of TGF-β signaling in the presence of TGF-β3 indicating a direct role of TGF-β3 addition to induce stable chondrogenic differentiation. This first-time detailed proteomics analysis would open up new avenues to identify articular cartilage-specific signaling pathways in a 3D bioprinted tissue-engineered construct to foster cartilage repair.

In this study we tested different approaches for co-expression of HGF and VEGF165 genes with known synergic effects on blood vessels formation and growth. Combined approaches by mixing 2 plasmid DNAs have limited prospect in clinical translation, so the development of a single vector carrying 2 therapeutic genes is a potential decision. We tested vectors with different design, including plasmids with internal ribosome entry sites (IRES), with bidirectional promoter or two independent promoters for each gene of interest. Studies on HEK293T and HUVEC cells showed that all plasmids provide synthesis of HGF and VEGF165 proteins with proper biological activity. However, tests in skeletal muscle explants showed dramatic difference and most plasmids failed to express HGF or VEGF165 in significant quantity. Only a bicistronic plasmid with two independent promoters provided expression of both grow factors in significant amount and near equimolar ratio. Efficacy tests of bicistronic pHGF/VEGF plasmid were performed in mouse model of hind limb ischemia. Intramuscular pHGF/VEGF administration induced significant restoration of blood perfusion compared to empty vector or saline administration which was confirmed by the difference in CD31+ capillaries density on histological sections of m. tibialis anterior.

Our study reports a first-in-class candidate gene therapy drug ready for preclinical use with shown pharmacological effectiveness in a relevant model. We assume that this construction can become a new generation gene therapy drug for "therapeutic angiogenesis" and treatment of ischemia associated diseases.

The study was supported by the state assignment of Lomonosov Moscow State University and RFBR grant #20-015-00181.

Osteochondral lesions are one of the most debilitating healthcare conditions in the world, in that it significantly affects one's quality of life. One of the promising methods to treat such lesions is to use microfracture, in which the subchondral bone is deliberately drilled in a controlled manner to allow the bone marrow to seep towards the defect site. Unfortunately, microfracture treatment typically leads to fibrocartilage formation instead of the hyaline cartilage found in native articulating cartilage tissue. This is due to the inability of the method to re-create the native structure found in articular cartilage.

This study hypothesize that the recreation of native tissue can be done if the right cell types are placed in accordance to where it needs to be found. This is performed by depositing different primary cells into a sterile tube sequentially by means of centrifugation, thus spatially controlling the co-culture of different cell types. This is performed by centrifuging a solution containing porcine nasal chondrocytes (pNCs) down first, forming a pellet. Without disrupting this initial pellet, a second solution containing porcine calvaria osteoblasts (pCOs) was centrifuged down, thereby effectively creating a pellet layer on top of the initial layer. This co-culture pellet was then cultured for up to 14 days, upon which immunohistological testing was performed. By using a double stain kit, with Collagen I and II being the targets, it was found that the pellets could form matrix of their respective regions.

A recent approach to engineer artificial cartilage involves seeding cells within a scaffold consisting of an interconnected 3D-printed lattice of polymer fibres combined with a cast or printed hydrogel, and subjecting the construct (cell-seeded scaffold) to an applied load in a bioreactor [1]. A key question is to understand how the applied load is distributed throughout the construct.

To address this, we use mathematical modelling to describe effective properties of this elastic–poroelastic composite material [2]. We treat the fibres as a linear elastic material and the hydrogel as a poroelastic material, and exploit the disparate length scales (small inter-fibre spacing compared with construct dimensions) to derive macroscale equations governing the response of the composite to an applied load.

To validate the model, predictions from finite element simulations of the macroscale, homogenised equations are compared to experimental data describing the unconfined compression of the fibre-reinforced hydrogels. The model is used to derive the bulk mechanical properties of a cylindrical construct of the composite material for a range of fibre spacings and to determine the local mechanical environment experienced by cells embedded within the construct.

Advances in tissue engineering of human tissues using 3D printing technology are of growing interest in developing micro physiological systems for biomedical applications. Proper designing is of important criteria while incorporating physiological and anatomical features for printing of tissues. Herein we describe the application of 3D printing technology in building tissue analogues by designing the anatomical and physiological features of tissue. We develop a simple yet effective approach using both 3D printing and 3D bioprinting technologies to construct tubular tissue constructs. In this proof of concept study, to mimic the structural similarity of bronchi, we have fabricated two concentric cylindrical structures using SLA 3D printer which are of 1 cm in height. The space in between is filled with decellularized smooth muscle extracellular matrix (dSMM) bioink. The surfaces of the cylinders have holes to enable efficient perfusion of media to the tissue. This structure provides support to the mechanically weak bioink to retain its shape while printing. The structure was cultured for 21 days under dynamic conditions in an in-house printed bioreactor. Characterization assays revealed viable cells that are functional in dSMM within the structure. We believe that this method can be applied to various cylindrical structures of human scale. Tissues such developed can be used for drug testing or for understanding many biological mechanisms or as a direct tissue-engineered implant for in vivo applications. We anticipate that this strategy will help us to overcome one of the key challenges of mechanical instability of decellularized ECM based bioinks during printing.

Mesenchymal stem cells (MSCs) experience many intercellular and extracellular forces and specific oxygen tension (pO2) inside their native in vivo stem cell perivascular niche. Many questions still remain regarding the complexity of this micro-environment and how oxygen concentration gradients and shear forces at the niche-tissue interface can affect MSC metabolism; which recently showed to play a determinant role in stemness maintenance or differentiation. Here by the use of a microbioreactor (MOAB) [1] suitable for high-resolution imaging coupled with fluorescence lifetime imaging microscopy (FLIM) [2] we profile cellular metabolism of human-MSCs (h-MSCs) in a simulated stem cell niche environment by controlling shear stress and pO2 gradients via interstitial flow velocity levels. The combination of these advanced modalities can reveal metabolic activity of cells in very specific micro-anatomic environments to analyse physiology and diseases. We were able to finely tune and detect the pO_2 spatial depletion along the micro-chamber in a range of interstitial flow velocities mimicking the transvascular extravasation of fluids during changings in vessels permeability. According to the specific decay in oxygen cells uptake, we detected a significant spatial metabolic transition towards glycolytic activity by measuring a bound NADH fraction linear decay towards the outlet hypoxic region. Our microfluidics/imaging platform demonstrated to sustain a microphysiological environment for stem cells culture enabling real-time high-resolution imaging of metabolic activity representing a powerful tool for MSC studies in metabolic controlled conditions.

Bone metastases are a common complication of highly prevalent cancer types such as breast and prostate cancers. They result in imbalances between bone-forming osteoblasts and bone-degrading osteoclasts and affect bone density, resulting in painful lesions. Yet, few in vitro models encapsulate both bone cell types to simultaneously study such interactions. Here we developed a patient-derived co-culture 3D model to study the reciprocal effects of osteoblasts/osteoclasts and a metastatic breast cancer cell line MDA-MB-231.Osteoblasts derived from human bone (hOBs) were cultured on 3D printed calcium phosphate-coated medical-grade polycaprolactone scaffolds and grown to obtain a highly mineralized matrix [1]. In parallel, human peripheral blood monocytes were differentiated into mature osteoclasts (hOCs), as shown by colorimetric assays, immunofluorescence (TRAP, CatK) and resorption pit assessment. The mature hOCs were then seeded on top of the hOB-seeded mineralized scaffolds and co-culture morphology and mineralisation (microCT) were further characterized.We found that the addition of MDA-MB-231 cells seeded on top of the constructs resulted in increased cancer cell proliferation when hOCs were present. As expected with breast cancer metastases, a decrease in mineralisation was also observed in the hOC/hOB-scaffolds after cancer cell seeding and co-culture for 3 weeks, consistent with osteolytic metastases.Including two of the key cellular drivers of bone remodeling in a reproducible tissue-engineered model therefore provides an advanced and broadly applicable research and drug testing platform of cancer metastases in bone.

INDUCING HUMAN RETINAL PIGMENT EPITHELIUM-LIKE CELLS FROM SOMATIC TISSUE

Cody Kime[P][1], Ivo Ngundu Woogeng[P][1]

[1] *RIKEN Center for Biosystems Dynamics Research*

Corresponding author's email: ivo.woogeng@riken.jp

Regenerative medicine relies on basic research to find safe and useful outcomes that are only practical when cost-effective. The human eyeball requires the retinal pigment epithelium (RPE) for support and maintenance that interfaces the neural retina and the choroid at large. Nearly 200 million people suffer from age-related macular degeneration (AMD), a blinding multifactor genetic disease among other retinal pathologies related to RPE degradation. Recently, autologous pluripotent stem cell-derived RPE cells were prohibitively expensive due to time, therefore we developed a new simplified cell reprogramming system. We stably induced RPE-like cells (iRPE) from human fibroblasts by conditional overexpression of broad plasticity and lineage-specific pioneering transcription factors. iRPE cells showed features of modern RPE benchmarks and significant in-vivo integration in transplanted chimeric hosts. Herein, we detail the iRPE system with comprehensive modern single-cell RNA (scRNA) sequencing profiling to interpret and characterize its best cells. We anticipate that our system may enable robust retinal cell induction for regenerative medicine research and affordable autologous human RPE tissue for cell therapy.

Induced Pluripotent Stem Cell (iPSC) holds a magnificent place in the medical revolution. Since Yamanaka's iPSC discovery in 2006, several works of research have proven that the enforced expression of transcription factors Oct-3/4, KLF4, and Sox2 in differentiated and matured cells induce genetic reprogramming of the cells into iPSC. However, the conventional reprogramming method of using viral vectors confers greater risk for unwanted genetic modification. Therefore, this current study utilised a non-viral reprogramming approach of using a novel protein transduction domain, namely trans-activator of transcription kappa (TATκ), a synthetic TAT-HIV, to deliver these transcription factors genes as an alternative method for iPSC generation. With this new strategy, this study established a stable clone of 293T cells expressing and secreting TATκ fusion pluripotent proteins (TATκ-KLF4, TATκ-Sox2, and TATκ-Oct-3/4). TATκ-GFP, a marker protein, and pluripotent proteins transduced the targeted (U937) monocyte cell line, proved this TATκ possesses the ability to penetrate across the cell membrane. Post 20 days of transduction, U937 cells elongated and started to adhere. However, the presence of bona fide iPSC colonies was unable to be obtained, which might have been due to the incomplete reprogramming or insufficient duration of protein transduction in generating iPSC cells.

Islet transplantation is a minimally invasive beta cell replacement therapy with the potential to cure Type 1 Diabetes (T1D). However, success rates are hampered by loss of islet transplanted in portal veins. Developing scaffolds that favor islet survival and allow transplantation in extra-hepatic sites is one solution to achieve a cure for T1D. Indeed, 3D-bioprinting has shown good islet viability and morphology. Delivered with biocompatible hydrogels, this approach could favor islet survival and reduce cellular stress.

Here, we fabricated implantable scaffolds for human islets using clinical-grade nanocellulose (80%)/alginate (20%) hydrogel (TUNICELL from Ocean TuniCell). Islets were embedded in hydrogel scaffolds using the INKREDIBLE+ 3D-bioprinter (CELLINK, Sweden). Fluorescent Recovery after Photo-bleaching with 3-5 kDa and 70 kDa dextrans was used to evaluate the diffusion properties of the hydrogel scaffolds. Cell viability and functional physiology were assessed using FDA/PI staining and glucose-stimulated insulin secretion on days 1, 8 and 13 post-print.

Our hydrogel showed 100% recoveries after photo-bleaching in 4-6 sec, or 5-18 sec, for scaffolds incubated with 3-5 kDa and 70 kDa dextrans, respectively. In vitro assessments of bio-printed scaffolds revealed viable islets on days 1, 8 and 13 post-print. Islets in scaffolds showed proper insulin secretion in response to basal and stimulated glucose levels over time (e.g. at day 8: basal insulin 481.3 ± 40.9, stimulated insulin 1186.0 ± 6.2, post-stimulation insulin 973.0 ± 12.2, n=4).

This study indicates that our hydrogel has proper diffusion properties that create a favorable islet micro-environment resulting in preserved viability and physiology of islets.

Background: Ideal printable biomaterials are demanding as tissue printing fields are explored. However, development of proper materials having good printability and photo-initiator free is challenging. Commonly used cross linking agents such as methanol, glutaraldehyde, EDC-NHS, photo-initiator and exposure to UV light would not be suitable for biocompatibility
Objectives: We investigated the possibility of using silk sericin combined with gelatin and glycerol to obtain this ideal 3D printable self-gelling biomaterial and evaluated its application potential for wound dressing patch in vitro and in vivo.
Methods: Formulation of sericin based hydrogels, and its physico-chemical property associated with printability, and biological properties in vitro and in vivo were investigated.
Results: Empirical data demonstrated the safety and effectiveness of sericin-gelatin-glycerol complex as a printable hydrogel. Silk sericin aqueous solution has a characteristic of forming a gel as a structural change from a random coil to a beta sheet occurs. Gelatin has high water absorption capacity and non-immunogenicity and biodegradability. Gelatin is a solid at low temperatures and has poor mechanical properties. Sericin was mixed with gelatin rendering stability under physiological conditions. Richness of acidic amino acids in sericin and basic amino acids in gelatin can be utilized for stable bonding which gives structural integrity of the complex. Another component in the complex, glycerol acts as plasticizer that gives flexibility to sericin.
Conclusion: A novel sericin-hydrogel produced a photoinitiator-free bioink. In vitro and in vivo studies demonstrated the safety and effectiveness of sericin-hydrogel as a printable patch for wound healing dressing.

MICROTECHNOLOGIES AS ENABLING TOOLS FOR THE DEVELOPMENT OF ADVANCED ORGANS-ON-CHIP MODELS

Marco Rasponi[P][1], Roberta Visone[1], Erika Ferrari[1], Paola Occhetta[1]

[1] *Politecnico di Milano*

Corresponding author's email: marco.rasponi@polimi.it

Organs-on-chip (OoC) refer to microfluidic in vitro models recapitulating functions of human organs. OoC provide unprecedented opportunities to recreate tissue-specific microenvironments and to analyze functional readouts. We here present a series of innovative technologies specifically designed to enhance different OoC features (i.e. integration of mechanical stimulation, 3D interfaces and sensors).

The uBeat® technology allows to provide three-dimensional cell microconstructs with a controlled mechanical stimulation, which can be tuned to model different patho-physiological states and tissues. Human cardiomyocytes derived from induced pluripotent stem cells were subjected to a uniaxial strain, yielding to functional cardiac microtissues in a beating heart-on-chip model[1]. The same stimulation applied to co-cultures of cardiomyocytes and cardiac fibroblast generated either fibrotic or pro-fibrotic states[2]. A pure confined compression was instead applied to a human cartilage-on-chip model, demonstrating the possibility to trigger an osteoarthritic phenotype merely with mechanical overload[3].

A technology to obtain multicompartmental microtissues was developed to generate neat interfaces between different 3D cell microconstructs, achieving both continuous (osteochondral) and barrier (blood-brain barrier, BBB) models[4].

Blind-ended microfluidic channels were implemented as guides for the precise insertion of microelectrodes in OoC models. Applied to the beating heart-on-chip, this technology allowed the continuous recording of cardiac electrophysiological parameters[5]. Moreover, electrodes were used in a BBB model to assess barrier functionality via trans endothelial-epithelial resistance measurements[6].

Integration and combination of described technologies in OoC setups thus allows not only to faithfully recapitulate the physical native cell microenvironment, but also to improve their applicability in biological studies, disease modelling and drug screening.

FRONT-LINE APPLICATION OF NEGATIVE PRESSURE WOUND THERAPY (NPWT) AND NON-VIRAL GENE AUGMENTATION FOR ENHANCED HEALING OF COMBAT-ACQUIRED POLY-TRAUMA

James Dixon[P][1], Amelie Savers[1]

[1] *University of Nottingham*

Corresponding author's email: james.dixon@nottingham.ac.uk

Current combat casualty care is based on rapid evacuation, and 'golden hour' interventions aim to provide life and tissue saving therapies in austere environments. Negative-pressure wound therapy (NPWT) is extensively deployed and is under-explored as a delivery system for front-line therapeutics. Our work has exploited this unique opportunity to marry enhanced delivery of growth-factor gene therapy with the biomechanical stimulatory activities of NPWT; aiming to enhance vascularisation and inhibit negative inflammatory responses. The goal of our strategy, delivered by non-viral gene therapy, is to precondition traumatised tissue for subsequent surgery and to enhance tissue retention and healing. We are exploiting our peptide nanoparticle (NP) system (termed Glycosaminoglycan-binding enhanced transduction; GET) which can be freeze-dried, reconstituted and administered by injection. To test our technology we are exploiting ex-vivo culture of abdominal full-thickness porcine or human skin. In this model we wound skin and test the delivery and effectiveness of our systems. We have also modified clinically deployed NPWT systems to apply pressure to these samples looking for synergy. We have demonstrated reporter gene and multiple growth factor/cytokine expression, such as VEGF and PDGF to enhance vascularisation, and in combination with IL10 and IL1Ra as anti-inflammatory cytokines. The therapy can be reapplied and a single dose can generate therapeutic levels in wounds for at least 2 weeks. Our ultimate goal is that state-of-the-art genetic augmentation approaches can be exploited in austere environments, applying regenerative medicine to the front-line.

Survivors with severe tissue injury have unmet clinical needs for better bone and soft tissue regeneration. Specifically they have progressive tissue loss due to inflammation, necrosis, infection and the development of critical size bone defects is a surgical challenge. The Reamer/Irrigator/Aspirator (RIA) system is used to recover patient bone (and stem cells) for autografting in severe trauma & infections. Addition of growth-factors (GFs) can be transformative is such systems; however, their short-term activity requires expensive high doses with significant side effects. We have developed a simple system to express any therapeutic gene in cells and tissues, including GF genes. Our GET technology acts 'transiently' meaning therapeutic proteins such as GFs are produced directly by the 'transfected' tissue over a short therapeutic period. We have previously shown that GF gene therapy (BMP2/VEGF) in rat calvarial defects can enhance bone repair both safely and cheaply (Raftery et al. 2019). Here we have exploited the reserve of stem cells in bone marrow (BM) and grafts, and the GET system to augment stem cell activity by rapid genetic augmentation of BMP2 and VEGF genes with the aim to re-administer them to augment reconstructive surgery. We demonstrate the efficacy of the gene delivery approach and the enhancement of ex vivo osteogenesis by graft-expressed BMP2 and VEGF augmentation. By delivering genes that cause the resident cells at the defect site to produce regulated levels of GFs could be the transformative approach needed to allow safe and effective bone regeneration for treating many diseases or injuries.

Abstract **#1287**

RAPIDLY TRANSDUCING AND SPATIALLY LOCALIZED MAGNETOFECTION USING PEPTIDE-MEDIATED NON-VIRAL GENE DELIVERY

James Dixon[P][1], Lia Blokpoel Ferreras[1], Sze Yan Chan[2], Saul Vazquez Reina[2]

[1] *University of Nottingham*

Corresponding author's email: james.dixon@nottingham.ac.uk

Non-viral delivery systems are generally of low efficiency, which limit their use in gene therapy and editing applications. We previously developed a technology termed glycosaminoglycan (GAG)-binding enhanced transduction (GET) to efficiently deliver a variety of cargoes intracellularly; our system employs GAG-binding peptides which promote cell targeting, and cell penetrating peptides (CPPs) which enhance endocytotic cell internalization. Herein, we describe a further modification by combining gene delivery and magnetic targeting with the GET technology. We associated GET peptides, plasmid (p)DNA and iron oxide superparamagnetic nanoparticles (MNPs); allowing rapid and targeted application of GET-mediated uptake by application of static magnetic fields. This produced effective transfection levels with seconds to minutes of exposure, and localized gene delivery two orders of magnitude higher in targeted over non-targeted cell monolayers using magnetic fields. More importantly, high cell membrane targeting by FLR-DNA-MNP co-complexes and magnetic fields allowed further enhancement to endocytotic uptake, meaning that the nucleic acid cargo was rapidly internalized beyond that of GET complexes alone (FLR-DNA). Magnetofection combined with GET-mediated delivery allows magnetic field-guided local transfection in vitro, and could facilitate focused gene delivery for future regenerative and disease-targeted therapies in vivo.

Since 2010, over 2 million small incision lenticule extraction (SMILE) procedures have been performed. The number will gradually supersede the LASIK due to the flap-less nature and faster visual recovery. The byproduct of the procedure is a refractive lenticule, which can be reimplanted within the stroma to correct refractive errors (e.g., presbyopia) and restore corneal volume of keratoconus patients [1,2]. Nevertheless, standardization of cryopreservation and regulatory adherence has to be followed to improve the practicality and worldwide implementation of lenticule banking. Here, we showed a proof-of-concept of lenticule banking service, established by Cordlife in collaboration with our group. Human lenticules, collected from our clinic, were stored for 1 year in DMEM+10% DMSO cryoprotectant in vapor-phase liquid nitrogen in Cordlife's cryofacility. After cryopreservation, the tissue transparency appeared reduced from 95% (fresh) to 90% due to the reduction in collagen fibrillar distance from 63.5±5.4 nm to 50.3±4.6 nm ($p<0.001$). The central 3mm of the thawed lenticules was trephined and implanted in 3 rabbits' stromal pockets for 4 months (steroids and antibiotics were withdrawn after 2 months). On the slit-lamp and in vivo confocal microscope, the lenticules appeared hazy for the first 4 weeks but resolved subsequently. The surrounding tissue, however, was clear. The corneal epithelial, stromal, and endothelial cells were unaffected by the implantation. Immunohistochemistry of the corneas revealed no fibrosis (fibronectin, CD90, and α-smooth muscle actin negative) but mild tissue reparation (tenascin-C and COL3A1) at the lenticular edge. In summary, we have demonstrated the feasibility and safety of long-term lenticule banking.

The epidermis is a multi-layered epithelium that consists mainly of keratinocytes which proliferate in its basal layer and then differentiate to form the stratum corneum. During differentiation keratinocyte composition, function and metabolism changee. Stressors, like ultraviolet (UV) radiation thus differently affect epidermal keratinocytes, depending on differentiation stage. Exposure to UV elicits DNA damage responses, detoxification, repair or death. Rapid diversion of glucose flux into the pentose phosphate pathway (PPP) is a mechanism to rapidly generate reduction equivalents and nucleotide precursors – after UV damage. There is little known about the correlation of such metabolic activity with differentiation state, cell damage and tissue localization of epidermal cells. We developed a method to correlate the activity of glucose-6-phosphate dehydrogenase (G6PD), the first and rate-limiting enzyme of this metabolic UV response, at cellular resolution to cell type, differentiation state and cell damage in human skin and in organotypic skin equivalents (SE). We thereby could verify rapid activation of G6PD as an immediate UVB response not only in basal but also in differentiating epidermal keratinocytes and found increased activity in cells which initiated DNA damage responses. UVB treatment of keratinocytes before organotypic culture led to abnormal distribution in the SE and reduced G6PD activity compared to neighboring cells. Finally, we found that the anti-diabetic and potential anti-aging drug metformin strongly induced G6PD activity throughout the SE. PPP activation may be useful to enhance the skin's antioxidant defense systems and DNA damage repair capacity on demand.

Nowadays, peripheral nerve injuries leading to acute disabilities still constitute a major clinical burden. Typical surgical procedures such as direct repair or autografting approaches are often limited by the nerve gap size and/or by several drawbacks. As an alternative, nerve guidance conduits (NGCs) comprised of biodegradable polymers have been tissue-engineered to guide axons and enhance nerve regeneration. Nonetheless, most of the developed NGCs do not concurrently possess both topographical and biochemical cues that recapitulate the properties of the extracellular matrix. Thus, good results in treating only small defects were achieved. Therefore, in order to repair critical nerve gaps, NGCs with advanced physicochemical properties are aimed at. To do so, electrospinning is employed to generate an NGC made of polycaprolactone/polylactic-co-glycolic acid with outer and inner walls composed of random and highly aligned nanofibers respectively. This design guiding axon growth (aligned fibers) while permitting nutrient supply (random fibers) is obtained in a one-step process using an innovative 2-pole air gap collector. In order to reach and bioactivate the inner NGC wall without damaging the nanofibers, a novel surface plasma treatment is performed making use of a purposely designed plasma reactor consisting of a hollow cathode discharge sustained in O2. X-ray photoelectron spectroscopy results reveal a successful incorporation of oxygen-containing functionalities on the inner wall thus enhancing its hydrophilicity. An extensive in vitro study involving PC12 cells shows greatly improved cell adhesion, proliferation and extension of unidirectional long neurites on plasma-treated NGCs. Overall, the proposed NGCs demonstrate great potential in nerve regeneration.

Adhesion between intrafollicular stem cells (IFSCs) is established by the formation of specific disc-like (200-500 nm in diameter) cellular junctional complexes including desmosomes. The desmosomal cell-cell attachments, especially in mechanically challenged tissue such as epidermis, are composed of two types of cadherins, desmocollins (DSC) and desmogleins (DSG). Of the DSG's, DSG2 is expressed only in the basal epidermal layer. Regarding the dynamic structure of desmosomal junctions, other cell-cell adhesion may also play a role during assembly. The initial cell-cell binding through adherence junctions (via E-cadherin) may facilitate assembly of immature desmosome junctions and finally lead to the development of mature desmosomes via DSG-DSC heterobinding. However, their combinatorial roles in desmosome assembly and cell behavior are not well understood in the epidermis layer.

In this work, nanopatterns of DSG2 and Ecad are created as mimics of the cellular interface and used to study the formation of desmosomal assemblies in adherent IFSC cells. Nanoscale engineering was used to create an inorganic chemical pattern which was used to assemble oriented Dsg2 Fc or Ecad Fc into created arrays of circular nanopatterns of the Dsg 2 Fc, Ecad Fc or their combination (50:50) with lateral size of 100, 300 or 500 nm. Between the protein nanopatterns, cell adhesion studies show that IFSCs adhere to the Dsg2Fc and EcadFc patterns and start differentiation or remain undifferentiated status under different conditions. The preliminary results show that the size of nanopatterned with desmosomal and adherence cadherins separately or together alter desmosomal formation.

Hair regenerative medicine has emerged as a promising approach for the treatment of hair loss. Considering the embryonic development of hair follicles is triggered by the formation of a hair follicle germ (HFG), we have proposed an in vitro preparation approach of HFGs and demonstrated efficient hair follicle generation upon transplantation into mice[1]. However, this approach is still challenging mainly because follicular stem cells (i.e., dermal papilla cells (DPCs)) tend to lose their hair-inductive capacity during subculture in traditional 2D expansion culture conditions[2]. In this study, we propose an approach to restore the hair-inductive capacity of human DPCs using collagen microgels in the HFG preparetion[3]. DPCs were encapsulated in 2-µl collagen microgels, which spontaneously contracted from 2 mm diameter to less than 700 µm during three days of culture though cell attraction forces. This phenomenon is probably similar processes observed in the earliest morphogenesis of hair follicle generation. Interestingly, this contraction was crucial for upregulating hair-induction markers including alkaline phosphatase gene of DPCs. The collagen microgels containing DPCs prepared in this approach were mixed with freshly isolated mouse embryonic epithelial cells and formed HFGs. De novo hair follicle and hair shaft generation were observed after transplantation of the HFGs into the backs of nude mice. This could be a practical approach to restore the hair-inductive capacity of DPCs for hair regenerative medicine.

Native tissues are highly organized structures, with an intricate cellular microenvironment. They are non-homogeneous and typically exhibit functional gradients in their architecture and composition over very small length-scales. Therefore, their regeneration is extremely difficult, and it is still a major challenge to produce biomimetic scaffolds using traditional manufacturing processes.

In our study, we propose to employ an emerging biofabrication technique: Melt Electrowriting (MEW), to more closely reproduce the complexity of native tissues. MEW, combining the fundamental principles of electrospinning and 3D printing, allows for precise control over material placement and high printing resolution. As a result, scaffold's morphology can be controlled at both macro and micro levels. We show that by finely tuning scaffolds design and controlling their structure, systems with mechanical and biological performance relevant for different tissues can be obtained. Particularly, we present the utility of MEW for reconstruction of the Human Trabecular Meshwork (membrane located in the eye), hard-soft interfaces and skin tissue.

We envision that the small-scale biomimetic scaffolds printed with high precision will serve in the future as implantable systems or an in-vitro more adequate testing models.

Gelatin has the intended biological properties resembling the native skin and potentially fabricated as skin substitute for full thickness wound treatment. This study aimed to fabricate and characterise the certified halal bovine gelatin using various crosslinking method. Porous gelatin sponge was fabricated by the freeze-drying approach. Crosslinking of gelatin sponge was completely performed via chemical or physical intervention by using genipin (GNP), 1-ethyl-3-(3-dimethylaminopropyl) (EDC), or dihydrothermal (DHT) method, respectively. The physicochemical, biomechanical, cellular biocompatibility and cell-biomaterial interaction with the fabricated gelatin sponge were evaluated. Increase in concentration and double croslinking, gradually increase crosslinking degree, enzymatic hydrolysis resistance, thermal stability, porosity, wettability, and mechanical strength were observed. However, the pore size, water retention, and water absorption ability were found decreasing trend. No changes in chemical content and crystal structure were observed. Human epidermal keratinocytes (HEK) and human dermal fibroblasts (HDF) revealed slight toxicity with double crosslinking. HEK and HDF attachment and proliferation remain similar with each crosslinking approaches. Immunogenicity was observed to be higher in double-crosslinking compared to the single crosslinking intervention. The selected crosslink gelatin sponge showed potential to be tailored according to a precise need of wound healing process by manipulating the crosslinking process.

In modern implant development, researchers focus on the enhancement of both biocompatibility and reproducibility. Even though cardiovascular implants are commonly used, they only have a limited lifetime which also affects their properties and functionality. Many research activities face the optimisation of implant properties. Formation of blood clots in mechanical implants (heart valves), bacterial biofilms (dental implants) or the degradation of bioprotheses should be prevented. In addition, the organ implant may still be rejected by the patient's body.

The aim of this work is the synthesis of a biohybrid heart valve consisting of a fibrin-based gel-matrix with a textile reinforcement. We could already demonstrate that the concentration of a linear poly(N-vinylpyrrolidone)-copolymer with functional epoxide groups has an influence on the mechanical behaviour of the hydrogel due to covalent crosslinking. Specific fibrin-binding peptides exhibit supramolecular interactions within the fibrin-matrix. Their influence on the mechanical properties of the fibrin-based hydrogels can be characterized by rheological measurements. The use of both, covalent and supramolecular crosslinkers, expand our innovative functional tool-box for fibrin-based biohybrid hydrogels for the patient-specific individualisation of implants. The hydrogel serves as an attractive environment for human stem cells. Experiments demonstrate that the use of copolymers have a high impact on the hydrogels' properties and their long-term stability. For the characterization various concentrations of fibrin-binding peptides and copolymer have been used. Future experiments will deal with the analysis of the cytocompatibility of the fibrin-binding peptides. Furthermore, the adhesion of the hydrogels on various substrates will be tested.

Tissues in the joint express a large amount of extracellular matrix (ECM) which interferes with transfecting agents. Current methods do not result in a satisfactory transfection of ECM-rich tissue. Biodegradable and bioresponsive polymer-based nanoparticles (Nanogel, 20Med Therapeutics) can be used as an oligonucleotide delivery technology and be optimized for transfection of specific cells. This makes it a promising candidate for in vivo delivery of therapeutic mRNA drugs. In this study, different transfection methods were evaluated in vitro for different cell types present in the synovial joint. Methods: Different concentrations of the Nanogel agent were tested besides Lipofectamine and NEON electroporation. Experiments were performed in monolayer culture on primary human bone marrow cells (hBMSC), human synovial stem cells (hSDSC), bovine chondrocytes (bCH), rat tendon stem/progenitor cells (rTDSPC). mRNAs were provided by Ethris GmbH. Successful transfection resulted in the translation of the respective fluorescent protein, which was evaluated by confocal microscopy and flow cytometry. Metabolic activity with AlamarBlue was performed after 24, 48, 72 and 96 hours. Results: Nanogel exposure did not affect cell viability as compared to lipofectamine and electroporation; however, the transfection efficiency varied based on the cell type. BMSCs and rTDSPC showed high protein expression for all the methods; on the contrary, bCH and hSDSC transfected with 30 µg/ml Nanogel and 480 ng mRNA showed a lower intensity in protein expression. Conclusions: Nanogel transfection proved successful for various cell types present in the joint and may be a promising method for tissues that exhibit a complex dense matrix.

Extracellular vesicles (EVs) have been used for tissue regeneration in multiple contexts. However, their naïve potential may not be sufficient for clinical application (1). Here we investigate how to load small EVs with therapeutically active microRNAs. Different methodologies for loading EVs were tested (i.e., electroporation, saponin, cholesterol, freeze-thaw and Exo-Fect™) and, using a fluorescently-labelled microRNA, we showed that ExoFect™ was superior to the other methods (~83% transfection efficiency). The internalization kinetics of the modified EVs was evaluated using endothelial cells (ECs) and their bioactivity was evaluated, in vitro, using a reporter cell line for the presence of the exogenously loaded microRNA (2). Subsequently, sEVs were loaded with a miRNA capable of enhancing the survival of EC (identified using high-content screening) and topically administered, twice a day for 10 days, on wounds of STZ-induced diabetic mice. Our results showed that microRNA-loaded EVs were able to improve wound healing in diabetic mice. Importantly, analysis of wound tissue revealed increased expression of the delivered microRNA into the affected area and enhanced survival of ECs. In conclusion, we showed that Exo-Fect™ is an efficient and functional way of loading microRNAs into EVs. Furthermore, modulated EVs can be used in vitro and in vivo as effective delivery agents.

Scaffolds that promote and sustain neuronal orientation and interconnectivity are of critical importance in regenerative strategies for the central and peripheral nervous systems. The biofabrication of scaffolds from materials with tuneable mechanical and physicochemical characteristics have the potential to mimic the microcellular 3D environment of native neuronal tissue [1]. Laser-based technologies have been applied in photoresponsive hydrogels to spatially tailor the aforementioned properties for a multitude of cell and tissue engineering applitactions [2]. In this study, a photocrosslinkable gelatin formulation was developed, with the aim to create an extracellular matrix mimetic construct with highly controlled spatiotemporal crosslinking properties [3]. By incorporating different moieties onto the free amines of the gelatin backbone, a bi-modular crosslinking mechanism was developed, resulting in a photoresponsive gel formulation capable of generating hydrogels with different degrees of stiffness through exposure with UV light. Furthermore, a femtosecond pulsed infrared laser was used in the presence of a biocompatible two-photon initiator [4] to induce microscale selective photodegradation/crosslinking of specific hydrogel regions. By creating 3D gelatin scaffolds possessing localised microscale regions of degradation/crosslinking, it was possible to initiate contact guidance induce neural cell alignment in a 3D hydrogel. In conclusion, we hypothesise that these physicomechanically patterned hydrogels can be used to fabricate tissue engineered neural conduits with selective spatial guidance.

In this study, we proposed a self-healing injectable HA-pAA hydrogel integrated system with in-situ gelling, and semi-permanent for delivering cells engrafted with multifunctional porous PLGA magnetic microcarriers (PPMMs) was proposed for repairing articular cartilage tissue. The self-healing injectable HA-pAA hydrogel was synthesized through the mechanism of guest-host interaction using HA-cyclodextrin (CD) as host polymer and poly (acrylic acid)-ferrocene (pAA-Fc) as guest polymer. Owing to high specific surface ratio of porous structure, PPMMs could be loaded with 75.1% of GSH as reductant to improve anti-oxidation and anti-inflammatory ability as well as to induce hydrogels self-healing ability when suffering damage. Furthermore, the PPMMs with iron oxide nanoparticles loading and HA coating could bind with chondrocytes by CD44 binding site and magnetically chondrocytes were guided to damaged site through external magnetic force. The results showed that the PPMMs owing to its high specific surface ratio and stable sustained release within 24 hours. According to the rheological analysis, pAA-Fc with r = 4.0 could react with HA-CD to form an injectable self-healing hydrogel with a higher mechanical strength than other conditions. HA-pAA composite hydrogel could control the GSH release to achieve the various degree of self- healing and self-heal rapidly within 24 h when suffered external destruction. The chondrocytes encapsulated in the HA-pAA complex hydrogel could be guided by PPMMs to a specific injured place by magnetic guidance. The above-mentioned results demonstrate the application of self-healing injectable HA-pAA hydrogel integrated system is highly promising in cartilage tissue repair.

As their name suggests, endocrine disruptors (ED's) are a class of chemicals able to interfere with the activity of the endocrine system. To date the effects of ED's on the transcriptome and proteome of the thyroid gland has not been extensively investigated and as a consequence data in public repositories are very scarce. In this study, we analyzed the transcriptome and proteome of human thyroid follicular epithelial cells, Nthy-ori 3-1, following exposure to several compounds representing different classes of ED's. The cytotoxicity of the ED's was also evaluated. Bis(2-ethylhexyl) phthalate (DEHP) was the selected compound for phthalates, triphenyl phosphate (TPP) for organophosphate flame retardants (OFR's), benzo[a]pyrene (B[a]P) for polycyclic aromatic hydrocarbons (PAH's), PCB-118 and PCB-153 for polychlorinated biphenyls (PCB's). None of the compounds resulted in a cytotoxic response at the concentrations tested after an exposure of 24, 48 and 72 hours. To generate a novel and comprehensive molecular picture of the impact of ED's on thyroid cells, RNA-sequencing (RNA-Seq) and liquid chromatography-tandem mass spectrometry (LC-MS/MS) were employed for the deep analysis of the transcriptome and proteome, respectively, following a 24 hours' exposure of Nthy-ori 3-1 cells to ED's. RNA-Seq analysis was performed using Combo-Seq, a method to capture and quantify both mRNA and microRNA from the same samples libraries. The latest results of this proteogenomics study will be presented.

Mesenchymal stem cells (MSCs) could participate in cartilage repair by direct differentiation to chondrogenic cells, or through the secretion of a plethoria of trophic factors, exerting paracrine function to the surrounding cells. MSCs are "environmentally responsive" to local micro-environmental cues and biophysical perturbations, including pulse electromagnetic field (PEMF) exposure. In this study, using an in-house designed PEMF delivery system producing precise magnetic field of low intensity and frequency, we demonstrate both augmentation of MSC chondrogenesis and secretome paracrine function by PEMF exposure. PEMF inductive effect are exquisitely dependent on the pulsing intensity and duration as well as the MSC culture platform (scaffold free pellet culture, hydrogel or fibrous scaffold culture). We further shown that PEMF directionality over the chondrogenic differentiation of MSCs laden on electrospun fibrous scaffolds of either random (RND) or aligned (ALN) orientations was governed by the interaction between magnetic field orientation and the cell micromechanical environment at the level of mitochondrial respiration. Further, PEMF-induced MSC secretome was capable of enhancing the migration of chondrocytes and MSCs as well as mitigating cellular inflammation and apoptosis. We provide evidence that brief exposure to low amplitude PEMFs enhanced the ability of MSCs differentiation, as well as secretory factors production capable of promoting cartilage regeneration as well as protecting against adverse inflammatory conditions. Collectively, our results indicate that PEMF stimulation could have broad clinical and practical ramifications for the enhancement and re-establishment of cartilage regeneration.

The reduced radial compliance of synthetic grafts, with respect to native vessels, is considered one of their major causes of failure, especially in case of small diameter (D≤6mm). To address this issue, a novel semi-degradable three-layered vascular graft, composed of a blend of silk fibroin and polyurethane (Silkothane®) and manufactured by electrospinning, was previously developed and characterized (D≥6mm) [1-3]. The current study explores the possibility to employ such technology in the development of compliance-calibrated smaller prostheses (D~1.5mm). To this purpose, two clusters of grafts were electrospun: a stiffer one, composed of silk fibroin only (SF), and a more compliant one, enclosing a Silkothane® core (SF/PU). Their radial compliance was measured by means of a stereo microscope (Nikon, SMZ1000) equipped with a digital camera (Fire-I, UniBrain), evaluating the dimensional variation with respect to the applied pressure; three pressure ranges (50-90, 80-120 and 110-150 mmHg) were considered, according to ISO 7198 (Section A.5.9) [4]. SF grafts displayed compliance of approx. 1%/100mmHg, while SF/PU grafts around 2.5%/100mmHg. An in vivo evaluation is currently ongoing in a rodent model (rats), to verify whether differences in graft compliance determine different performances in terms of patency (presence of flow monitored by echo-doppler), platelet activation (evaluated via Platelet Activity State - PAS - assay), neointima formation and endothelialization (evaluated via histologic analyses).Two implantation sites (abdominal aorta and femoral arteriovenous shunt) and two explant time points (30 and 90 days) are being considered. Preliminary results are encouraging, since all implanted animals survived with blood flow inside the grafts.

Keywords

Hybrid vascular grafts; Compliance; Silk fibroin

ENGINEERING PREVASCULARIZED COLLAGEN-BASED HYDROGEL TO ACCELERATE REGENERATIVE REPAIR OF VOLUMETRIC MUSCLE LOSS INJURY

Ting-Lun Hsu[P][1], Wei-Lin Chen[1], Shih-Yen Wei[1], Ying-Chieh Chen[1]

[1] *Department of Materials Science and Engineering, Tsing Hua University, Taiwan*

Corresponding author's email: whu930029@gmail.com

Volumetric muscle loss (VML) resulted from accidents or surgery, is associated with the irreversible loss of the muscle mass and function. In VML, the destroyed basal lamina resulted in the muscle cannot regrow without sufficient blood supplied by host vasculatures, even if skeleton muscle has an innate repair mechanism through activating satellite cells induced by the basal laminae and connective tissue. This leads to infiltrating fibroblasts dominate the regeneration, forming the functional scar tissue with mostly fibrosis, rather than muscle fiber regeneration.

Here, we aimed to develop collagen-based hydrogel that can tune a wide range of physicochemical properties to control engineered vascular network formation in vivo. Human umbilical vein endothelial cells (HUVECs) and mesenchymal stem cells (MSCs) laden hydrogels were implanted into subcutaneous space in nude mice to prepare high, intermediate and low degrees of cell-mediated prevascularized constructs by tailoring the crosslink degrees . After 7 days, the prevascularized tissue was implanted into the left rectus femoris muscle injury of mouse. After 1-month, large portion of repaired muscle with larger muscle fibers were well distributed at the injury site in the high prevascularized group. In contrast, more fibrosis and small muscle fibers were found in the intermediate and low prevascularized. Furthermore, to understand and highlight the importance of prevascularization, non-prevascularized cell-laden hydrogels were formed directly at the injury site. The results highlighted that prevascularized tissues accelerated muscle fiber repair through timely supply enough blood supply by pre-engineered blood vessels and avoided host fibroblasts invading, which assisted the repairment of VML.

Impaired vision can affect a person's independence, education, employment, socio-economic status. As estimated by the World Health Organization (WHO), approx 1.3 billion people around the world are living with vision impairment. Corneal opacity is a leading cause of sight impairment worldwide, which results from scar formation due to infections from bacteria, fungi, viruses and protozoa or chemical injury or other accidental injuries. There have been few attempts to develop artificial corneal using both cell-based and matrix-based approaches; however, they have their own limitations. Recently, a few groups have tried to bioprint the corneal stroma; however, their corneal tissue regeneration potential is yet to demonstrate. We bioprinted corneal stroma and epithelium with decellularized cornea matrix (DCM) hydrogel that was developed by a novel protocol capable of preserving key ECM components while eliminating the maximum cellular contents. We also show the functionality of our bioprinted cornea tissue using various in vitro cellular assays and observed high cell viability, cellular migration, and maintenance of keratocyte morphology and function. We observe higher-order assembly of these cellular constructs with organized spatial patterns and tissue-specific gene expression. The most striking feature of the DCM hydrogel is its ability to prevent corneal scar tissue formation. The bioprinted cornea with DCM hydrogel has extraordinary translation potential for different corneal pathologies including traumatic injuries, subsequent scar formation, and even for regenerating entire cornea and thereby may eliminate the current dependency on the corneal donor tissue.

The development of a novel flexible tissue engineering bioreactor requires optimal design and operating parameters. Initial uniform cell distribution is an important prerequisite as underpopulated areas can be a result of poor cell suspension but also nutrient deprivation and unsuccessful bioreactor design. Furthermore, cell distribution throughout the scaffold is often a design requirement of tissue-engineering products. To achieve even cell distribution, three seeding methods were tested for seeding efficiency. Several repeats of 3cm long electrospun PCL scaffolds were propped into three custom built stages and subsequently seeded with human hamstring cells, one with the scaffold filaments aligned along gravity, one aligned perpendicular to gravity, and one moved onto a rocking plate immediately after seeding. Cells were left to attach for 1 hr and subsequently fixed in 2.5% glutaraldehyde. Cell distribution was assessed using Osmium Tetraoxide stain and micro-CT analysis. Images were analysed using the Fiji 3D-Object counter to visualize cells above the threshold. Quantitative results were binned and plotted in a frequency distribution and heat map. SEM and Elemental x-ray analysis were used to confirm the findings. Results showed that cells readily adhere to the scaffold material and that seeding cells in a dynamic fashion greatly improved even cell distribution. The method of assessing this is a needed alternative for large tissue constructs as cryo-sectioning on large scale is time consuming and scaffold materials do not always withstand processing.

Objectives.This work aimed to develop a culture model of primary skeletal muscle cells obtained from human muscle biopsies.Material and methods.Muscle biopsies were taken post-mortem from the vastus lateralis. The biopsies were enzymatically digested. Then, the satellite cells were purified by two methods: pre-plating or immunomagnetic cell sorting using an anti-CD56 antibody. The performance of these cell purification methods was evaluated by FACS. We also compared two proliferation media (10%FBS vs. 10%FBS + 2%Ultroser G (UG)) on the cell doubling time. Finally, we studied the expression of several muscle cell markers during myogenesis by qRT-PCR and immunofluorescence.Results.The cells obtained from the digestion of the biopsy contained varying proportions of CD56+ satellite cells (83.79 ± 11.88%). The immunomagnetic cell sorting method enable a higher enrichment with CD56+ satellite cells (95.59 ± 3.36%) than the pre-plating method (81.29 ± 7.76%). The proliferation media containing 10%FBS and 2%UG allowed to obtain a significantly shorter doubling time and than the proliferation medium containing only 10%FBS (25.46±4.9h vs. 70.19±22.9h, p=0.0286). Finally, the increase in MyoD1, myogenin and MYH demonstrated the phenotypic transition of our cells to a myogenic phenotype.Discussion.Immunomagnetic cell sorting allowed a better satellite cells purification than the conventionally preplating technique. UG serum substitute accelerated cell proliferation and improved the differentiation of myoblasts into myotubes. Conclusion.This culture model of human primary skeletal muscle cells could be helpful for the screening and the study of the mechanisms of action of compounds developed to treat muscle diseases like sarcopenia.

Corresponding author's email: tim1013.eed03@g2.nctu.edu.tw

Inhalation of particle matters (PMs) is the major route of PMs exposure and has led to adverse effects on the lung. It is of vast concern to evaluate the potential risks of PMs for human health during lung exposure. Here, we developed a human lung-on-a-chip integrating a newly aerosol exposure system to recreate the organ-level structure and functions of the human lung that allow us to assess the pulmonary toxicity of PMs under physiological respiratory airflow conditions in vitro. This novel lung-on-chip exposure platform was designed to connect up to 16 lung-on-chips and mimicked the range of flow rate of the human lung microenvironment. It cyclically inhaled microliter volumes of air through the upper epithelium-lined channel of the lung-on-chips with a programmable pump machine to regulate breathing behavioral parameters, including breathing frequency, and the inhalation duration, interval, and volume per channel, according to the expected values of human pulmonary. Furthermore, an aerosol generator exposed PMs into epithelial channels to observed the interaction of particles with critical cellular barrier functions at an air-liquid interface and assess the toxicity. Our biochip exposure systems not only highlight the prospects of realistic in vitro exposure tests in recapitulating typical local in vivo deposition results but also provide opportunities for advanced in vitro exposure tests for safety assessment for toxicity of particles, preclinical cytotoxicity, and drug screening applications.

Chronic Obstructive Pulmonary Disease (COPD) is an irreversible obstructive airway disease which is the third leading cause of death in the world. The possible causes are smoking, air pollution or industrial dust and chemicals. However, there is still no accurate prognosis, diagnosis and treatment strategy for COPD. Therefore, in vitro Establishing disease models with functions similar to the human body has become important. This research focuses on establishing an in vitro model of human small airway epithelium and remodeling human physiological behaviors, and found that the accumulation of LC3B nuclear import in COPD in the small airway play an important role in the differentiation model of cilia and mucous cells. In this study not only uses clinical drugs to regulate LC3B nuclear metastasis to improve the effect of COPD cilia differentiation also combine the high-throughput screening to analyze the lung function and drug responses. We found that Chloroquine (CQ) and Ivermectin (IVM) can be the treatment strategy for repairing cilia damage and mucus accumulation in COPD patients, and find the potential for analysis and treatment of COPD. On the other parts, we try to apply organ chip technology to reproduce the microenvironment of the small airways and bronchial tubes of the lungs to achieve personalized precision medicine.

Currently there are no good off-the-shelf solutions available for small diameter vascular applications due to limited patency of conventional synthetic grafts. Therefore, patients need to rely on their own veins, which are painfully harvested, mostly from the leg. A restorative graft, designed to be permeated by and replaced with the patient's own tissue through Endogenous Tissue Restoration (ETR) may help overcome current limitations. The ideal graft allows cellular infiltration leading to formation of functional neotissue, while the implant gradually absorbs. However, despite massive efforts in investigating new materials, up to date no restorative vascular graft is clinically available. Thus, there is an increasing demand for a better understanding of the mechanisms that direct graft regeneration or failure and for potential in situ tools to monitor these parameters.

The aim of this study was to investigate vascular remodeling processes in a restorative polymeric graft after 6 and 12 months implantation in a sheep carotid interposition model. Molecular and structural changes in biomaterial and tissue structures of the newly formed neointima were assessed by marker-independent and molecular-sensitive Raman microspectroscopy and imaging combined with multivariate analysis tools. In vivo polymer degradation was further compared to an in vitro degradation assay mimicking oxidative degradation. The biomaterial spectra revealed specific peaks that changed upon implantation duration and could be assigned to degradative processes originating from reactive oxygen species (ROS) present in the tissue. Imaging of the neointima allowed to identify and localize different extracellular matrix structures and determine the tissue maturation based on collagen I.

Skin is the largest organ of every mammal and protects against sources of danger like hypothermia or dehydration. Skin defects are often caused by soft tissue trauma, burns, or surgical resections. Consequently, treatment efforts are aimed at restoring skin integrity on the one hand. Nevertheless, reconstruction of the underlying connective tissue is important for a full functionality of the tissue as well, on the other hand.

Therefore, new technologies are under investigation, allowing for the de novo engineering of connective tissue and skin within the patient's body. The arterio-venous (AV) loop technique represents one such promising approach. To this end, a vascular loop is generated microsurgically, placed inside a Teflon chamber, accompanied by a decellularized matrix, and subsequently implanted under the patient's skin for three to four weeks.

In the present study, we investigated new stereolithographic strategies to print patient tailored chambers. These newly designed chambers can help address several new properties: their geometry is tailored to the individual implantation site of the patient and their material is more elastic allowing for more comfort during the cultivation phase.

We investigated new classes of photopolymers, which are more elastic than Teflon and can be photo crosslinked. We tested them for their biocompatibility using 3T3-fibroblast cell culture and optimized the crosslinking protocols of the polymer using FTIR-analysis and improved the respective washing protocols. Furthermore, their mechanical properties and sewability are important for fixation of the chamber during the time of cultivation. Therefore, simple mechanical tests have been carried out.

The aim of the study was to investigate GelMA/alginate hydrogels blends for bioprinting of smooth muscle cells (SMCs). Our long-term goal is to engineer a platform to study the mechanisms that control the maturation of SMCs in the muscular layer of the urethra. Four hydrogel blends were prepared by mixing different concentrations (in %w/v) of GelMA/alginate: G1(5/1.5), G2(5/3), G3(7.5/1.5), G4(7.5/3). GelMA (10%) was used as control. The mechanical properties of the hydrogels, before and after crosslinking, were measured by rheometry. Ring-shaped constructs containing human bladder smooth muscle cells were fabricated using an extrusion-based printer. Following bioprinting, live/dead and metabolic assays were used to evaluate cell viability and proliferation. Rheometry analysis revealed that, in contrast to pure GelMA, addition of alginate significantly stabilized the variation in mechanical properties against changes in the temperature. The groups containing highest GelMA concentrations (G3, G4) displayed the largest viscosity, which, after crosslinking, resulted in constructs showing higher stability and lower swelling over time. The viability of the SMCs remained above 80% and was not significantly affected by the blend type. In all groups, cells adopted a spindle-like morphology and displayed a similar growth rate over a 5-day period. Overall, groups G3 and G4 appeared to offer better printability without compromising cell viability and growth. Although the optimal mechanical properties of the blends in terms of supporting optimal SMCs maturation still needs to be determined, the results of this work suggest that GelMA/alginate hydrogels constitute versatile and tunable hydrogels for smooth muscle tissue engineering.

The biofunctionalization of otherwise essentially inert materials is usually done using linear adhesion peptides that partially lose their conformation upon binding, hence bioactivity, and without integrin specificity. In this work we addressed this issue and developed a gellan gum (GG) hydrogel modified with integrin-selective mimetics, aiming applying it as a promoter of the revascularization of spinal cord tissue following injury by locally implantating it with encapsulated ASCs and HUVECs. Indeed, faulting vascular repopulation is a key hallmark of spinal cord injury and decisively contributes to the poor prognosis associated to the condition.

Initially, different reaction stoichiometries were tested and characterized by varying the polymer:ligand ratio and the bioactivity of each condition tested and compared with GG functionalized with RGD employing the same ratios. The polymer grafted with the mimetic ligand in a certain ratio significantly promoted the adhesion of ASCs both at 3 and 7 days of culture. The same was observed even when reducing the GG:RGD ratio, proving that increased ligand specificity leads to enhanced bioactivity. The neurite extension from DRG explants was increased when combining the mimetic-functionalized hydrogel with cells (ASCs or ASCs+HUVECs). Preliminary in vivo data in a spinal cord injury transection rat model shows that the combination of modified GG and cells leads to a significant motor recovery, as well as to the decrease in pro-inflammatory serum markers during the acute phase of the condition. We show for the first time the potential of using integrin-selective ligands to enhance the bioactivity of hydrogels for CNS applications.

The microenvironment where cells reside provides them with a range of cues that collectively affect their fate. These include biochemical cues, mediated by interactions with the extracellular matrix (via integrins) and between cells (via cadherins), and physical properties, such as stiffness and viscosity. While the effect of stiffness on cell fate has been widely studied, the role of viscosity has been only recently addressed (1). In our group, we demonstrated that cells sense viscosity using the same mechanotransductive mechanisms that they use for stiffness (2). Here, we investigate the role of viscous interactions in controlling stem cell fate. We designed mobile surfaces based on supported lipid bilayers of controlled viscosity, which target the adhesive crosstalk between integrins (RGD receptors) and cadherins (HAVDI-containing proteins) (3).
Using human mesenchymal stem cells, we observed an increase in cell adhesion and a decrease in actin flow when the viscosity of the surface and the concentration of RGD increased. When HAVDI was added to the surface, cell adhesion was reduced, while the actin flow increased. These changes provoked alterations in the activation of mechanotransductive pathways: the nuclear translocation of mechanosensitive YAP increased with viscosity and decreased with HAVDI ligation. Finally, early differentiation markers were differentially expressed, revealing an effect of viscosity on cell fate: while more mobile surfaces favored adipogenesis and HAVDI ligation on them triggered chondrogenesis, more viscous substrates promoted osteogenesis. Further investigations on the signaling pathways involved will allow to establish a paradigm to collectively understand and exploit cell response to viscous interactions.

There is an urgent need to explore disease-modifying drugs for osteoarthritis (OA). Six small molecules (RCGD-423, Wogonin, XAV-939, Zingerone, THSG, and Paeonol) were thoroughly evaluated for their anabolic and anti-inflammation effects on 3D pellets of human OA chondrocytes in vitro.

3D pellets of human OA chondrocytes were cultured in chondrogenic medium for 7 days to generate cartilage tissue followed by small molecule treatment for 3 days within chondropermissive medium supplemented with 1 ng/mL IL-1β + 1 ng/mL TNF-α [1]. Compared with IL-1β+TNF-α group, Zingerone and Paeonol down-regulated MMP3 gene expression. Paeonol, XAV, THSG, and Wogonin up-regulated COL2 and ACAN gene expression. Wogonin, XAV, RCGD, Zingerone, and THSG down-regulated expression ratio of inflammatory/anti-inflammatory genes IL6/IL10 and IL8/IL10. At protein level, Zingerone, Wogonin, and XAV down-regulated IL-8 expression; RCGD up-regulated IL-10 expression. Compared with the pellets cultured in chondrogenic medium, pellets from the inflammatory model group did not show proteoglycan staining in extracellular matrix. Paeonol, Wogonin and XAV enhanced proteoglycan accumulation in pellets. To summarize all the factors evaluated, XAV and Wogonin showed the most pronounced anti-inflammatory and regenerative effect, as indicated by the highest positive effect factor numbers.

Human OA femoral heads were used to isolate osteochondral explants from the non-load bearing part. With the stimulation of IL-1β+TNF-α at different doses, a pro-inflammatory and catabolic effect was induced to mimic the OA condition. Explant OA models will be used to further evaluate the anti-inflammatory and regenerative effects of the most promising compounds ex vivo.

Corneal diseases accounted for approximately 1,500,000 cases of blindness worldwide in 2015 (1). Yet whilst effective treatments are available, a key limitation is the availability of good quality epithelial cells that in vivo derive from the stem cell compartment, the limbus. Characterising the limbal niche is crucial for enabling the translation of novel therapies, but traditionally, this research uses primary mammalian corneal tissue due to the lack of a commercially available in vitro alternative.We have therefore developed a novel hanging drop spheroid model of the rabbit limbal cornea by surrounding stromal keratocyte (SK) cores with an envelope of limbal epithelial cells (LECs). Over 10 days, models were pulsed with EdU, cryosectioned and immunolabelled for key corneal markers or examined by transmission electron microscopy.Batches of up to 100 models were created with consistent cellular architecture. LEC envelopes showed discrete organisation and differentiation within four days of co-culture, characterised by the formation of a proliferative p63+, CK14+, vimentin+ basal population, with suprabasal and superficial LECs subsequently differentiating and upregulating CK12/3 and PAX6. The SK core adopted an in vivo phenotype, determined by the expression of vimentin and fibronectin, and negative expression of α-SMA. This data shows that our models recapitulate key limbal markers in both epithelium and stroma. Furthermore, LEC polarisation demonstrates the epithelial-stromal intercommunication taking place during model co-culture. Further work will develop our model as an in vitro high-throughput platform for use by the drug/cosmetics industry, and as a screening tool for selecting high-grade LECs suitable for transplantation.

Although a complete healing is possible after most bone fractures, there are adverse situations, such as large bone defects, where the conditions for the bone to heal are not present, leading to a non-union. In this study we investigated in silico the influence of a bioengineered periosteal membrane (coated with growth factors and/or cells and combined with oxygen releasing beads) as treatment strategy. An existing bioregulatory, oxygen-dependent fracture healing model [1,2] was used, capturing processes at the tissue, cell and intracellular scales. A large gap size was considered in the geometrical domain to simulate bone regeneration in a large skeletal defect. Several parameters sets were run in simulations of 90 days to capture delayed bone healing and non-union, where different scenarios were tested to analyze the influence of the periosteal membrane. These scenarios involved bioengineered membranes consisting of electrospun polycaprolactane meshes, combined with cells, growth factors and oxygen-related stimuli (either addition of oxygen releasing beads or by using hypoxia resistant cells). These simulations predicted successful healing for a number of the tested strategies. Although the current model lacks a description of the inflammatory phase and the implementation of different membrane geometries, this work provided a first insight for the identification of the most impactful in vivo conditions to be tested experimentally.

Tissue engineering innovation has relied extensively and understandingly on animal products. Given the need for increasingly ethical, safe and economical alternatives, our postulate was to open up to vegetal matter seeking out tissue engineering concepts as cellular polarity, attachment, differentiation and extracellular matrix expansion. We found in the freshwater green alga Volvox carteri and its phylogeny a unique and global representation of this dimensional shift. Drifting from the unicellular alga Chlamydomonas reinhardtii, Volvox carteri colonies consist of an up to 500 µm spherical cohesive monolayer of ~ 2000 somatic cells surrounding a mucosal core, mainly composed of polysaccharides and hydroxyproline-rich glycoproteins holding progenitor cells.

Volvox carteri has displayed high stability and cellular adhesion capacities both on the surface and on extracts, offering multiple biomaterial shaping. Seeded Primary Normal Human Dermal Fibroblasts (HDFn) and Human umbilical vein endothelial cells (HUVECs) adhere to Volvox surface, forming cell carrier beads. Cellularized beads cultured for 21 days self-organize to develop three-dimensional dermis-like structures. Subcutaneous implantations of these pseudo tissue in a mouse model appeared stable and non-inflammatory in vivo even after 2 months.

Our data show how versatile and powerful Volvox-derived biomaterial can be in supporting eukaryotic cell growth as well as promoting self-organization. To our knowledge, our work represents the first step towards innovative use of volvocine algae as a bio-inspired material for tissue engineering, offering a wide range of applications from in vitro testing to regenerative medicine.

Corresponding author's email: higuchi@cc.ncu.edu.tw

Thermoresponsive surfaces enable the detachment of cells or cell sheets by decreasing the temperature of the surface when harvesting the cells. However, human pluripotent stem cells (hPSCs), such as embryonic stem cells and induced pluripotent stem cells, cannot be directly cultured on a thermoresponsive surface; hPSCs need a specific extracellular matrix to bind to the integrin receptors on their surfaces [1-3]. We prepared a thermoresponsive surface by using poly(N-isopropylacrylamide-co-butylarylate), recombinant vitronectin and/or laminin-511 to provide an optimal coating concentration for hPSC culture. In particular, we developed a repeated and continuous cultivation method of hPSCs on the same thermoresponsive plates where hPSCs were partially released from the same thermoresponsive plates by lowering the temperature of the thermoresponsive plates below the LCST of the thermoresponsive copolymer. Subsequently, the residual cells on the thermoresponsive plates were repeatedly and continuously cultivated in fresh cultivation media, and the detached stem cells were continuously collected. These cultivation cycles (passages) of hESCs as well as hiPSCs were successively repeated for ten cycles in this investigation. The detached cells, even after continual culture for over ten passages, showed high pluripotency, the ability to differentiate into cells derived from the 3 germ layers in vitro (Embryoid body formation assay) and in vivo (teratoma formation assay) as well as the ability to undergo cardiac differentiation.

Background and motivation: As a cheaper and more accessible alternative to the traditional photolithographic techniques, the templating methods based on 3D printing have become more popular in different areas of microfluidics and biofabrication research. However, the current 3D printing approaches fall short in generating delicate micro-structures in the range below 100 microns. In order to address this limitation, herein we present the first report on processing of water-soluble sugars by melt electrowriting (MEW). MEW provides the feasibility of direct writing for patterning with high flexibility in design and shape, making this method a powerful tool in fabrication of micron-scaled templating structures.

Methods: After evaluation of the thermal and physical properties of the sugar by DSC, TGA, and rheology, an operational window for MEW process was established and the influence of applied pressure, electrical field and tip-to-collector distance on the critical translation speed and the resulting fiber diameter were identified. Templating of the microchannels was achieved by embedding the printed structures in PDMS resin, followed by removal of the template through washing by water.

Results: It was successfully demonstrated that by fine-tuning the MEW process parameters during deposition of sugar-based microfibers, a wide range of structural resolution within a single design could be implemented. Our results show that complex designs with fiber diameters ranging between 10–200 µm were readily fabricated. Following a facile casting procedure, the resulting structures could be embedded within PDMS resin. A subsequent washing step resulted in a microfabricated PDMS devices with delicate perfusable internal structure.

Scaffolds in organ reconstruction are vital as they provide a growth environment and mechanical supports for cells, and form the tissue structure. Compared to conventional synthetical scaffolds, a decellularized scaffold has advantages such as maintenance of structure and composition in the original extracellular matrix (ECM). Among many decellularization methods, high hydrostatic pressurization (HHP) stands out for its superior effects in ECM preservation. In the HHP method, due to the higher pressure tolerances of ECM than cells, tissue can be decellularized using an appropriate pressure condition. Otherwise, ECM may be disrupted or decellularization cannot be achieved. Moreover, unique structures and compositions in organs result in distinguished pressure resistance. These factors urge the optimization of pressure conditions for each specific organ. In this study, we optimized the pressure conditions by fabricating the decellularized scaffolds under different pressure and evaluating cell removal, ECM preservation, and in vivo regeneration. Results showed 250 MPa, 500 MPa, and 980 MPa can decellularize uterine tissue and retain ECM structural protein composition and mechanical properties. However, only 250 MPa scaffold presented regeneration of all layers in a uterine wall, especially the smooth muscle layer, after implantation. Thus, 250 MPa is considered as the optimal pressure of the HHP decellularization method for uterine tissue.

For the recovery of the severe damaged tissues or organs, artificial scaffolds have been fabricated using various biofabrication techniques. Among the techniques, bioprinting technology serves as a powerful tool for fabricating tissue in the field of tissue engineering. Since applying the proper bioink for successful bioprinting is important, naturally derived hydrogels such as collagen have been widely used in the field of study due to their biocompatible and physiological properties. However, there are still limitations to mimic the exact extracellular matrices (ECM)-like environment using the hydrogels. In this study, we prepared the bio-ink consisting of decellularized bone ECM (bECM), β-TCP, and human dental pulp stem cells (hDPSC). The composition of the bio-ink and bioprinting processes were optimized based on the cell viability and printability. Based on the optimized conditions, hDPSCs-laden bECM/β-TCP scaffolds (BTS group) were fabricated. To evaluate the cellular activities, collagen/β-TCP-based cell-laden structure (CTS) was chosen as a control group and various in vitro tests, such as MTT assay, immunofluorescence analysis, and RT-PCR were performed. According to the data, better cell proliferation was observed at the BTS groups. Moreover, the cells laden at BTS group showed improved expression of odontogenic differentiation markers (dentin matrix acidic phosphoprotein-1 (DMP-1), dentin sialophosphoprotein (DSPP), osteopontin (OPN)) than control groups. Therefore, we expected that this new bioink using ECM can be used for the research about hard tissue regeneration and has the potential for the tissue engineering field.

Keywords

decellularized bone ECM; cell-laden scaffold; dentin regeneration

Introduction

The development of ECM-derived hydrogels and their application in bioprinting remains challenging since disruption of ECM structure during decellularization can result in no hydrogel being formed (1). In this study, we propose the development of decellularized ECM hydrogels hybridized with collagen to enable cardiomyocyte embedded bioprinting in order to develop a physiologically functional myocardial construct.

Methods

Ventricular tissue was isolated from porcine hearts, cut into 1x1 mm2 cubes and treated with 1% (w/v) sodium dodecylsulfide (SDS) and 1% (v/v) triton at 4°C until the tissue was decellularized. DNA assay was done to analyze efficiency of cell removal. The decellularized tissue was then lyophilized and digested with pepsin to obtain 1.5% (w/v) ECM hydrogel. The ECM hydrogel was combined with 4mg/ml collagen gel solution in a 1:1 ratio to form the hybrid hydrogel. HL-1 cardiomyocytes were incorporated within the hybrid hydrogel. This 'bioink' was then extruded through a 0.2 mm internal diameter needle at 15-17 kPa and 15-25 mm/s. The constructs were either bioprinted using a grid (45°/90°) or a parallel fiber (80°/20°) design. Cell viability and proliferation was evaluated using a live/dead staining and DNA assay. Cardiac immunostainings were performed using antibodies against MEF2, SERCA2, α-actinin and cardiac troponin T. Gene analysis for cardiac specific genes was also conducted.

Results

The constructs were bioprinted upto 4 layers with fiber size 200 µm. Bioprinting of cardiomyocytes using the hybrid hydrogel showed good viability after 48 hours. Cardiac biomarkers were expressed in the bioprinted cardiomyocytes after two weeks of cell culture.

Vertical slender nanostructure including nanopattern, nanowire, and nanospike, which can be directly interacted with living cells, have a great potential in biomedical applications. It was usually used as minimally invasive tools for drug delivery and intracellular sensing at the single cell level. Contrary to popular cognizance, we tried to investigate the potential of geometrically controllable nanospikes for regulating living cell behaviors including stem cells and bacteria cells. Therefore, we developed a nanospike patch with precisely controlled sizes using sophisticated nanoengineering (e.g., capillary force lithography). The structures of the stem cells were sensitively controlled by the nanospike, and the stimulation from the sharp corners induce the behaviors such as proliferation, differentiation, and cytokine excretion of stem cells. On the contrary, bacteria cells were damaged by the nanospike, and the antibacterial effects were promoted. In addition, stem cells integrated nanospike patches were easily engrafted onto the cranial bone defects, and the bone regeneration and calcium expression were significantly promoted by nanospike patches with stem cells. Likewise, geometry-controllable nanospike can play important roles as multifunctional biomaterials in the biological systems, and it can be used in the fields of tissue engineering and regenerative medicine for improving life of the living systems.

In the cancer microenvironment (CME) a heterogeneous cell population co-exist that communicates with the surrounding vasculature, inducing local neovascularization. In-vitro models recapitulating the in-vivo milieu are needed to evaluate new compounds and predict potential treatment effects in-vivo. Generating models which simulate the whole CME is challenging, and state-of-the-art 3D in-vitro vascularized cancer models have mostly been developed using microfluidics with limited high throughput scalability- which makes drug discovery long and expensive.

Using SIM technology in multi-well plates, we spatially organized human umbilical vein endothelial cells (HUVEC) into reproducible patterns. HUVEC rings (2 mm diameter, 100±50 µm thickness) were created in fibrin-gel in 60 seconds and self-assembled into a microcapillary network in 48h. A donor-specific heterotypic-cancer-spheroid, previously generated in a low-adherent 96-well plate, was superimpose on the microcapillary network and co-cultured for 4 days.

We investigated the presence of crosstalk among the model's elements and the effects of selected drugs on the system over 48 h. The microcapillary network's time-evolution, cancer spheroid sprouting and apoptosis were chosen as readouts, acquired by confocal microscopy and analyzed with imageJ. The microcapillary network area increased by 20% with an increase in branches of 60% compared to HUVEC-network alone, suggesting crosstalk between the microcapillary network and cancer spheroid. Following anticancer treatment, cancer spheroid sprouting decreased 75% and apoptosis increased 4-fold. Following antiangiogenic treatment, cancer sprouting decreased 45% but no increase in apoptosis was observed.

This platform offers an advanced in-vitro-model, compatible with high-throughput setups, in which spatially arranged microcapillary network co-exists with patient-specific cancer spheroid.

Recent advances in bioprinting techniques have led to the investigation of novel hydrogel formulations to overcome the extensive in vitro culture required by the seeding of prefabricated 3D scaffolds. In this framework, the combination of different materials arises as a promising route to develop hydrogel matrices with cytocompatible gelation mechanisms and tailored chemo-mechanical behavior[1]. Thus, tunable properties can be achieved through the integration of multiple solidification/gelling mechanisms and multi-step cross-linking systems[2–4].

Here, a thermoresponsive Pluronic/alginate semi-synthetic hydrogel is used to bioprint 3D hepatic constructs, with the aim to investigate liver-specific metabolic activity of the 3D constructs compared to traditional 2D cultures[5]. A novel method for bioprinting hepatic cells is presented, via a robust and reproducible manufacturing process, characterized by high-shape fidelity, mild depositing conditions and easily manageable gelation mechanism. Furthermore, the dissolution of the sacrificial Pluronic templating agent significantly ameliorates the diffusive properties of the printed hydrogel.

The findings herein demonstrate high viability and liver-specific metabolic activity, as assessed by synthesis of urea, albumin, and expression levels of the detoxifying CYP1A2 enzyme of cells embedded in the 3D hydrogel system. A markedly increased sensitivity to a well-known hepatotoxic drug (i.e. acetaminophen) is observed for cells in 3D constructs compared to 2D cultures. Therefore, the developed 3D model may represent an innovative in vitro platform, alternative to in vivo tests, for investigating drug-induced hepatotoxicity.

Cellulose aerogel microfibers as a biobased material with high porosity, low density, and high specific surface area are suitable for various biomedical applications including wound dressings. The high viscous solution of the cellulose (9% w/v) in ZnCl2 molten salt hydrate was spun in two different diameters (100 and 300 µm) by a customized wet spinning line at 70 oC and regenerated in isopropanol. The salt-free wet spun alcogel fibers were dried and loaded with model drugs using supercritical CO2 (sCO2), and the white opaque cellulose aerogel fibers with surface area in the range of 100-160 m2/g were fabricated. Scanning electron micrographs of the cross-section of the aerogel fibers showed macro-porous outer shell with a nano-porous inner core. Fourier transforms infrared spectroscopy and X-ray diffraction analyses confirmed that the spinning and sCO2 drying of microcrystalline cellulose did not change the cellulose structure but weakened the inter- and intra-cellulose hydrogen bonding, and thereby disrupted the final aerogel fiber crystalline formation. The fibers absorbed moisture up to 15% weight ratio in the relative humidity of 80% over 24 hours mainly due to cellulose hydroxyl groups and microfibers' porous structure. Finally, drug-loaded fibers with specified morphological characteristics containing different model drugs and non-loaded fibers to provide thermal insulation and drainage of wound exudate were needle punched as a nonwoven aerogel textile. This new method of fiber fabrication can provide a novel concept in the design of the multi-functional wound dressings.

Fighting microbial biofilms on biomaterials is usually addressed by incorporating antimicrobial agents. Nevertheless, as usual in the natural life, intrinsic properties of the material surface can also be a complementary approach. They may reduce the quantity of adhered microorganisms and the remaining microorganisms can be treated with classical drugs. Mechanical properties of materials recently emerged as a possible way to impact biofilm formation. However, many questions have still to be elucidated so far. Roles of coating hydration, bacterial motility on the surface or the involvement of adhesion proteins and structures in the biofilm development on such coatings are especially questioned.

In this context, we investigated whether hydrogel and non-hydrogel soft and stiff films may differently impact microbial adhesion, motility and further biofilm formation. The films have been characterized in terms of viscoelasticity, hydration and chemistry, and microbial mobility, adhered quantity and production of biological structures for adhesion have been specifically investigated. The study has been conducted with yeast (Candida albicans) and bacteria species (Escherichia coli) as models, and by using fluorescence confocal microscopy and proteomic approaches.

Our results reveal that the stiffness differently impacts the amount and mobility of the adhered cells according to the nature of the film. The softness- and hydration-dependent microbial phenomena also vary with bacteria and yeast species. Finally, this may confirm the relevance of using some soft coatings to prevent biofilm formation on a material but also clarifies the risks to get opposite effects as desired if other crucial surface properties have not been associated.

Osteoporosis, a bone pathology with a high socio-economic impact is rapidly increasing due to an ageing population. The GIOTTO project [1] aims to develop a medical device to treat osteoporotic fractures in long bones. Here, we report on the materials designed, fabricated and biologically evaluated. The materials include poly(ε-caprolactone) (PCL), poly L-lactic acid (PLLA), blends of PLLA, PCL, poly(3-hydroxybutyrate-co-3-hydroxyvalerate) (PHBV) (90:5:5%wt), and hybrid blends containing (5% w/w) strontium-substituted nano-hydroxyapatite (Sr-nano-HA) produced by wet chemical precipitation. For the blended materials the blend ratios were selected on the basis of the resulting mechanical properties. All materials were melt processed by extrusion into 1.75 mm diameter filaments. The osteogenic potential of the pre-osteoblastic cells cultured with filaments was evaluated by determining the alkaline phosphatase (ALP) activity, the secretion of collagen, the matrix biomineralization, and the gene expression of the osteogenic markers ALP, bone sialoprotein (BSP-1) and collagen I (Coll-a1). Our results demonstrate that all of the materials are not genotoxic and support a strong cell adhesion, viability and proliferation of pre-osteoblastic cells. The alkaline phosphatase (ALP) activity levels show significantly higher values for the blend containing Sr-nano-HA for all time points, while all other materials show similar levels to TCPS. A significant gene expression of ALP, BSP-1 and Coll-a1 was observed. All materials indicate high levels of secreted collagen with PLLA indicating a significant increase. The latter results in combination with the high levels of calcium deposition in all materials provide solid evidence of the formation of a healthy mineralized extracellular matrix.

Keywords

bone tissue engineering; osteogenesis

One of the key challenges in engineering three-dimensional tissue constructs is the creation of a mature microvascular network capable of supplying sufficient oxygen and nutrients to the tissue which makes ready-to-use vasculature a serious need in clinical treatments. The goal of this work is to investigate vascularization potential within a polyethylene glycol (PEG) based click hydrogel in vitro. Our functional hydrogel has two properties: i) it can degrade in response to matrix metalloprotease (MMP) enzymes due to the conjugated enzymatically degradable peptide within the network, and ii) can promote angiogenesis within the network through induced pluripotent stem cell-derived endothelial cells (iPSC-ECs). Our hydrogel retains covalently conjugated KLTWQELYQLKYKGI (QK) peptide sequence through a light cleavable o-Nitrobenzyl (ONB) linkage. QK peptide sequence can be released upon demand with a light exposure to manipulate the process of vascularization and has been established to promote vascularization. Our hydrogels were synthesized with 4-arm PEG-Azide and 4-arm PEG-DBCO through strain-promoted azide–alkyne cycloaddition (SPAAC) reaction at physiological temperature in the presence of ONB-containing QK-Azide and degradable peptide. Synthesis of materials and hydrogel was verified through advanced characterization techniques such as attenuated total reflection-Fourier-transform infrared spectroscopy, nuclear magnetic resonance spectroscopy, scanning electron microscopy and others. Our design will be of significant value for cardiovascular diseases and cell transplantation technology in regenerative medicine.

Single protein delivery systems are oversimplified and do not represent the physiological environment. Biphasic protein release strategies will allow electrospun scaffolds to meet the varied demands of the different phases of regeneration within in vivo environments.1Therefore, the need to develop multiple protein delivery systems in tissue engineering has become a fundamental and urgent need. However, finding a suitable biomaterial and an encapsulation technique that are compatible for the release of multiple proteins is challenging.2-3In this study, proteins were physically and chemically loaded into a single coaxial electrospun fibre scaffold to obtain bi-phasic release profiles.Cyto-compatible polymers were used to construct the scaffold, using polyethylene oxide(PEO) for the core and polycaprolactone (PCL) reacted or mixed with Jeffamine (JFA) for the shell. Horseradish peroxidase, a model protein, was loaded in the core and functionalised onto the scaffold surface by coupling of protein carboxyl groups to the available polymer amine groups. The electrospun fibre scaffolds generated by reacting PEO/PCL with 1,6-diaminohexane and those from mixing PEO/PCL with JFA were further characterised for protein conjugation and release.Fibres prepared by the mixed PEO/PCL/JFA system were found to be the most appropriate for the simultaneous release of protein from the core and the immobilisation of another protein on the shell of the same scaffold.Moreover, JFA enhanced scaffold properties in terms of porosity and elasticity.Finally, we successfully demonstrated the cytocompatibility and the response to the protein-loaded scaffold using HepG2 cells by assessing cell attachment and metabolism respectively to a bovine serum albumin-conjugated scaffold and a retinoic acid-loaded scaffold.

Introduction: Osteoarthritis (OA), the most common form of arthritis, is a major global health burden. Microfracturing (MF), a technique used to treat patients with OA results in a transient improvement of symptoms and the formation of fibrocartilage. We do not know what effects MF have on the Skeletal Stem Cell (SSC).

Aims: 1) To investigate the effect on MF on SCC 2) Augement the SSC niche to regenerate cartilage in a mouse model 3) Develop a translational xenograft model.

Materials and Methods: Animals- Jaxx mice b-Actin Cre-ER, R26Rconfetti, C57BL/6J, NSG. Human tissue: adult femoral heads, foetal phalangeal bones. Methods: FACS, microarray, CFU, EdU, in vitro culture, in vivo models: MF, DMM, renal capsule transplants, parabiosis, xenograft. Statistical analysis-Prism Software: Ordinary one way ANOVA test with Sidak post hoc analysis.

Results: Validated in mouse and human tissue: With age there is a significant ($p<0.001$) reduction in resident SSC. Acute injury results in a significant ($p<0.0001$) local increase in resident SSC and a significant ($p<0.012$) increase in proliferation of resident SSC. SSC intrinsically change in their in vivo differentiation capacity (renal capsule and orthotopic) and gene expression (microarray) following acute injury. Augmentation of the niche with BMP2 and VEGFr1 regenerates stable hyaline-like cartilage confirmed on histology (IF and Pentachrome) and Atomic Force Microscopy.

Development of functional tissue-engineered constructs benefits from non-destructive longitudinal imaging methods to assess ECM production. Contrast-enhanced micro-computed tomography (CECT) has emerged as a novel technique for 3D visualisation and longitudinal assessment of glycosaminoglycan (GAG) content in articular cartilage tissue-engineered constructs [1]. However, it has not been used for structures with a different ECM composition to articular cartilage; e.g. auricular cartilage. This study aims to test the feasibility of CECT for auricular cartilage compared to articular cartilage and investigate the influence of ECM composition.Bovine cartilage plugs (ø5 mm) from knees and ears were incubated in 12 mgI/ml CA4+ and scanned at 4µm using microCT. Total GAG content was assessed using DMMB assays. GAG distribution was evaluated using microCT, Safranin-O histology, and immunohistochemistry.GAG content normalised to volume shows a significant difference between articular cartilage (14.17±3.27 µg/mm3) and auricular cartilage (27.83±5.21 µg/mm3). Furthermore, mean attenuation is significantly higher in auricular cartilage (2.15±0.12 cm-1) compared to articular cartilage (1.31±0.14 cm-1). MicroCT images match the attenuation profiles. CA4+ shows significantly slower diffusion in auricular cartilage (τ=1.51) compared to articular cartilage (τ=0.78). In this study, CECT was successfully used to assess GAG distribution and content in auricular cartilage. CECT has potential for non-destructive longitudinal assessment and 3D visualisation of ECM production. The results suggest that incubation times should be adapted depending on tissue types and if attenuation is being compared to DMMB results, care must be taken to normalise results for different tissue densities.Thanks to Professor Mark Grinstaff, Boston University, for the CA4+.

There is recent evidence that beyond bulk mechanics driving cell response, microstructural features regulate tissue-to-cell mechanotransduction in cartilage. Glycosaminoglycans (GAGs) are well known for their load-bearing properties, and there is significantly different viscoelastic behaviour in two cartilage types due to heterogeneity of GAG and ECM fibres [1]. Understanding how the mechanical microenvironment influences cellular response and cell-material interaction is important for functional tissue-engineering. This study aims to incorporate chondroitin sulphate (CS) in gelatin methacrylate (gelMA), a widely used hydrogel in tissue-engineering, at tuneable concentrations. This will allow for customising GAG-rich domains in cartilage tissues, and will enable investigation of the interaction of cells with the ECM in tissue-engineered constructs.10%w/v gelMA was enriched with up to 10% CS using reductive amination and crosslinked using Irgacure2959. The resulting hydrogels were characterised for sol fraction, macromere retention, swelling ratio, and mechanics. Sol fraction and macromere retention show successful incorporation of CS in gelMA at different concentrations. The resulting swelling ratio of gelMA hydrogels with CS is larger compared to gelMA alone. Furthermore, gelMA with CS shows different mechanical properties compared to gelMA alone.In this study, CS was successfully incorporated in gelMA using reductive amination. The resulting hydrogel characteristics resemble the load-bearing properties of native cartilage. This allows for fabrication of 3D hydrogel microenvironments with tuneable CS that mimics the heterogenous ECM in cartilage; an optimal platform for the investigation of mechanobiological processes. Further studies will shed light on the role of GAGs in mechanotransduction and reveal cellular responses to mechanical cues.

We report on the development of novel biomaterials containing pure as well as strontium-substituted nano-hydroxyapatite (nano-HA) within the GIOTTO project [1] that aims to target specific osteoporotic fractures using innovative customized therapeutic devices. Both, the pure hydroxyapatite forms nano-HA_powder and nano-HA_paste, as well as the 50 and 100% strontium-substituted hydroxyapatite (Sr-nano-HA_50 and Sr-nano-HA_100, respectively) were produced by wet chemical precipitation in the NETmix® reactor (FLUIDINOVA S.A.), using calcium, strontium and phosphorous salts as starting materials. The slurries obtained were washed to remove the unreacted remaining salts and final aqueous pastes were concentrated up to 15% wt. Each material was diluted to a final concentration of 0.25% v/v and cultured with pre-osteoblastic cells for the evaluation of the cell viability, genotoxicity, alkaline phosphatase (ALP) activity, calcium biomineralization, collagen deposition and expression profile of the osteogenic genes ALP, bone sialoprotein (BSP-1) and collagen type I (Coll-a1). All materials are not genotoxic, show high cell viability and indicate a higher ALP activity on days 3 and 7, with the Sr-nano-HA_50 showing a significant increase. Calcium mineralization was higher on all materials compared to the control after 7 days in culture. Collagen secretion was high in all nano-HA materials, with the nano-HA_powder showing significantly higher collagen secretion after 14 days. Real-time quantitative polymerase chain reaction showed that the expression of bone sialoprotein (BSP-1) and collagen type I (Coll-a1) was significantly higher on nano-HA_powder, and higher than the control on all other materials. These results indicate a high osteogenic potential of the nano-HA materials.

The repair of peripheral nerve injuries is limited by current clinically available nerve guide conduits (NGCs), which do not provide adequate levels of regeneration compared to the gold-standard of a nerve autograft.

Studies suggest that the use of individual extracellular matrix (ECM) components can improve nerve regeneration (1), yet fewer studies have investigated the effect of incorporating a more native-like extracellular matrix as a scaffold for nerve regeneration, containing all the components present in a peripheral nerve.

The current project aimed to incorporate a neuronal native-like ECM in NGCs by using chick dorsal root ganglia, a source of primary nerve tissue that contains neuronal, glial and non-glial cells within the ganglia.

The cellular components were removed by decellularisation, resulting in a naturally-obtained decellularised ECM maintaining features of the native peripheral nerve tissue. The decellularised ECM showed improved cell attachment, neurite extension and neurite length compared to control tissue culture plastic, highlighting the potential for a naturally cell-derived ECM in nerve repair.

In order to further support the deposition of ECM, electrospun microfibres can be used as intraluminal scaffolds within nerve guide conduits, providing both physical and chemical cues to regenerating nerve fibres across injuries. Nerve guide conduits were fabricated from photocurable polycaprolactone by microstereolithography, while aligned polycaprolactone fibres were produced by electrospinning and plasma treated with oxygen. Nerve regeneration was assessed in vitro using a relevant neuronal NG108-15 cell line.

Future studies will assess regeneration in vivo using the transgenic YFP mouse line with fluorescent nerve fibres.

INTRODUCTION

The clinical translation of cellular therapies has been limited due to a lack of convincing safety and efficacy data. Greater understanding of the mechanisms of action of cell therapies, as well as their fate and biodistribution, requires non-invasive imaging strategies(1). Hybrid PET/MRI imaging systems can offer superior cell tracking capabilities than their standalone counterparts(2). For this, cells must be labelled with imaging agents that can show a signal in both PET and MRI.

METHODS

Polymer coated Superparamagnetic-Iron-Oxide-Nanoparticles(SPIONs) were synthesised and labelled with the PET-tracer, Zirconium(Zr)-89. To assess colloidal stability, Zr-SIONs were incubated in cell culture medium (CCM). Particles were assessed for toxicity using an ATP assay, and their uptake into macrophages was assessed with Prussian Blue (PB) staining and a ferrozine assay.

RESULTS

Zr-SPIONs were found to aggregate in 10% and 0% FBS containing CCM. To improve colloidal stability, the polymer conformations of Zr-SPIONs were varied. Particles with a 1:4 ratio of DEAE-dextran to CM-dextran were colloidally stable in 10% FBS containing CCM. Zr-SPIONs did not affect the viability of the macrophages. From the PB staining assay, particles were found to take up efficiently into macrophages. A maximum intracellular iron content of 5 pg/cell was determined by the ferrozine assay.

CONCLUSIONS

Colloidally stable Zr-SPIONs, which showed minimal toxicity to macrophages and sufficient cellular uptake for contrast in PET/MRI imaging systems, were successfully synthesised. The next steps are to assess the biodistribution of Zr-SPION labelled macrophages in vivo in uninjured mice, and in an ischemia reperfusion model of kidney injury.

To develop functional cartilage tissue-engineered constructs, it is important to understand how they carry, distribute and respond to load as they develop. Current methods cannot investigate the role of tissue microenvironments on cell behaviour because they require direct manipulation of the cell to elicit a response. Thus, investigating how the load-bearing capacity of tissue components change as the tissue develops remains a challenge for engineering functional materials. Understanding the complex biomechanical behaviour of living tissues requires accurate measurement and visualisation of these systems in action.To address these questions an image-guided micromechanical evaluation approach is proposed using multiphoton microscopy coupled with mechanical compression of cartilage samples and tissue models in a custom-built device. To measure tissue strain under load, tissue volumes are acquired during the relaxation phases of a step stress-relaxation test. Using the open source digital volume correlation software, TomoWarp2 [1], displacement maps of the 3D structure are calculated. In this work, we present bovine auricular cartilage plugs (ø3-mm) with cell nuclei stained using SYTOX Green, and autofluorescence of fibrous components. The samples were imaged using multiphoton microscopy (Leica TCS SP8 MP) while mechanically compressed, and tissue displacement maps were calculated.The custom-device allowed for 3D imaging of cartilage samples under compressive load and, for the first time, a strain map of the cartilage tissue microenvironment at the individual matrix component level. In future this will be used to investigate the contributions of cells and ECM components to structural integrity, tissue development, and gain insight into tissue structure-function relationships.

Electroconductive biomaterials, with promising effects on the regeneration of electrically active biological tissues such as neural, orthopaedic and cardiac tissues, have great potential in regenerative medicine applications. In this study, a chitosan-based composite scaffold has been developed by incorporating graphitic carbon obtained from cork (natural and sustainable source) as an electroconductive filler and subsequently characterized. Several concentrations of pyrolysed cork (PC) granules (0.01, 0.1, 0.5, 0.75, 1 wt%) were homogeneously dispersed into chitosan (Ch) slurry and freeze-dried. The prepared Ch-PC scaffolds were characterized in terms of electrical, mechanical, physicochemical and biological properties. An electroconductivity of 5.5x10-5 S/cm, i.e. in the range of cardiac tissues [1], was registered when a PC concentration of 1% wt was used. Though FTIR and XPS measurements showed no evidences of chemical bonds between the two components, the mechanical strength of composites scaffolds resulted significantly higher than pure Ch one, indicating that weak interactions arise between the two components, leading to an enhancement of the mechanical properties of the polymeric scaffolds. The biocompatibility of Ch-PC composite scaffolds has been verified by SH-SY5Y neuroblastoma cell viability assay. The ability of Ch-PC scaffold to support induced Pluripotent Stem Cells (iPSCs) differentiation into cardiomyocytes (iPSC-CMs) were also tested. In conclusion, this study shows that a composite made using an innovative electroconductive filler deriving from a natural source, such as PC, might have great perspectives in cardiac tissue engineering.

Optimum mechanical signals are necessary to maintain the health of chondrocytes in articular cartilage. Abnormal mechanical signals can lead to departure from the stable chondrocyte homeostasis and a switch to hypertrophy, as observed in osteoarthritis(OA). For cartilage tissue engineering, the progenitor cells must be subjected to proper mechanical loading to stimulate chondrogenic differentiation and cartilage production. In this study, a coupled multiscale model of the human knee joint was developed to estimate the mechanical signals that the articular chondrocytes experience as a result of (patho)physiological loading at the joint-level. The intracellular processes triggered by said mechanical signals are modeled using a gene/protein regulatory network for mechanotransduction. Subsequently, changes in cell phenotype and activity of the relevant cell secreted factors are estimated. Using this multiscale model, the effect of meniscectomy on the progression of osteoarthritis is studied. Meniscectomy leads to increased strains in the articular cartilage as compared to a healthy joint, resulting in higher forces sensed by the chondrocytes and thereby initiating degenerative processes. With increased inflammatory cytokines in the meniscectomized joint, degeneration is increased further with the phenotypic switch of stable chondrocytes to hypertrophy when combined with mechanical loading experienced by the chondrocytes in the different zones of the cartilage. This multiscale model has huge potential in not only unraveling the role of mechanical loading in progression of OA but also delineating the role of mechanical loading in cartilage tissue engineering by quantifying the properties of osteochondral implants that will provide appropriate mechanical stimulation to the embedded progenitor cells.

This study aimed to determine whether meniscal tissue could be healed by the implantation of scaffold-free three-dimensional formed fetal cartilage-derived progenitor cells (FCPCs) (A-paste) in in vitro and in vivo evaluations. For in vitro, the characterization of A-paste cultured with/without fibrogenic induced medium resulted in increased meniscus formed features at 4 weeks. The in vitro remodeling process analysis of A-paste showed improved meniscus repair characteristics over time, with a higher integrated fibrocartilaginous matrix compared to meniscal autograft controls at 3 weeks and 6 weeks. The in vivo healing of meniscal defect was also confirmed at 6 weeks post-transplantation in a nude mouse model. In vivo investigation, twenty white New-Zealand rabbits (aged 20 weeks, 3.0-3.5 kg) were assigned to 2 groups. Defects 2 mm in diameter were created in the anterior horn of the medial meniscus. The defects were left empty in the control group and were filled with A-paste in the experimental group. Histological observations (Safranin-O stain, Masson Trichrome stain, and type 1 collagen) and meniscus repair scores were significantly better in the experimental group compared to the control group after 6 weeks and 12 weeks. In conclusion, our finding demonstrated A-paste has a fibrocartilaginous matrix formation and promotes meniscus healing in vitro, in vivo transplantation.

Introduction

A drug-loaded cardiac patch can provide cues for stem cell maturation and function. Istaroxime is a novel therapeutic drug that enables upregulation of calcium signaling in cardiomyocytes to improve heart tissue function. Yet, istaroxime is severely limited by its short half-life of less than an hour (1). This renders the drug ineffective by the time it reaches the heart via the bloodstream. We therefore propose the combination of a drug-release mechanism with cardiomyocytes to treat heart tissue damage. The mechanism of drug embedding proposed here will therefore have the benefit of enabling sustained release of istaroxime from the biodegradable polymer.

Methods

Istaroxime was dissolved in hexafluoro-2-propanol (HFIP) and water (6ul/ml) to get 2% (w/v) istaroxime in 25% (w/v) Polyactive (300PEOT55PBT45) solution in solvents chloroform:HFIP (7:3). 25% Polyactive polymer solution without istaroxime was used as control. The scaffolds were electrospun and seeded with HL-1 cardiomyocytes. Cardiomyocytes were cultured on tissue culture plastic (TCP) and TCP supplemented with a daily dose of 100nM/100ul for 16 days. Cell proliferation was determined by metabolic activity and DNA assay. Live/dead imaging was used to assess cell viability over several time-points. Immunofluorescence staining was performed for several markers (SERCA2, actin and sarcomeric α-actinin). PCR analysis was carried out for cardiac specific genes.

Results

Metabolic activity showed increasing activity over time for all samples. DNA assay showed highest DNA content at day 16. Live/dead staining confirmed majority of live cells in culture over time. PCR analysis showed differences in several cardiac gene expression at day 8.

The use of nanomaterials-based technologies in biomedical applications poses challenges in terms of their vascular bioactivity/safety evaluation. Several methodologies have been proposed, however, they involve animal testing, are low-throughput, and they do not account for the biological differences between animals and humans. In this sense, the development of personalized human in vitro platforms to evaluate the interaction of nanomaterials with the vascular system would be important for therapeutic and regenerative medicine purposes. Here,we have used human induced pluripotent stem cells (hiPSCs)-derived endothelial cells (ECs) with “young” and “aged” phenotypes in 3 vascular network formats: 2D (polystyrene dishes), 3D (Matrigel) and a blood vessel-on-a-chip, to study their response to a library of 30 nanoparticles (NPs) used in imaging, antimicrobial and pharmaceutical applications, using, as a proof of concept, vascular toxicity as the main readout. The toxicity profile of NPs to hiPSC-ECs was dependent on the “age” of hiPSCs and the vascular network format. hiPSC-ECs were less susceptible to the cytotoxicity effect of NPs when cultured in flow than in static conditions, being the protective effect mediated, at least partially, by the glycocalyx. The results presented here highlight the relevance of in vitro hiPSC-derived vascular systems to screen vascular toxicity.

The long-term goal of this work is to develop a proteolytic enzyme digestion model of the intervertebral disc (IVD) for the study of regeneration therapies. In this study, we induce tissue digestion in a bovine organ culture model with two different enzymes, papain or chondroitinase ABC (ChABC), and assess the influence of dynamic loading on gene expression and disc dimensions after day 7 of culture. Papain and ChABC both induced glycosaminoglycan (GAG) loss and disorganization of tissue structure, but repetitive dynamic loading during enzymatic digestion induced significantly faster disc height loss compared to unloaded culture conditions ($p < 0.001$). ChABC was the only enzyme to induce statistically significant changes in gene expression compared to PBS injected controls. In the inner AF, mRNA expression relative to day 0 for ACAN and COL2 significantly increased ($p < 0.05$), whereas COL1 showed a trend towards downregulation. Loading did not induce any significant changes in gene expression in the inner AF. However, in the outer AF, loading induced a significant upregulation of COL1 ($p<0.05$) and downregulation of ACAN and COL2 ($p<0.05$). Currently, we are evaluating the cellular and molecular response of the IVD tissues over long term organ culture to understand if the observed patterns mimic that of human degeneration.

The work described is part of the iPSpine project, which has received funding from the European Union's Horizon 2020 Research and Innovation Programme (Grant No 825925).

One of the main challenges raised when engineering in vitro therapeutic systems is to combine multiples tissues to uncover the influence that other tissues have in the one under study. This interaction becomes essential since physiological responses are interconnected and they cannot be considered as isolated systems. In the case of bone metabolism, it has been shown that osteogenic events, angiogenesis and tissue repair are under neural control through direct interaction with neuropeptides [1],[2].

In the present work, a biological-inspired 3D vascularized bone model is introduced as a platform that presents vascular endothelial growth factor (VEGF) [25 ng/mL] and neuropeptide substance p (SP) [10-8M] tethered to poly-ethyl acrylate/fibronectin (PEA/FN) microbeads and embedded in a fibrin gel to induce vascularization. Human mesenchymal stem cells (hMSCs) seeded on the gel are close to the vascular system and the model is nanokicked to induce mechanically stimulated hMSCs osteogenesis. We hypothesized that SP may bind to FN, protecting it from degradation and creating a more stable presentation for the cells. Enzyme-linked immunosorbent assay, immunofluorescence and ellipsometry results show for the first time co-localization between both molecules, giving a thickness of 3 nm of SP bound on PEA/FN surfaces. On cellular studies with human vascular endothelial cells (HUVECs), results suggest that the combination of matrix-bound VEGF and SP synergistically enhances the sprouting, leading to a greater invasion of the gel after 7 days. In vitro evaluation of hMSCs also showed the highest osteogenic protein profile for osteopontin within the GF/peptide group after 14 days.

Detergent perfusion is the most common decellularization technique in producingextracellular matrix-derived renal bioscaffolds. However, it usually takes long treatmenttimes and large volumes of detergent solutions. Coupling this technique with sonicationtreatment has the potential to decrease the decellularization time but the combinedeffects of these two strategies can induce damage to the resulting bioscaffold. Thisstudy aims to determine the optimum decellularization parameters of sodium dodecylsulfate (SDS) concentration, flow rate, and sonicator power, which are parametersknown to have the most significant influence on the decellularization time andmicroarchitecture integrity of the scaffold, by using a response surface methodology.Cadaveric porcine kidneys were subjected to detergent perfusion and sonicationtreatment with varying SDS concentration, flow rate and sonication power.Decellularization time was recorded as the time it took for the kidney to transition into awhite translucent color upon SDS perfusion while the microarchitecture integrity scorewas done through a scoring system based on the H&E stained structures of theglomerulus, tubules, and blood vessels. Results show that using the optimumdecellularization parameters of 0.71% wt/vol SDS, 45 mL/min flow rate, and 60 Wsonication power, an acellular ECM scaffold was obtained after 3 hours with onlyminimal to moderate disruption of the renal structure. Colorimetric assays andimmunohistochemistry tests showed the retention of ECM proteins such as total solublecollagen, fibronectin, and laminin. The optimum parameters of sonication-assistedperfusion result in the efficient production of acellular renal bioscaffolds with preservedstructural integrity.

Introduction: Following cardiac injury, the adult epicardium becomes a source of a multipotent cardiac progenitors and paracrine signals contributing to the repair process(1) and therefore represents a unique target to improve post-ischemic recovery. We developed a robust ex-vivo 3D organotypic model enabling the study of the epicardium and the development of strategies to enhance its potential.

Methods: Thin epicardial/cardiac slices (EpCardio-TS) are obtained from porcine hearts and cultured for up to 72h in a bioreactor system based on a 3D printed chamber connected to a control system ensuring stable and tuneable culture conditions and maintaining the air-liquid interface. Epicardial cell tracking is performed using localised nanoinjection(2) of fluorescent dyes or by immunostaining. 3D slices morphology is visualised by immunofluorescence on decolourised slices.

Results: EpCardio-TS presents both a healthy epicardium and an electrically connected myocardium. The optimized culture conditions preserve the viability of the epicardium upon culture as indicated by calcein staining (T0: 68.0±3.9%; 24h: 60.2±8.2% 48h 72.9±8.5%) and apoptosis quantification (T0: 7.42±1.69%; 24h: 24.9±6.6%; 48h: 25.5±7.2%). Treatment with thymosin β4 (Tβ4) reactivates the epicardial cells increasing the expression of embryonic and epithelial-to-mesenchymal transition genes and resulting in improved motility into the myocardium and mesenchymal differentiation.

Discussion&Conclusions: Our 3D organotypic culture uniquely enables drug and gene therapy screening to boost the epicardial contribution to heart repair and remodelling. Our data from porcine heart tissue are physiologically relevant to the human heart, confirming the prominent role of the epicardial cells in the myocardial repair in this patient-relevant model.

Extracellular microenvironment and cell-ECM crosstalk strongly influence cellular behavior through their mutual exchange of bio-chemical and physical signals [1-2]. Several in vitro studies showed the importance of a three-dimensional (3D) microenvironment architecture in many cellular processes, such as migration and differentiation [3-4]. 3D culture systems have been successfully proposed to construct analogous tissues for tissue engineering and regenerative medicine applications and, in the last decade, as disease models, useful for evaluating drug effects in vitro [5-6]. In this perspective, hydrogels are valid biomaterial candidates that can be used as 3D culture systems, featuring highly tunable physical-chemical and biological properties. Aiming to recapitulate in vitro the Neuro-Muscular Junction (NMJ), we propose chitosan-based thermo-sensitive hydrogels capable of gelling at 37°C with the addition of organic and inorganic saline solutions (beta-glycerol phosphate and sodium hydrogen carbonate, respectively). The developed formulations have physico-chemical properties suitable for cell encapsulation, show long term stability (up to three weeks) and tunable mechanical properties (in the range 6-10 KPa) and permeability. Biological analyses revealed that the proposed hydrogels are biocompatible, showing a marked viability (>90%) and metabolic activity of both neural (NSC34) and muscle (C2C12) murine cells. Finally, the hydrogels demonstrated to be able to support neuronal (neurofilament-H) and muscle cell (Myo-D, myogenin, myosin heavy chain) differentiation.

Current in vitro 3D cardiac tissue models do not fully replicate mature myocardial function or micro-architecture. Previously, we fabricated melt electrowritten (MEW) hexagonal microfiber meshes with biomechanical properties that mimic native myocardium, thereby supporting human induced pluripotent stem cell-derived cardiomyocytes (hiPS-CMs) contraction and driving tissue organization and maturation[1]. We hypothesized that incorporating cardiac fibroblasts and providing contact guidance and reinforcement through strategically stacked MEW meshes, enables the replication of transmural 3D macrostructure and function. In this study, we present the generation of a bioengineered transmural cardiac construct (TmC).

Hexagonal MEW meshes were fabricated using a 3DDiscovery (RegenHU). TmCs of 8mm in diameter and 10mm in thickness were produced by stacking multiple MEW meshes, seeded with gelMA-collagen hydrogels encapsulating hiPS-CMs and hiPS cardiac fibroblasts (hiPS-cFBs)[2] (9:1), and cultured for four weeks. Function, morphology, and maturation were evaluated using construct contraction analysis, histology, and cardiac marker expression (immunofluorescent staining and qRT-PCR).

Beating cell clusters were observed 3-4 days after TmC seeding, proceeded by whole construct synchronized beating (40bpm) after 10-14 days, including construct radial deformation of 1-2mm. Histological sections exhibited a clear multi-layered structure with a uniform cellular distribution. Immunofluorescent staining showed hiPS-CMs and hiPS-cFBs organized into tissue-like structures, aligned with the hexagonal microarchitectures. An increased expression of cardiomyocyte maturation-related genes (RYR2/TNNI3/CPT1B) was observed in TmCs compared to single-mesh constructs.

Our study provides an important step towards the generation of 3D in vitro cardiac models of relevant dimensions with native-like tissue architecture and function.

Chronic lung diseases such as idiopathic pulmonary fibrosis (IPF) involves extensive remodeling of the extracellular matrix (ECM), primarily in the periphery of the lung. This leads to altered mechanical properties, which in turn results in altered mechanical stimulation of the cells. In stiffer and less elastic ECM found in IPF, fibroblasts are thus exposed to altered strain compared to a healthy ECM. Our aim is to investigate the impact of mechanical stimulation on fibroblast activity in IPF. Decellularized lung slices (350 um thickness) were attached to a custom-made device for cyclic stretch built in polydimethylsiloxane and repopulated with healthy primary distal lung fibroblasts. The lung scaffolds were either exposed to cyclic stretch (0.2 Hz, 10% strain) or cultured under static conditions upto 3 days and analyzed for cell viability, histology, RNA expression, and released mediators. Compared to healthy scaffolds, fibroblasts on IPF scaffolds showed increased metabolic activity, both at static and cyclic stretch condition. Scaffolds under cyclic stretch showed preserved tissue morphology with dispersed elongated fibroblasts shown with H&E staining. Interestingly, we see a shift in released mediators linked to angiogenesis in cyclic stretch cultures, mostly pronounced in IPF scaffolds. We demonstrate that we have developed a physiological more relevant ex vivo model to study cellular responses in lung tissue. Our data indicate that there is a change in cellular activity in IPF tissue under cyclic stretch. This allows us to study the effect of alterations in mechanical and matrisome properties in chronic lung disease.

Biomaterials should be characterized by a controlled capacity to activate the immune system promoting wound healing and regeneration process, while avoiding chronic inflammation and "foreign body" responses. Majority of studies on silk fibroin have naively claimed this polymer scaffold/hydrogel material as 'biocompatible' or 'biologically safe'. This term 'biocompatible' should be used with caution, as this claim indicates that silk fibroin-based biomaterials can augment tissue regeneration, smooth integration with host tissue and trigger biological functionality without causing chronic inflammation and foreign body response1. Physical characterization (FTIR, AFM, XRD) of Silk fibroin Bombyx mori (BM) and Antheraea mylitta (AM) 3D silk textile braids were compared with 2D BM film (β-crystallized using water-annealed and ethanol treatment). Monocyte cell line THP-1 and T cells isolated from healthy donors were cultured over those scaffolds. We have selected a specific panel of cytokines microarray, cell surface markers, Nitric oxide estimation, cellular morphological changes that will help to elucidate the different stages of macrophage polarization and T cell activation on silk biomaterial surface in a synchronize pattern. This comprehensive study will largely help to elucidate the basic paradigm of immune response in context with surface topography, 3D structure, matrix stiffness, processing parameters, conformational changes of different form of silk-based biomaterial and provide future direction to build proper immune instructive silk-based biomaterials for tissue regeneration.

Understanding the complex communication between different cell populations and their interaction with the microenvironment in the central and peripheral nervous systems is fundamental in neuroscience research. Due to the lack of suitable animal models capable of faithfully reproducing the physio-pathological mechanisms of many human diseases, the development of appropriate in vitro approaches and tools, able to selectively analyze and probe specific cells and cell portions (e.g., axons and cell bodies in neurons) has become therefore crucial in this direction. Here, a protocol was established to microfabricate a microfluidic chip by multi-level optical lithography. We evaluated different microfluidic setups and coating materials, as well as several geometric features: three perfusable cell compartments (500 µm wide and 6 mm long) with distinct inlets and outlets were interconnected through a series of narrow and parallel microgrooves (either 2.5, 5 or 10 µm wide and 250 µm long). We showed that an accurate choice of device geometrical features and cell culture parameters (i.e., cell density and coating procedures) allowed to: i) maximize cell adhesion and proliferation of neuron-like human cells (SH-SY5Y cells) and primary rat Schwann cells, ii) perform on-chip cell differentiation towards more physiologically relevant phenotypes (i.e., differentiated mature adherent neurons and mature myelinating Schwann cells), ii) control the inter-compartment cell migration, iii) execute long-term cell culture studies. These results can lead to a plethora of in vitro co-culture studies in the neuroscience research field, where tuning and investigating cell-cell and cell-microenvironment interactions are essential.

Calcium phosphate cements (CPC) are widely used as bone substitutes because of their similar composition with the mineral phase of bone and of their injectability, making them of particular interest in mini-invasive surgery. However, their bone healing properties are not sufficient to promote osteogenesis due to a poor macro-porosity or an inadequate resorbability preventing cell migration and vascularization. In order to combine interconnected macro-porosity and injectability, we perfected a promising approach, using a dual syringe mixing technique1, to produce foams composed of CPC and polymer with foaming agent. Among a dozen of formulations containing calcium deficient hydroxyapatite cement (CDHA) associated with different hydrogels were tested (e.g., alginate, chitosan, hyaluronic acid, gelatin). We selected two of them based on their biocompatibility and ability to form a hydrogel foam: 1) a silanized hyaluronic acid hydrogel creating the three-dimensional network and Albumin as foaming agent (Si-Hya Ac + RSA); 2) a foaming gelatin-based hydrogel (Gel). Their macro-porosity between 100 and 300 µm and their young's modulus of 0.5 GPa for CDHA/Si-Hya Ac + RSA and 1.8 GPa for CDHA/Gel respectively were closed to the porous ceramics2. Moreover, CDHA/Si-Hya Ac + RSA and CDHA/Gel on STRO1 cells allowed to maintain their viability over 3 days. In vivo, critical size defects (6x10mm, n=6/condition) were performed in femoral metaphysis of New-Zealand white rabbits. Defects filled with the two new biomaterials exhibited greater mineral formation compared to the control, one week after the surgery suggesting a bone regeneration potential of our new biomaterials.

Cardiovascular diseases like myocardial infarction are still significant causes of morbidity and mortality worldwide1. The limited intrinsic self-regeneration ability of cardiac muscle tissue after damage by myocardial infarction, as well as restricted therapies and the lack of donor organs demand new strategies. Among those, the cardiac patch strategy represents an important approach, which can not only provide mechanical support to the infarcted area but also be a platform for healthy cell delivery2. To achieve a highly functional cardiac patch, collagen, hyaluronic acid, and polyaniline (PANi) were electrospun to form the top layer of a bilayered patch3. Homogeneous and defect-free fiber mats with fiber diameter in a range between 120 and 350 nm were obtained. Increasing PANi concentration led to stronger, but less elastic fiber mats. Electrical conductivities close to the human myocardium with up to 2.0 ± 0.6 mS/cm were achieved. Although the cardiomyocyte viability was slightly decreased with the addition of PANi, the beating rates of cardiomyocytes did not show significant differences for the different compositions. The highest PANi composition revealed a significant increased contraction amplitude and connexin43. This physico-chemically mimetic fiber mat could now be combined with a highly patterned scaffold. Thus, a combination of the polyester poly (glycerol sebacate) (PGS) and the maiz protein zein was 3D printed using an extrusion-based system to achieve sufficient mechanical properties close to native myocardium. PGS-Zein obtained good printability with little shrinkage during heat crosslinking. Cyclic fatigue tests indicated no significant material damage to the printed structure after 5000 cycles.

TAILORING OF FLOW PROPERTIES OF GELATIN METHACRYLOYL VIA UV PHOTOCROSSLINKING TO YIELD EXTRUDABLE HYDROGELS FOR 3D BIOPRINTING

Paulo Alexandre Amorim[1]

[1] *KU Leuven*

Corresponding author's email: pauloalexandre.amorim@kuleuven.be

Gelatin methacryloyl (gelMA) hydrogels are widely used biomaterials in tissue engineering, such as bioprinting [1]. However, due to its highly predominant elastic behavior, the 3D bioprinting of this material via extrusion results in poor surface aspect and mechanical integrity[2], which is probably associated with their low ability to flow, culminating in brittle fracture. Hereby, we report the obtention of a gelMA chemical hydrogel capable of transitioning from solid to liquid-like behavior under stress, enabling the conception of inks for extrusion-based bioprinting. Samples of gelMA hydrogels with high degree of substitution (95%) at the concentration of 10 w/v% were photocrosslinked in presence of a photoinitiator, lithium phenyl-2,4,6-trimethyl benzoyl phosphinate (Li-TPO-L), at the concentrations of 0.1 and 0.5 w/v% for 10 min at 365 nm. To assess the chemical hydrogels ability to flow and the presence of gel state, strain amplitude and frequency sweep tests were performed at 37 °C using a Anton Paar Physica MCR 501 rheometer, 25 mm paralallel plates and solvent trap. The physical hydrogel was tested under the same setup at 20 °C. Strain-amplitude tests showed that the formulation containing 0.1 w/v% of Li-TPO-L, photocrosslinked for 10 min presented transition from solid to liquid-like behavior whereas the GelMA/0.5 w/v% Li-TPO-L and the physical hydrogel remained as viscoelastic solids. Frequency sweep tests showed that all the materials behave as gels throughout the applied frequency range, which is key for the development of bioinks. Therefore, this strategy can be useful for obtaining constructs of superior integrity.

There is a growing need of in-vitro human skin models for skin disease modelling and drug testing. To mimic native skin, conventional models utilize scaffolds such as collagen. However, scaffold-based methods undergo tissue contraction that prohibits it´s use for long-term study. Here, we fabricated scaffold-free skin models to eliminate such limitations. The skin models were engineered using the cell-coating and accumulation technique where human fibroblasts were coated layer-by-layer with extracellular moieties and accumulated in cell culture inserts. Keratinocytes were seeded on top of the scaffold-free dermis and the full-thickness skin model was cultivated in air-liquid interface. This scaffold-free technique resulted in highly durable non-constricting skin constructs. Owing to this stability, the skin models were utilized to initiate psoriasis skin disease, test anti-psoriatic drug for a time-frame of 14 days and observe the influence of the drug on psoriasis phenotype. Another goal of the study was to incorporate endothelial cells and fabricate a long-term vascularized skin models. Vascularization, however, led to several challenges such as degradation of the dermal compartment and abnormal vessel growth due to the interplay between keratinocytes and vessels. This hindered the stability of the fabricated vascularized skin tissue. Keratinocytes were observed to influence vessel architecture by releasing excess growth factors such as the vascular endothelial growth factors (VEGF). To combat these challenges, engineered skin models were provided with a dynamic environment which prevented the dermal degradation and vessel abnormality. Together, in this study, we engineered a long-term and durable vascularized and non-vascularized skin models.

TGF-BETA INDUCES RIBOSOME ACTIVITY, ALTERS RIBOSOME COMPOSITION AND INHIBITS CITE-MEDIATED TRANSLATION

Guus G.H. van den Akker$_P$[1], Alzbeta Chabronova[1], BAS A.C. Housmans[1], Andy Cremers[1], Don A.M. Surtel[1], Marjolein M.J. Caron[1], Mandy Peffers[2], Tim J.M. Welting[1]

Ribosomes are required for the continuous translation of all proteins in cells. Recently, it was discovered that thousands of human mRNAs contain a 5' untranslated region that regulates protein translation through Cap independent translation elements (CITE). We used a candidate approach in a chondrocytic cell line to identify growth factors or cytokines that differentially regulate CITE-mediated translation.

Our screening revealed that TGFβ3 consistently decreased CITE activity in favor of Cap-mediated translation. A concentration of ≥ 1 ng/ml and at least two days of stimulation was required for this effect. Mass-spectrometry with label-free quantification was used for proteomic analysis. In the cellular proteome we found that TGFβ3 induced protein expression of known TGFβ transcriptional target genes compared to control. This was also reflected in the secretome. Finally, we isolated ribosomes with their associated proteins from control and TGFβ3-treated cells. Ribosomes isolated from TGFβ3-treated cells contained significantly lower amounts of HNRNP family members. The majority of these HNRNPs were not differentially expressed in the cellular proteome and are known to be involved in CITE translation. Finally, a small but significant increase of specific ribosomal proteins was found in ribosomes extracted from TGFβ3- treated cells.

We demonstrate that a growth factor/cytokine can induce ribosome activity, alter ribosome composition and modulate the preferential mode of translation in eukaryotic cells. Future experiments will focus on functional validation of the link between ribosome-associated HNRNP abundance and alterations in CITE-mediated translation. Ribosomes might present a drugable target in complex diseases where TGFb plays a role.

Fused Deposition Modelling (FDM) technique has been widely utilized in fabrication of 3D porous scaffolds for tissue engineering (TE) applications. Surprisingly, although there are many publications devoted to the architectural features of the 3D scaffolds fabricated by the FDM, none of them give us evident information about the impact of the diameter of the fibres on material properties. Therefore, the aim of this study was to investigate the effect of the diameter of 3D-printed PCL fibres on variations in their microstructure and resulting mechanical behaviour. The fibres made of poly(ε-caprolactone) (PCL) were extruded through commonly used types of nozzles (inner diameter ranging from 0.18 mm to 1.07 mm) by means of FDM technique. Static tensile test and atomic force microscopy working in force spectroscopy mode revealed strong decrease in the Young's modulus and yield strength with increasing fibre diameter in the investigated range. To explain this phenomenon, we conducted DSC, WAXS, FTIR, IR and PLM imaging. The obtained results clearly showed that the most prominent effect on the obtained microstructures and mechanical properties had different cooling and shear rates during fabrication process causing changes in supramolecular interactions of PCL. The observed fibre size-dependent formation of hydrogen bonds affected the crystalline structure and its stability. Summarising, this study clearly demonstrates that the diameter of 3D-printed fibres has a strong effect on obtained microstructure and mechanical properties. Moreover, results suggest the impact on cellular response.

Functional polymers play a significant role in the development of novel biomaterials for various applications. Among them six-arm star-shaped poly(ethylene oxide-stat-propylene oxide) with NCO terminal groups (NCO-sP(EO-stat-PO)) had demonstrated a great potential. Apart from its use as a functional surface coating, NCO-sP(EO-stat-PO is embedded within fibrous polymer networks that are fabricated via electrospinning. As a versatile cytocompatible pre-polymer, NCO-sP(EO-stat-PO can be used to stabilize fibrous gelatin network in aqueous conditions, and negates the use of possibly toxic additional crosslinking agents. Its star shaped functional arms form into a dense crosslinked network which creates a highly hydrophilic shell. Hence, when blended with synthetic hydrophobic polymers such as PCL and PLGA and spun into fibrous meshes, it increases the hydrophilicity of scaffolds and minimizes the non-specific protein adsorption. This bioinert surfaces with low protein adsorption inhibit adhesion of e.g. fibroblasts, hMSCs. In contrast, such interfaces help to mitigate excess anti-inflammatory responses caused by macrophages. Scaffolds can be further specifically bioactivated with cell instructive cues e.g. adhesion peptides, via -NCO terminal groups on star-shaped polymer. Overall, the possibility of multi-modal bioactivation, tuning the density of NCO-sP(EO-stat-PO on the surface of fibers together with the relevant bioactive molecules manifest a tremendous capacity for the fabrication of cell-instructive scaffolds.

As a result of global rise in ageing populations, heart valves diseases have become a major health issue world-wide. The most widely used treatment for heart valve diseases are surgical replacement strategies with mechanical or biological heart valves implants. However, there are large drawbacks including the formation of blood clots (mechanical implants), short durability and limited growing, repair and remodel ability. In the current work, researchers focus on tissue engineered heart valves supporting both biocompatibility and reproducibility of implants.

Here, three-dimensional cell/hydrogel constructs are synthesized for the application in biohybrid heart valves. An investigation of the mechanical properties of fibrin-based hydrogels with L929 cells is conducted and a bioprinting process of the cell/hydrogel construct is explored. The gels are synthesized from natural fibrin and synthetic linear reactive copolymers based on poly(N vinylpyrrolidone) and can provide a three-dimensional environment for cell proliferation and growth. Due to cost and easier handling of cell lines compared to patient-derived, primary cells, L929 cells are used for initial experiments to determine the influence of the cells on the mechanical properties of the hydrogels and for the optimization of the bioprinting process. Rheological experiments proof that the cell concentration has no significant influence on the hydrogels mechanical properties. Furthermore, the possibilities to fabricate cell/hydrogel constructs with different forms (e.g. microbeads or films) will be explored using extrusion based bioprinter. In future experiments we will focus on the development of the printing process of cell/hydrogel constructs and the analysis of the cell viability after the printing process.

The urethral stricture, which develops due to scarring process, is treated by urethral dilation and urethrotomy; but in complex and long urethral strictures, substitution urethroplasty is the only option. Autologous genital skin and buccal mucosa grafts are currently used in urethral reconstruction; however risk of complications such as hair ingrowth in the urethra, stone formation and donor site morbidity, restrict the application of these grafts. To overcome this complication, a full thickness, human urethra consisting urothelium and smooth muscle layers on a self-assembled scaffold derived from adipose derived stem cells (ASCs) had been constructed. To obtain a thick self-assembled scaffold, the effect of cell seeding density, O2 level concentration and ascorbic acid concentration were examined under static and dynamic culture conditions. Findings showed that reducing the oxygen level, increasing the ascorbic acid concentration and mechanical stimulation during ASCs culture increases the cell sheet thickness. The biocompatibility assessment of ASC-based self-assembled scaffold showed that seeded urothelial cells (UCs) and smooth muscle cells (SMCs) on the cell sheet were able to grow and proliferate for up to 14 days. Immunocytochemistry analysis revealed that ASC-based self-assembled scaffold was able to maintain the UCs markers (Ck7, CK20, UPIa and UPII) and SMC markers (α-SMA, MHC and Smootheline) expression by UCs and SMCs respectively, over the period of 14 days culture. In conclusion, the ASC-based self-assembled scaffold seeded with UCs and SMCs has potential to be developed into a tissue-engineered human urethra for urethral reconstructive surgeries.

Utilising MEW it is possible to create membranes with micrometre accuracy. However, the use of high voltage in the printing process imposes special challenges for the use of and the printing on support materials when compared to other 3D printing processes [1]. By combining fused deposition modelling (FDM), extrusion printing and MEW on one commercially available 3D printer, it was possible to reproduce the conical shape, the structural and acoustic properties of the human tympanic membrane. Extrusion printing was used to create a conical support structure over which the MEW fibres were deposited. FDM was used to print a ring around the MEW structure, which improved the handling of the scaffolds. The design of the support structure had significant influence on the placement of the individual MEW fibres and their diameter. Consequently, the mechanical properties of the manufactured scaffolds as well as the attachment and growth of keratinocytes on the scaffolds highly depended on the specific design of the support structure.

CYTO-COMPATIBILITY AND BIOACTIVITY OF "SPRAYED" SILK FIBROIN ON HUMAN INTERVERTEBRAL DISC CELLS AND MESENCHYMAL STROMAL CELLS

Andreas Croft$_P$[1]

[1] *Tissue Engineering for Orthopaedics & Mechanobiology (TOM), Department for BioMedical Research (DBMR) of the Medical Faculty of the University of Bern, University of Bern, Bern, Switzerland.*

Intervertebral discs (IVD) are essential for six Degree-of-Freedom motion. However, a great drawback of an IVD is its minimal capacity for self-repairing. A promising approach to solve this problem could be the application of Bombyx mori silk. In this study, we aimed to test the cyto-compatibility and bioactivity of "sprayed" silk films in-vitro on primary patient-derived cells.

Human bone-marrow derived mesenchymal stromal cells (hBMSCs) were either seeded on a silk film or onto plastic as controls. Cells were then expanded for one week and subsequently cultured for 21 days with the addition of three growth factors (GFs); either TGFβ1, GDF6 or FGF2 to achieve a more disc-like phenotype. Then, the cell's metabolic activity, the DNA and glycosaminoglycans (GAGs) content and cell viability (CV) were analyzed.

HBMSCs' CV in medium containing TGFβ1 was higher on silk than on plastic, i.e., 92% vs. 66%.; with GDF6 it was 93% vs. 97%, and with FGF2 it was even reduced to 31% vs. 96%, respectively. In serum-free medium it was 96% and 95%, respectively. However, the cell's metabolic activity on silk was only between 36% and 65% of that on plastic after 21 days of culture, except for FGF2, where a 20% higher activity was observed on silk. Furthermore, cells cultured on silk produced half as many GAGs as the controls.

Current silk's cyto-compatibility revealed that fibers possibly should be functionalized with fibronectin or similar. Future work will focus on functionalization of the silk with specific growth factors and scaffold design.

In our previous research, we found that in addition to the well-known extracellular matrix-related expression of Sox9, chondrogenic differentiation of progenitor cells is driven by a defined bi-phasic expression of Sox9: an immediate early and a late (extracellular matrix associated) phase expression. In this study, we aimed to determine what biological processes are driven by Sox9 during the early phase of chondrogenic differentiation.

Sox9 expression in ATDC5 cells was knocked-down by siRNA transfection at the day before chondrogenic differentiation or at day 6. Samples were harvested at 2 hours, and 7 days in differentiation. The transcriptome (RNA-seq) and proteome (LC MS/MS) were compared using pathway and network analyses. Total protein translational capacity was evaluated with the SuNSET assay, active ribosomes with polysome profiling and ribosome modus with bicistronic reporter assays.

Early Sox9 knockdown severely inhibited chondrogenic differentiation weeks later. Sox9 expression during the immediate early phase of ATDC5 chondrogenic differentiation regulates the expression of ribosome biogenesis factors and ribosomal protein subunits. To validate functional consequences of siSox9 treatment for ribosome function, we evaluated total translational capacity, polysome profiles and ribosome modus. Translational capacity was decreased by siSox9 treatment and this correlated to lower amounts of active mono- and polysomes. Finally, cap- versus IRES-mediated translation was altered by Sox9 knockdown.

Here we identified an essential new function for Sox9 during early chondrogenic differentiation. A role for Sox9 in regulation of ribosome amount, activity and composition may be crucial in preparation for the demanding proliferative phase and subsequent extracellular matrix-production of chondroprogenitors.

Abstract **#1377**

3D BIOPRINTED COLLAGEN-GELATIN: BIOINKS FOR ADVANCED WOUND HEALING

3D bioprinting has brought the biofabrication arena to an optimistic end by advancing the patterning approaches towards mimicking the extracellular matrix (ECM) of the native tissues. However, this approach is highly associated with the limitations of bioinks selection and availability. In wound healing, the major remaining challenge is the fast biodegradation of the existed bioinks post-implantation resulting in tissue regeneration failure, especially in large wounds. This study investigates the ability to print a hybrid of collagen-gelatin hydrogels (Col-Gel) for potential application in extensive wound healing. Col-Gel was first formulated printable by crosslinking with different concentrations of natural crosslinking agent (genipin). Further assessment was done by measuring the swelling ratio, viscosity, crosslinking degree, biodegradability, mechanical testing, and in vitro biocompatibility. The gross appearance results showed that the printed Col-Gel preserves high shape fidelity post-printing. The Col-Gel rheological properties were highly dependent on the crosslinking degree as increasing genipin concentrations leads to lower swelling ratio and viscosity. The biodegradation results confirm the ability of Col-Gel bioink to maintain its shape up to 14 days post-printing. Furthermore, the bioink showed over 90% cell viability with excellent cell adhesion and proliferation. Our results represent a new potential bioink for 3D bioprinting in wound healing.

Biomaterials for tissue engineering aim not only to possess adequate biodegradation rate, mechanical strength, and structural properties but also to effectively deliver specific growth factors to actively and timely guide cellular differentiation.

Polycaprolactone (PCL) meshes have been extensively used for bone tissue engineering due to their excellent mechanical properties and biocompatibility. However, PCL has high hydrophobic properties and lacks surface functional moieties, which often result in insufficient bone inductivity. Their bone-forming capacity can be improved by immobilization of bone morphogenic protein-2 (BMP-2), a strong osteoinductive factor, by various techniques. However, protein immobilization onto PCL is associated with challenges such as: (i) Impaired biological activity due to conformational changes of proteins during immobilization and (ii) influence of stability of BMP due to solvents used during the chemical conjugation processes. In this study, we aim to circumvent these problems by subjecting melt-electrowritten PCL meshes to low-pressure plasma treatment and subsequent exposure to an additional grafting procedure to immobilize BMP-2 onto the fiber surface. Surface characterization was performed using X-ray photoelectron spectroscopy for surface chemical analysis and scanning electron microscopy for morphological visualization. Surface analysis of the nanofibers confirmed the successful immobilization of protein. Moreover, luciferase reporter cells will be used to monitor the activation of BMP signaling. Taken together, we conclude that non-thermal plasma technology is a potent tool for protein immobilization and may be an effective modification method for improving and tailoring scaffold properties for bone defect regeneration.

Microphysiological systems (MPSs), also known as Organ-on-chip (OOC) are in vitro microfluidic models of organ function that attempt to mimic the in vivo microenvironment of the component tissues of an organ. However, when applied to toxicity testing of pharmaceuticals, multi-organ interactions are sometimes necessary. Cocultures or Body-on-chip (BOC) can link up to 10 MPSs microfluidically[1]. This brings two important challenges, the pharmacokinetic tissue:tissue and tissue:media ratio, as well as the need for a universal media formulation that will provide optimum cell growth in all linked microenvironments [2] Machine Learning and Artificial Intelligence methods have been proposed to address these challenges[3]. We address the latter by constructing a stoichiometric matrix of 10 commercially available cell culture medias. Using machine learning algorithms we show that optimal universal media formulations can be found for several configurations of body-on-chip systems.

Bone-associated diseases account for more than 145 billion euros per year in the US and Europe alone, so being able to understand underlying mechanisms and having reliable models is key in the future of not only medicine and pharma but also economy and society. In vitro models are a widely used tool in order to explore diseases, biological processes or for drug-screening purposes. However, traditional 2D models lack most of the interactions present in in vivo microenvironments whereas existing 3D models lack the geometrical, heterogeneity and spatial distribution needed to better mimic bone architectures. 3D Bioprinting, which uses Computer Aided Design (CAD) to deposit chosen materials and biological components in predefined architectures emerges as a key tool for achieving higher complexity models that could integrate both 3D culture features, along with specific material properties or cell types (co-culture) in different compartmentalized areas. In this work we propose a customizable 3D Bioprinting platform that can be used to reproducibly manufacture high-throughput multimaterial interphases in in vitro models granting control over special physical, chemical and biological properties, and its application for vascularized bone studies. These interphase-based vascularized-bone-chips are composed of an inner circular region, with stiffnesses below 10 kPa which holds HUVEC cells stimulated by VEGF, surrounded by an outer ring, with stiffnesses over 30 kPa that contains BMP-2 to stimulate osteogenesis of hMSCs cells. The model emulates the endothelial and osseous components of bone, which we will use to investigate appropriate phenotyping and effect of interphases in paracrine signaling between compartments.

The high failure rate of osteosarcoma (OS) drug discovery is steadily increasing owning to the limited predictability of the current preclinical models. Advances in functional and biomimetic materials from natural or synthetic origin have been contributed to the faithful recapitulation of a broad range of diseases' pathophysiology.1,2 In this scope, the potential of methacryloyl platelet lysates (PLMA)-based hydrogels for cell culture purposes3,4 are herein explored to establish an OS tri-culture model for tumor invasiveness studies and drug screening.
The architecture and synergistic interaction of an invading OS tumor was recapitulated encapsulating OS spheroids in PLMA hydrogels, alone or co-cultured with human osteoblasts and human bone-marrow mesenchymal stem cells (hBM-MSC). PLMA hydrogels supported tumor growth and the formation of tumor invasive branches from the spheroid in both settings. However, the presence of surrounding stromal cells potentiated tumor invasiveness ability into the ECM-mimicking matrix. The deposition of bone-related proteins and minerals were also observed. The exposure of the established models to doxorubicin revealed a higher IC50-value of PLMA-based models, comparing with scaffold-free spheroids. The proposed 3D OS models highlighted the potential of PLMA hydrogels to support an invasive tumor behavior and recapitulate tumor-stromal cell crosstalk, exhibiting a physiologically predictive microenvironment for OS drug discovery.

The scaffolds based on natural polymers can be used for various treatments of bone injuries. This scaffold loaded with biological factors or active substances can lead to bone regeneration and suppress the patient's pain or the immune response. Gelatin is a promising polymer for this application because of its biocompatibility, biodegradability and availability, but it has poor mechanical properties. To overcome this problem we blended gelatin with polyvinylpyrrolidone (PVP) because of its amorphous structure and favorable adhesive behavior. The synthesized scaffold was cross-linked with glutaraldehyde and lyophilized. We also added ibuprofen to reduce pain and tissue inflammation. The aim of this work was to optimize the composition of scaffold fabricated by semi-solid 3D printing, as well as to examine the impact of PVP and ibuprofen on the mechanical and thermal properties of fabricated scaffolds. Chemical interactions during processing were investigated by FTIR spectroscopy. Thermal analysis of scaffold was done using DSC method. Scaffold morphology was followed by SEM analysis. In vitro drug release study under physiological conditions was performed to investigate the influence of gelatin/PVP ratio and scaffold morphology on drug release profiles. Mechanical properties such as hardness, toughness, tensile strength and bone adhesion were investigated by Texture Analyzer.

Acknowledgment: This project has received funding from the European Union's Horizon 2020 research and innovation programme under grant agreement No. 952033.

Abstract **#1385**

FROM CLASSICAL BIOMATERIALS TO MODERN CONCEPTS FOR BONE AND OSTEOCHONDRAL TISSUE ENGINEERING – DEVELOPMENT OF MODULAR MATERIAL SYSTEMS FOR 3D (BIO)PRINTING

Anja LodeP1

[1] *Technische Universitaet Dresden, Centre for Translational Bone, Joint and Soft Tissue Research*

Corresponding author's email: anja.lode@tu-dresden.de

The advent of additive manufacturing technologies in tissue engineering has revolutionized this research field by strongly extending the options for the development of complex tissue substitutes and models. In the last years, enormous progress was made to adapt biomaterials for 3D printing technologies and to refine the techniques to allow bioprinting – the integration of biological components, i.e. cells and/or growth factors, in the fabrication process. Extrusion-based 3D (bio)printing has great potential for skeletal applications as volumetric constructs with clinically relevant dimensions can be produced in an appropriate time window and various biomaterials and/or multiple cell types can be combined within one construct by using multi-channel tools.

This presentation describes the development of modular material systems suitable for extrusion 3D (bio)printing: Based on classical bone replacement materials, self-setting calcium phosphate cements (CPC) and mesoporous bioactive glasses (MBG), printing materials were generated with tailorable degradation properties and various drug delivery functions. Bioinks with excellent printing fidelity, consisting of alginate and methylcellulose, were functionalized with microparticles (e.g. MBG or magnetite), nanoclays (e.g. Laponite) or natural matrix components to obtain growth factor delivery and cell supportive features or to allow magnetically actuated mechanical stimulation of the embedded cells. Methods for combined processing of bioinks and CPC-based printing materials, by using tandem or core/shell printing, were established and successfully applied towards the fabrication of individualized, complex bone and osteochondral implants.

In vitro tumor invasion modelling combining 3D biomimetic materials and multicellular spheroids has sought to achieve the complexity of tumor microenvironment, including for osteosarcoma (OS).1-3 However, the lack of mechanical stimuli, tumor-stromal cell interaction and tumor angiogenesis are critical limitations. Recent advances in engineered organ-on-a-chip platforms have revealed the potential of these microsystems to recapitulate pathological features.4,5 In an attempt to provide a dynamic platform for OS tumor invasion modelling, the aim of this study is the development of a human osteosarcoma-on-a-chip to establish the vasculature-bone tumor barrier.

A microfluidic chip was designed to comprise a channel to introduce an ECM-mimicking matrix and perfusable channels to recreate vascular vessels through endothelial cell culture. Exploring a fully human-derived approach, MG-63 tumor spheroid was embedded in human methacryloyl platelet lysates (PLMA)-based hydrogel. The synergistic tumor-stromal cell and cell-extracellular matrix interaction of an invading tumor was studied in mono- and co-culture configurations. As result, the tumor growth was supported and an increased spheroid invasion into the co-culture model was verified. The development of microcapillary-like protrusions into the hydrogel was also evaluated, opening up the opportunity to recreate the tumor intravasation process. The presented human 3D dynamic model provides the first osteosarcoma-on-a-chip to study tumor progression events, offering an innovative platform for anticancer therapies screening.

EFFECT OF INNERVATION ON PANCREAS INFLAMMATION

Adrián Seijas Gamardo[P][1], Lorenzo Moroni[1], Paul Wieringa[1]

[1] MERLN Institute for Technology-Inspired Regenerative Medicine, Complex Tissue Regeneration Department, Maastricht University, The Netherlands

Corresponding author's email: a.seijasgamardo@maastrichtuniversity.nl

Patients that undergo an islet transplantation suffer from 50% loss of transplanted islet mass postintervention, during engraftment period. Among other causes inflammation plays a detrimental effect on them. Here, we present endogenous innervation as a novel regenerative medicine approach to improve tissue implantation outcomes. During islet transplantation in diabetic patients, several proinflammatory cytokines are expressed, including interleukin 1ß (IL-1β), tumor necrosis factor-a (TNF-α) and interferon-g (IFN-γ). This inflammation decreases the viability and functionality of islets, negatively affecting transplantation outcomes. Transplanted pancreatic islets can become innervated depending on the transplantation site. These neurons influence cell behavior by secreting neuropeptides, such as substance P (SP), vasoactive intestinal peptide (VIP), or calcitonin gene-related peptide (CGRP). Little is known about the effect of these neuropeptides on pancreas inflammation. However, understanding which cytokine combinations lead to cell death pathways, and the neuropeptides that modulate this response, will help understanding their mechanism of action. Thus, improving the outcome of islet transplantation. In this study, we cultured INS1E cells and assessed cell viability after exposing them to pro-inflammatory cytokines in different combinations with neuropeptides. Pseudoislets were also cocultured with neurons derived from iPSCs in order to show the innervation that can occur after transplantation. We confirmed the detrimental effect of cytokines when applied to cell cultures and observed mitigation of these effects in the presence of neuropeptides. These results suggest that a correct innervation is key for maintaining homeostasis in the pancreas and give insights into mechanisms involved in cell survival, informing future strategies for tissue implantation.

MULTIFACETED POLYACTIVE® GUIDANCE CONDUITS WITH DISTINCTIVE DOUBLE-LAYERED ARCHITECTURE AND PLASMA-INDUCED INNER CHEMISTRY GRADIENT FOR THE REPAIR OF CRITICAL-SIZED NERVE DEFECTS

Rouba Ghobeira[P][1], Paul Wieringa[2], Stijn Van Vrekhem[1], Sheida Aliakbarshirazi[1], Iuliia Onyshchenko[1], Nathalie De Geyter[1], Lorenzo Moroni[2], Rino Morent[1]

Despite all tissue engineering advances, the lately designed nerve guidance conduits (NGCs) are still failing in repairing critical-sized nerve defects. Our goal was therefore to tackle large nerve gaps (2 cm) by designing an NGG possessing refined physicochemical properties enhancing Schwann cell (SC) performances and thus triggering a potent nerve regenerative capacity. To do so, a combinatorial strategy adopting novel plasma-induced surface chemistry and architectural heterogeneity was considered. A mechanically suitable copolymer (Polyactive®) was selected and electrospun to produce nanofibrous NGCs mimicking the neural extracellular matrix. An innovative double-layered architecture consisting of an inner wall comprised of bundles of aligned fibers with intercalated random fibers and an outer wall fully composed of random fibers was conceived to synergistically provide cell guidance cues and a sufficient nutrient inflow. NGCs were then subjected to argon plasma treatments making use of a dielectric barrier discharge (DBD) and a plasma jet (PJ). The DBD treatment homogeneously increased the inner O-content from 17% to 28%. The PJ treatment created a chemistry gradient with an O-content gradually increasing from 21% to 30% along the inner NGC wall. In vitro studies revealed enhanced SC adhesion and elongation on plasma-treated NGCs. Interestingly, a cell gradient was observed on PJ-treated NGCs thus underlining the favorable chemistry gradient in promoting cell chemotaxis towards high O-contents. A gradual change from circular to highly elongated SC morphologies mimicking the natural bands of Büngner was visualized along the gradient. Overall, plasma-treated NGCs are promising candidates paving the way towards critical nerve gap repair.

Soft tissue injuries are common in daily clinical and surgical practice. Outcomes of degradable and non degradable suture materials are often affected by mechanical mismatch, excessive fibrosis and inflammation. This study introduces a mandrel-less electrodeposition method able to fabricate continuous microfiber wires, with controlled micro-architecture and tunable mechanics. Poly(ester urethane) urea (PEUU) microfiber wire morphology and mechanical properties have been characterized by scanning electron microscopy uniaxial tensile test respectively Furthermore, the in vitro response of mouse bone marrow-derived macrophages to PEUU degradation products, PEUU electrospun and casted scaffold, PEUU electrospun wires was evaluated by immunoblotting and immunolabeling. Moreover, the host response to electrospun wires in vivo was tested: twenty rats, randomized in 5 groups, received a 2cm infra-scapular incision and the skin was closed using PEUU microfiber and cast wires and the most common suture materials used (polyglycolic acid, polydioxanone and polypropylene). After one month, mechanical and histological evaluation of explants and suture wires was performed. In vitro results have shown an anti-inflammatory macrophage response associated to PEUU microfiber scaffold and wires. In vivo, PEUU electrospun wires group showed better mechanical performance compared to the other groups, a favorable collagen remodeling comparable to the healthy group and a mild host response reaction. These results suggest that microfiber wires reduce macrophage pro-inflammatory response and improve collagen deposition, which make it an ideal candidate for soft tissue suture applications.

There have been many studies conducted into the delivery of factors, such as small molecules, to support and augment new bone formation. It is essential to control the spatio-temporal release kinetics of such factors in order to enhance their efficiency and reduce the side effects of their high dose [1]. This study aimed to investigate the effect of adenosine release from microparticles designed for local release of adenosine for bone tissue engineering applications. Polymer microparticles (MPs) were formed using a solid-in-oil-in water(s/o/w) emulsion based on a previously published protocol [1]. Primary human mesenchymal stem cells (MSCs; Batch No: 18TL262066 from Lonza) were seeded into MPs sintered to form disks and cultured in osteogenic induction media. Alizarin Red staining were conducted after 3 weeks to evaluate the mineralisation and hence differentiation of MSCs to the osteoblast lineage. Alizarin Red staining and quantification analyses illustrated a significant increase ($p < 0.0001$) in mineralisation when MSCs were cultured in the MPs releasing adenosine after 3 weeks of induction. Microscopy imaging also demonstrated improvement of calcification around the cells in the PLAGA/Ad samples. These data clearly illustrate the beneficial effect of release of adenosine from MPs in the osteogenic differentiation of MSCs on these microparticles. Further in vivo studies will investigate osteoinductivity of PLGA/Ad MPs when implanted in critical-sized bone defects.

ENGINEERING ORTHOPAEDIC CELL THERAPIES: TRANSLATION TO THE CLINIC

Alicia El Haj[P][1,2]

[1] *Healthcare Technology Institute*

[2] *University of Birmingham*

Corresponding author's email: a.elhaj@bham.ac.uk

Regenerative medicine principles are based on the power of progenitor cells to regenerate and grow tissues in vitro and in vivo. Engineering provides the platforms and tools which enable the control and manufacture of cells used for clinical therapy and regenerative models. Biological and physical factors play a key role in enabling the cell niche which supports the capability for rebuilding tissue complexity. Using our knowledge of controlling in vitro tissue growth, we can begin to engineer new ways to implement regenerative approaches in vivo for treating patients. One aspect of this is how to control injectable cell therapies, which can then be used routinely within a hospital or primary care environment.

Here, we describe a novel bio-magnetic technology, MICA, where magnetic nanoparticles (MNPs) are used to remotely deliver mechanical stimuli to the cell-surface mechano-receptor, TREK-1, resulting in activation and downstream signalling via an external magnetic array which can be used for multimodal targeting and imaging. In these studies, we have translated MICA to a pre-clinical ovine model of bone injury to evaluate functional bone repair. We present evidence to support early accelerated repair and preliminary enhanced bone growth in MICA-activated defects within individuals compared to internal controls. The variability in donor responses to MICA-activation was evaluated in vitro revealing a clear relationship between responders to MICA in vitro and in vivo. These unique experiments offer exciting clinical applications. Translation and commercialisation of this 'novel' technology presents challenges in regulatory and clinical adoption which will be described.

Introduction: Engineered and decellularized extracellular matrices (dECM) are receiving increasing interest in bone tissue engineering. Current limits mainly arise from the important variability of performance which can result from the use of primary cells but also from the decellularization method. In this study we propose to overcome these barriers using a customized human mesenchymal stromal cell line (hMSCs) capable of reproducible cartilage formation. We here investigate the possibility to efficiently decellularized our cartilage graft while maintaining its osteo-inductive capacity.

Method: Our graft consists of in vitro engineered cartilage tissue produced by the hMSCs. Subsequently, the tissue is decellularized by a combination of hypertonic/hypotonic, detergent (SDS) and DNase washes. To assess the capacity to instruct bone formation by endochondral ossification, the decellularized constructs are implanted subcutaneously in the back of ID mice for 12 weeks. Readouts consists in histochemistry, biochemical analysis and micro computed tomography (µCT).

Results: We demonstrated the reproducible engineering of decellularized cartilage by exploitation of a mesenchymal line. Decellularization resulted in a drastic reduction of DNA (96%) with a minimal impact on tissue structure and composition (collagen, GAGS and embedded growth factors). After 12 weeks in vivo, extensive tissue remodelling was found on decellularized material as confirmed by µCT.

Conclusion and discussion: Our study illustrates the capacity of exploiting customized human lines to produce osteoinductive dECM. The strategy offers both reproducibility of performance and unlimited tissue availability, opening new avenues for the manufacturing of dECM for bone repair.

CHEMICALLY DECORATED DECELLULARIZED CORNEA AS FULL-THICKNESS STROMAL SUBSTITUTE

Juhi Chakraborty[P][1], Subhadeep Roy[1], Sourabh Ghosh[1]

[1] *Indian Institute of Technology Delhi*

Corresponding author's email: chakraborty.juhi21@gmail.com

During the ongoing Covid-19 pandemic, collection and donation of human cadaveric corneas are cumbersome. Decellularized corneas (DC) have gained intense popularity as a possible scaffold for corneal remodeling and as an alternative tissue source for corneal replacement. However, DC elicits immune response inspite of elimination of the cellular contents/antigens due to distortion of the collagen fibrils that exposes certain antigenic sites, which often lead to graft rejection. Therefore, here, we tested the hypothesis that cross-linking DC with chondroitin sulfate (CS) may help in restoring distorted conformational changes of the fibrous matrix and would reduce graft rejection. An in vitro immune response study confirmed that the cross-linked DC elicited the least immune response than DC. We implanted three sets of corneal scaffolds obtained from goat, i.e., native, decellularized, and DC conjugated with CS into rabbit stroma. Histology analysis, three months post-implantation confirmed seamless graft integration, cell migration, and no sign of inflammation in the crosslinked cornea. However, so far we have checked the immunogenic potential of decellularized and crosslinked cornea among cross-species(goat to rabbit). Now, before moving to a human clinical trial (patients with infectious keratitis), we are validating the decellularization of the human stromal layer using discarded human corneas not suitable for implantation, for the regeneration of the corneal endothelial layer. The decellularized, chemically decorated cornea will be tectonically strong, offer less immunogenicity, can be sterilized, and will have a longer shelf life. Through this novel study, we can meet the demand for alternative bioengineered human cornea for keratitis patients.

Current methods for chordae tendineae (CT) replacement do not recapitulate the micro-architecture nor the mechanics of the native CT and do not promote healthy tissue regeneration. This study introduces a mandrel-less electrodeposition methodology to create a biomimetic engineered CT (BECT) using a bio-absorbable polymer. Human and porcine CT were harvested and tested to evaluate mechanical and histological native tissue structure. Poly(carbonate-urethane) urea was used to fabricate BECT via mandrel-less electrodeposition. Moreover, BECT were micro-integrated with NIH-3T3 rat fibroblasts. Micro-integrated BECT were divided in 3 groups: static culture in plate, tension culture in plate and dynamic culture using a stretch bioreactor. All groups were conditioned for 1 week. Finally, scanning electron microscopy (SEM), uniaxial tensile testing and histological evaluation were performed to compare native tissue and BECT micro-architecture and mechanical properties. BECT mimicked native CT shape, diameter, and length. SEM analysis showed highly aligned fiber microstructure recapitulating the arrangement observed in native CT. BECT mechanical characterization showed a lower elastic modulus than native tissue that increased with dynamic conditioning for cell microintegrated BECT. The histology of cell-seeded BECT demonstrated cell adhesion and infiltration after one week. This mandrel-less electrodeposition method allows the bio-fabrication of BECT that demonstrate the ability to recapitulate native CT structure with use of a scaffold. Micro-integration preliminary data provided evidence of cell proliferation and viability, demonstrating an early proof-of-concept for potential host cell recruitment.

THE COMPARATIVE EFFECTS OF MESENCHYMAL STEM CELL TRANSPLANTATION THERAPY FOR SPINAL CORD INJURY IN HUMANS AND ANIMAL MODELS: A SYSTEMATIC REVIEW AND META-ANALYSIS

Louis Johnson[P1], Eustace Johnson[1]

[1] *Chester Medical School, University of Chester, UK*

Corresponding author's email: eustace.johnson@chester.ac.uk

Animal models have been used in preclinical research to examine potential new treatments for spinal cord injury (SCI), including mesenchymal stem cell (MSC) transplantation. MSC transplants also have been investigated in early clinical human studies and trials. Whether and how well the animal studies inform and represent the human outcomes is unclear. In this study, we have completed a systematic review and meta-analysis to examine the effects of MSC transplants on functional outcomes in humans and animal models (mostly rats) of SCI. Following defined searches in PubMed, clinicaltrials.gov and the Cochrane library, identified papers were screened and available data extracted and analysed. The findings are promising. MSC transplantation was associated with significantly improved American Spinal Injury Association (ASIA) motor and sensory scores in humans and significantly increased locomotor function scores in animals. However, there were major discrepancies between the human and animal studies, including timing of MSC transplant, cell source, scale, modes of MSC delivery, and reports of adverse events. Additionally, difficulties in the comparing functional outcome measures across species limit the predictive nature of the animal research. Previously, we reported on the neurotrophic effects of canine MSCs [1], demonstrated that these activities are influenced by the CNS wound microenvironment [2], and, recently, quantitatively compared the neurotrophic effects of canine and human MSCs [3]. The findings of the systematic review and meta-analysis will be considered in the context of these recent papers, with recommendations for research that better enables the translation of animal models of SCI to human MSC-based therapies.

This study combined Duchenne's muscular dystrophy (DMD) patients' induced pluripotent stem cells (iPSCs) from Centro Cardiologico Monzino's Cardiovascular Biorepository with a re-design of the beating-heart-on-a-chip developed by Marsano et al [1]. DMD is a genetic disease caused by dystrophin gene mutations that frequently cause juvenile-onset cardiomyopathy. Specifically, cardiomyocytes from DMD patients' iPSCs (iPS-CMs) were cultured in the new 'upside down' (UD) chip which consists of two layers: an upper actuation layer that transfers mechanical stretch to cells within a 3D fibrin hydrogel housed in the lower layer bonded to a glass coverslip. Healthy and DMD iPS-CMs harvested from the 2D cultures were transferred to the UD chip and used to optimize: i) day of harvesting from 2D, ii) cell aggregation level (single cells-SC or small aggregates-SA), and iii) fibrin gel concentration (7.5, 10, 20 mg/ml). Cultures were maintained under dynamic conditions (0.5 bar, 1 Hz, 50% duty cycle, 4h post-seeding) and cell viability was assessed after 0, 7 and 14 days. The optimal culture parameters for healthy and DMD iPS-CMs were observed for iPS-CMs harvested on day 17, triturated as SA and seeded in 7.5 mg/ml fibrin. Healthy iPS-CM maturity was demonstrated in the UD chip by high-resolution cardiac troponin T imaging and field potential electrical recordings. The platform is versatile being also suitable for co-cultures and ELISA of cell-conditioned media. Thus it could be exploited for disease modelling to further investigate DMD disease readouts, e.g. calcium dynamics, and gauge the impact of potentially therapeutic drugs.

PROFILING IMMUNE CELL-MATERIAL INTERACTIONS IN INJURY MODELS THROUGH QUANTITATIVE CELL-LEVEL ANALYSES

Ying Luo[P][1], Fang Wang[1], Ni Su[1]

[1] *Department of Biomedical Engineering, Peking University*

Corresponding author's email: yluo.pku@gmail.com

Biomaterials have found important applications as carriers of biological entities for developing next-generation regenerative therapies. However, biomaterial mechanisms and associated functions remain to be elucidated within the context of the immune responses induced in the body. Here we investigate two biomaterial-based systems respectively carrying small RNA molecules and exosome vesicles and report systematic cell-level analyses to understand how cargo biologics were interacting with and taken up by different types of cells in the host tissue. First, polyamindoamine dendrimeric nano materials complexed with small RNA molecules were studied in injured heart tissue in zebrafish. The whole-heart analyses indicated that non-macrophage leukocytes at day 1 and 7 ingested close to 50% RNAs, followed by macrophages, endothelial cells and cardiomyocytes in the injured area. In another system, fluorophore-labeled exosomes derived from mensenchymal stromal cells (MSCs) were immobilized to fibrous polycaprolactone scaffolds and were studied in skin wound-healing models in mice. The analyses on the wounded tissues treated by scaffolds revealed that the exosome vesicles on day 7 were mainly taken up by macrophages at 70% level while the macrophage population accounted for 25% of the total cells. In responding to MSC exosomes, the macrophages in wounds were polarized to the M2 anti-inflammatory subtype, which could further induce beneficial adaptive immune responses. Our study suggest that immune cells were major responders to biomaterial-based systems and mediated heterogenous reactions to affect the delivery pattern and tissue responses. The immune cell-mediated reactions have important implications for guiding the function design of biomaterials.

Implantation is a complex and interactive event between endometrium and hatched blastocyst. The success of implantation depends on the synchronization of endometrium receptivity as well as the capacity of the blastocyst to implant. Use of embryo transfer media enriched with extracellular matrix components or pre-activation of endometrium might not be sufficiently effective for embryo transfer. The aim of this study was to mimic 3D blastocyst implantation environment with endometrial cells seeded onto synthetic polymer foams. The scaffolds were prepared with a blend of poly(D,L-lactide-co-glycolide) and poly(L-lactide-co-D,L-lactide) at different concentrations and lyophilized. The morpholgy and pore size of the foams were investigated with scanning electron microscope. It was observed that the polymer concentration and the freezing temperature before lyophilization affected the pore size of foams. It was decided to use foams with about 60µm pore size in in vitro studies. The foams were coated with collagen, and then seeded with endometrial (epithelial and stroma) cells. Mouse blastocysts were seeded on this construct, and incubated for 48 and 96 hours. The expression of certain implantation markers was investigated by qRT-PCR. It was observed that the expression of genes related with adhesion and invasion like L-selectin, laminin, E-cadherin, collagen IV, integrin, MMP9 were significantly altered within 48-96 hours. The results showed that synthetic polymer foams with endometrial co-culture would be a potential 3D in vitro blastocyst implantation model by supporting adhesion and invasion phases of implantation. Background and aim – Therapeutic application of hiPSC-derived cardiomyocytes (CMs) is considered a promising approach for heart repair. We hypothesized that injection of human iPSC-CM aggregates (hiCMAs) leads to improved cell retention and superior engraftment compared to single cell injection. It was our aim to investigate the regenerative potential of hiCMAs after sub-acute myocardial infarction in a pre-clinical NHP model.

Methods – Myocardial infarction (MI) was induced by coronary artery ligation in cynomolgus monkeys (Macaca fascicularis; n=11). Cardiac function was assessed via telemetric ECG recording, echocardiography and MRI. hiCMAs expressing a fluorescent reporter gene were generated by targeted differentiation in large-scale suspension cultures. 5 - 7 x 10 7 hiPSC-CMs were injected directly into the myocardium 2 weeks after MI. 2 weeks or 12 weeks later, animals were sacrificed and graft survival and cell distribution was assessed histologically.

Results and Conclusion – Both 2 weeks and 12 weeks after cell transplantation, large hiPSC-CM grafts (>1 mm2) were identified in myocardial tissue sections based on their reporter gene expression and after staining with a species-specific antibody targeting human cardiac troponin I. Human iPS-CMs showed alignment and expressed cardiac markers, visible cross striations reflected sarcomeric structures. After hiCMA transplantation, MRI data showed a remarkable functional improvement of LVEF after 12 weeks (n=3), in contrast to the non-treated control. In conclusion, we demonstrated formation of large hiCMA-derived heart muscle grafts 2 and 12 weeks after transplantation in our pre-clinical NHP model associated with a substantial functional improvement.

HOMOGENISATION OF BIOINSPIRED VOXEL-BASED COMPOSITES VIA MACHINE LEARNING ESTIMATION

Mauricio Cruz Saldivar$_P$[1], Mohammad J Mirzaali[1], Eugeni L Doubrovski[2], Amir A Zadpoor[1]

[1] Department of Biomechanical Engineering, Faculty of Mechanical, Maritime, and Materials Engineering, Delft University of Technology (TU Delft), The Netherlands

Corresponding author's email: m.cruzsaldivar@tudelft.nl

Composite design via Voxel-based methods allows manufacturing a wide variety of complex architectures [1]. A grid of volumetric pixels (voxels) enables this advanced digital fabrication method, where each pixel's value represents either a 'soft' or 'hard' composite phase. This point-wise freedom allows incorporating complex bioinspired paradigms (e.g., functional gradients [2,3], multi-hierarchical organisation [3,4]) within designs. Nevertheless, computational modelling of large structures may be computationally expensive. Therefore, we developed a machine learning-based framework to homogenise the non-linear mechanical behaviour of voxel-based structures and tested it on different bioinspired designs.

We designed different sets of particle-reinforced composites with various reinforcement ratios. Then, we manufactured tensile tests samples of these structures with an Objet350 Connex3 printer (Stratasys® Ltd.). The test results and respective reinforcement ratios helped us generate a machine learning-based homogenisation model of any composite's non-linear mechanical behaviour. We performed validations with a subset of the designs using commercial FEM software (Abaqus v.6.14). Finally, we tested the model's performance by downscaling several bioinspired structures' resolution and comparing their mechanical behaviour.

The homogenisations accurately predicted the hyperelastic to elastoplastic transition observed in bitmap structures. We were also able to estimate both elastic and plastic regions for any composite's reinforcement ratio. Downscaling of structures with functional gradients and structures with features of low aspect ratios such as helixes was possible. Nevertheless, decreasing the resolution of fibre-like features showed a significant difference in property estimation. Future work will focus on developing algorithms that consider the unit-cell's overall orientation and its anisotropic properties.

Progenitor cells from the periosteum are major contributors in fracture healing through involvement in the formation of a cartilaginous fracture callus. Recently, differentiated microspheroids assembled into scaffold-free constructs were shown to effectively heal murine long bone defects [1]. In this work, cartilaginous microspheroids were combined with designed melt electrowritten meshes to create a bioengineered callus-like membrane which resulted in bone formation through endochondral ossification.

Melt electrowritten polycaprolactone (PCL) meshes were tailored to contain pores (116 ± 28 µm) designed to allow efficient seeding of microspheroids (180 ± 15 µm). PCL meshes were coated with gelatin whereafter microspheroids attached and spread onto the mesh. After 14 days in chondrogenic media, gene expression analysis demonstrated up-regulation of chondrogenic (SOX9) and prehypertrophic (IHH) gene markers. To assess the bone forming capacity of the "living membranes" (day 14), they were implanted ectopically with meshes-only as control. No mineralization was detected in mesh-only explants but bone and mineralized cartilage was detected in all "living membranes" (25 ± 4 % MV/TV). These data demonstrated differentiation towards prehypertrophic chondrocytes in vitro and that the PCL scaffold did not notably hinder bone formation in vivo.

The high versatility of this biofabrication approach lies in the possibility to tailor the scaffolds to dimensions corresponding to robust biological building blocks, in this case microspheroids. We believe that these strategies will be instrumental in the development of designed living tissues with predictive clinical results upon implantation.

The dynamic conditioning of in vitro tissue-engineered heart valves (TEHVs) is essential to promote synthesis and organization of the extracellular matrix and, ultimately, valve's functionality. To quantify the impact of the individual stimuli (i.e. cyclic stretching, pressure and shear stress) on the maturation of TEHVs, a novel bioreactor was developed in which engineered heart valve tissues can be conditioned under independently controlled mechanical stimuli. Four rectangular tissue specimens (20 x 10 x 1 mm) can be conditioned simultaneously in individual chambers with independent medium circulation. Computational fluid dynamic (CFD) was performed to support the design of the chamber to meet the requirement of creating laminar flow in the region of interest of the tissue specimen and a shear stress up to 71 dynes/cm2. Steady or pulsatile flow (max. average flow rate 2.3 l/min) can be generated, where the amplitude and frequency of pulsatile flow in each chamber can be independently controlled. Furthermore, axial tensile strain up to 25% can be applied to the tissues and physiological aortic pressure (80-120 mmHg) can be reached. The presented bioreactor provides a robust tool for the mechanobiological investigation of engineered heart valve tissue under physiological aortic hemodynamic conditions.

Despite organ-on-chip technologies are now widespread in academic research, translation to commercial products is limited, due to high costs for large scale manufacturing [1], [2].

We have developed and validated a novel system fabricated with low-cost thermoplastic materials, exploiting CO2 laser machining [3], in view of possible adaptation to conventional industrial processes. The platform allows to perform compartmentalized cultures and to monitor in real time the culture growth. It consists of a multilayered cartridge, where the biological sample is hosted and of a 12-well plate compatible static module in which the cartridge is inserted. The versatility of the platform enables to host microporous membranes on which seeding cells, scaffolds, thin tissue biopsies, and precision-cut tissue slices (PCTS)[4]. At the end of the culture, the cartridge can be retrieved by means of a controlled snap-crack mechanism (patent pending) and reused to perform other experiments or analyses. This feature breaks new ground in the field allowing to subject the same sample to different sequential conditionings in different devices recapitulating various pathophysiological microenvironments, and to maintain the morphological integrity for subsequent analysis. We have biologically validated the device with Caco-2 cells and EAhy-926 cells, poured on microporous, commercially available, polycarbonate membranes (Whatmann Nucleopore® 5 µm pore size and it4ip ipCELLCULTURE™ 3 µm pore size, respectively), in static conditions. Cells confluence and density (DAPI), differentiation (JAM for Caco-2, CD-31 for EAhy-926) and gene expression (p53 for Caco-2, VEGF-A for EAhy-926) have been evaluated, showing results comparable with Transwell inserts, our golden standard.

DEVELOPMENT OF A NOVEL TECHNIQUE TO CREATE AN ANISOTROPIC HYBRID MESH FOR HERNIA REPAIR

Alessandra Grillo[P][1], Augustin Barna[1], Zargham Hyder[2], Vivek Mudera[1], Alvena Kureshi[1]

Most common commercial meshes for repair of abdominal hernia are made of synthetic materials, much stronger and stiffer than native tissue, causing recurrence and pain (1). Biological meshes derived from animal tissue provide good biocompatibility but they lack mechanical strength and often fail during tissue regeneration (2). Hence, hybrid meshes have been developed to overcome these issues, combining the strength of synthetic materials and the biocompatibility of biological components. Moreover, surgical meshes are isotropic while the fascial tissue mostly involved in herniation, displays anisotropy with highly aligned collagen fibres (3). This study aims to develop a hybrid mesh combining the benefits of synthetic and biological materials but also offers a unique feature of structural anisotropy to mimic the structure of native tissue. Hybrid constructs were fabricated by embedding a synthetic mesh into a standard collagen type I hydrogel. We developed a novel technique to create anisotropy within the gel which simultaneously combines horizontal shear flow to align the collagen fibres and the principles of the established RAFT technique to increase collagen density to tissue levels (4). The resulting collagen construct showed significant alignment of its fibres in the direction of shear flow. Importantly, this alignment is generated without the use of cells so the method has potential to be used in the fabrication of a novel mesh. Our next step is to demonstrate that this method can be used to generate an aligned collagen component that can be combined with the synthetic mesh to create our unique aligned hybrid mesh.

DECELLULARISED PLEURAL PATCHES FOR PROLONGED ALVEOLAR AIR LEAKS

Trisha Vikranth$_P$[1], Tina Dale[1], Nicholas Forsyth[1]

[1] *Keele University*

Corresponding author's email: t.vikranth@keele.ac.uk

Prolonged alveolar air leaks (PALs) as post-surgical complications to lung resections at an incidence of 26%, is a source of patient morbidity. The gold standard approach to managing PALs is conservative, through extended duration of chest tube drainage, often associated with thoracic pain, pulmonary and pleural infections, and extended length of hospital stays.

Aim:

Develop a tissue-engineered alternative with decellularised porcine pleural membranes (DPPM) as bioactive sealants, reinforcing conventional surgical procedures to seal air leaks, reducing the severity of PALs. The distinction is in its role as bioactive extracellular matrix scaffolds comparable in biochemical and mechanical attributes to native PPM, stimulating endogenous regeneration of lung tissue. Decellularisation ensures retention of native microarchitecture and composition of the membrane with reduced immune intolerance through removal of cellular antigens.

Methods:

PPMs were decellularised and characterised using histology, nuclear DNA staining (DAPI), membrane thickness estimation, and tensile testing.

Results:

H&E staining showed absence of purple stained nuclei in the DPPM, quantitatively confirmed with a significant difference in DAPI stained nuclei between DPPM and native PPM samples ($p < 0.0001$). Membrane thickness of DPPM (218 ± 68 µm) vs native (145.3 ± 33.1µm) were comparable ($p > 0.05$). Tensile testing estimated Young's modulus of DPPM (804±670kPa) vs native (828.4±177kPa) with no significant difference.

Conclusion:

Histological and mechanical studies indicate an efficient strategy to derive DPPM, with the removal of nuclear and cellular antigens and minimal disruption to native structural and mechanical properties. This represents the first step towards a clinical alternative to managing PALs.

Cancer cell immobilization in polymer hydrogels serving as extracellular matrices and cultivation in perfusion bioreactors that provide appropriate chemical signals, efficient mass transfer and hydrodynamic shear stresses is a promising strategy for development of physiologically relevant tumor models. In this work, perfusion cultures of 2 cancer cell types (C6 rat glioma and embryonal carcinoma NT2/D1 cells) immobilized in alginate microgels were established, while static cultures served as controls. Continuous perfusion had different effects on the cultured cells inducing enhanced proliferation of the glioma cells immobilized in microfibers (8x10^6 cell/ml), while reducing the viability of the NT2/D1 cells immobilized in microbeads (1x10^6 cell/ml). In order to elucidate the observed effects, chemical engineering principles were applied to assess mass transfer and hydrodynamic conditions. The second Fick's law was solved analytically while the diffusion-advection-reaction equation was solved numerically to model mass transport in the static and bioreactor cultures, respectively. Moreover, Reynolds numbers, pressure drops and shear stresses in bioreactor cultures were calculated for assessment of flow regime and hydrodynamic conditions. The modeling results have indicated that oxygen transport is diffusion-controlled through the alginate hydrogel, while medium perfusion improves mass transfer of larger compounds having smaller diffusion coefficients (~10^(-13) m^2/s), which possibly stimulated glioma cell proliferation. On the other hand, the obtained shear stress (~50 mPa) in the perfused packed bed of microbeads was above physiological levels, which provided the explanation of the poor NT2/D1 cell survival. This study stresses the importance of multidisciplinary approach in addressing such multifactorial diseases as cancer.

Cardiovascular disease (CVD) is the leading cause of death in individuals over 60 years old. Ageing is associated with decrease in myocardial function and a poorer prognosis following of myocardial infarction (MI). We have demonstrated that oxidative stress induced myocardial senescence contributes to both of these observations. In aged mice, prophylactic treatment with the senolytics drug navitoclax reduces senescence and the expression of SASP associated proteins, resulting in attenuated maladaptive myocardial remodelling and improved survival and functional outcome following MI. Furthermore, MI directly induces senescence and the SASP, as a result of increased oxidative stress, which are detrimental to outcome. In young animals, navitoclax treatment following MI with reperfusion improved left ventricular function, increased myocardial vascularisation, and decreased scar size. Proteomics revealed that elimination of senescent cells attenuated biological processes associated with maladaptive remodelling including fibrosis and inflammation. Cytokine array demonstrated navitoclax reduced expression of proinflammatory, profibrotic and anti-angiogenic cytokines, including interferon gamma-induced protein-10, TGF-β3, interleukin-11, interleukin-16 and fractalkine. Together our studies provide proof-of-concept evidence that cellular senescence and the proinflammatory SASP promote myocardial remodelling in multiple disease settings impairing heart function. Subsequently, senolytic treatment represents a potential novel therapeutic avenue to improve patient outcome for these CVDs.

Multidrug resistance (MDR) has been considered as a main impediment to cancer chemotherapy. In order to overcome drug resistance and inhibit cancer cells viability simultaneously, it is essential to develop a drug delivery system able to carry multiple therapeutic agents. Injectable hydrogel has been widely used in this aspect due to its in situ gelation property and the ability to encapsulate different bioactive molecules. In this study, tetra-armed PEG is crosslinked by complementary DNA sequences to form the network structure of hydrogel system with an MMP-2 cleavable peptide motif in between. Additionally, laponite nanoclay is added to finely tune the gelation and mechanical properties of the hydrogel. Due to specific hydrogen bonds formation between nucleobase pairing, the hydrogel is injectable and self-healable. MDR-targeted siRNAs including Pgp and Bcl-2 siRNAs, were encapsulated in the hydrogel to enhance therapeutic efficacy by overcoming MDR. In this hydrogel, both nucleic acid sequence and laponite nanoclay can be tailor-designed as delivery agents for anti-cancer drug, DOX. The two delivery agents attribute to sequential release of DOX, releasing DOX both before and after the effect of MDR siRNA. Moreover, the MMP-2 cleavable peptide between tetra-armed PEG and DNA deliberately controls hydrogel degradation; thus, resulting in the release of therapeutic cargo. With the tailored design of the hydrogel, we develop a drug delivery system by carrying multiple therapeutic molecules simultaneously to achieve synergistic effect and spatial-temporal control release for cancer therapy.

Silica-based mesoporous nanocarriers (MSNs) have received widespread interest due to their ordered structure and high specific surface area, which allow fine control of drug loading and release kinetics1,2. Ca-containing MSNs are promising bioactive mesoporous drug carriers, as they can release Ca and Si ions that stimulate osteogenic differentiation of stem cells3. Moxifloxacin is an antibiotic with broad antimicrobial activity against aerobic and anaerobic bacteria, which could be applied locally for bacterial elimination in cases of periodontal or peri-implant desease4. The aim of this study was the evaluation of different Ca-doped MSNs in terms of moxifloxacin loading/release profiles, biocompatibility and hemolytic activity. The synthesis of MSNs was performed by the sol-gel method5. Their drug loading and release profiles were assessed with High Performance Liquid Chromatography (HPLC) and their cell viability with the MTT assay on human periodontal ligament cells (hPDLCs). Their hemolytic activity was evaluated in contact with human red blood cells at various concentrations. The loading capacity of Ca-doped MSNs (21-38%) was higher than pure silica (15%), revealing the beneficial effect of Ca. Prolonged release of moxifloxacin was apparent even after eight days. They presented limited hemolysis and no cytotoxicity, while promoting the mitochondrial activity and proliferation of hPDLCs.

This research is co-financed by Greece and the European Union (European Social Fund- ESF) through the Operational Programme “Human Resources Development, Education and Lifelong Learning” in the context of the project “Strengthening Human Resources Research Potential via Doctorate Research” (MIS-5000432), implemented by the State Scholarships Foundation (IKY).

INTRODUCTION: One of the main hypotheses in mesenchymal stromal cells (MSCs) research is that the microenvironment determines the way that cells behave. Our aim is to investigate how bioprinting and 3D culturing lung resident MSCs in porcine lung-derived extracellular matrix (ECM) hydrogels produce changes in cell behavior. METHODS: Rat primary lung resident MSCs were bioprinted and 3D cultured in porcine lung ECM hydrogels presenting a stiffness of 0.7kPa. After seven days of 3D culture, cells were harvested from the scaffolds. Cell adhesion and actin/paxillin staining tests were conducted with the harvested and control cells by seeding them onto specific well-plates for optical imaging and allowed to attach them to the plate for 2h. The expression of surface chemokine receptor CXCR4 was quantified by qRT-PCR. RESULTS: Compared with cells cultured in standard tissue culture plates, cells harvested from the lung ECM hydrogel scaffolds formed focal adhesions 2-fold longer. Moreover, 10-fold more cells were adhered to the substrate after 2h. Finally, the expression of CXCR4 chemokine receptor showed a more than 20-fold increase in the preconditioned cells. DISCUSSION: The data indicate that culturing lung MSCs in the ECM has major impact in their adhesion capacity and in the expression of one the main receptors involved in several relevant processes in vivo. Thus, lung ECM-derived hydrogels have the potential to be used as a scaffold to develop novel in vitro models to better understand mechanisms in MSCs.

3D scaffolds are in the center of attention for tissue engineering applications. So far, there has been continuous progress and competition in design and engineering of biomaterials as scaffold candidates for regenerative medicine[1]. Whilst biomaterials-engineering approaches have mostly focused on a few mechanisms (mostly chemical), achieving suitable tissue biomechanical function remains an important challenge[2]. Besides, there are concerns that sustainable tissue engineering may not be achievable with current approaches[3]. This calls for further profound studies, emphasizing the need to imitate the structural and mechanical properties of the target tissue. Conventional 3D scaffolds suffer from limited depth of infiltration for cells due to their low porosity and/or not meeting the biomechanics of the target tissue, especially for regeneration of load-bearing tissues. In this study, we have designed and fabricated a model of silk fibroin knit scaffold, which along with post-fabrication degumming, results in a more bulky and less open structure compared with conventional knit fabrics. Our scaffold shows outstanding cell-scaffold interaction including full 3D cell attachment, 360-degree cell coverage around individual filaments, and full-thickness cell infiltration depth. The optimized structure alleviates the need for the in-advance filling of the pores and provides users with full depth access to the knit structure for increased cell adhesion and infiltration. From a mechanical viewpoint, the scaffold shows high elasticity and recovery upon unloading (up to around 90% strain), thanks to its intermeshed loops. Overall, our SF weft-knitted construct represents appropriate characteristics for the regeneration of load bearing tissues.

Cells can transmit mechanical signals to their interior via sub-cellular organelles including mechano-sensors, signalling molecules and cytoskeletal proteins, which play pivotal roles in cellular activities such as migration and orientation. Our previous results discovered mechano-responsive, omni-directional and compression-induced actin protrusions (CAPs) in human mesenchymal stem cells (MSCs) encapsulated in 3D collagen micro-tissues, but the mechano-regulation of CAP formation is still unknown. Here, we investigate the roles of three major RhoGTPases on mediating the formation of CAPs via an alteration of actin cytoskeletal reorganization in MSCs. Cyclic compression loading markedly upregulated Rac1 (but not CDC42 and RhoA) gene expression and its activity, suggesting its critical roles on the regulation of CAP formation. Upon GTPase suppression by specific inhibitors during compression, only Rac1 activity was significantly repressed, associating with significantly reduced CAP formation. Silencing the upstream regulators, including Rac1, of these pathways dramatically disrupted actin protrusions and elongated cell morphology. Silencing cortactin (CTTN), a proximal effector of Rac1 pathway, induced a compensatory activation of Rac1 signalling and its related downstream proteins without CAP formation but compression loading partially restored CAPs. The dominating role of Rac1 signalling and corresponding expression of lamellipodial markers suggest that these CAPs are very likely to be lamellipodia formed in 3D configurations upon compression loading-based stimulation. This study delineates the mechanism of compression-induced cytoskeleton reorganization in MSCs, rationalizing mechanical loading regimes for functional tissue engineering.

IMPRESSIVE ACCELERATION OF BONE REGENERATION BY ALLOGENEIC DEVITAL SOFT CALLUS MIMETIC CONSTRUCTS

Debby Gawlitta[P][1], Alessia Longoni[1], Lizette Utomo[1], Abbie Robinson[1], Riccardo Levato[2], Antoine Rosenberg[1]

Corresponding author's email: d.gawlitta@umcutrecht.nl

Clinical implementation of endochondral bone regeneration (EBR) could be significantly accelerated by the use of allogeneic devitalized cartilaginous templates. Nevertheless, previous attempts involving devitalized cartilaginous constructs showed subpar bone regeneration compared to their living counterpart (1,2). The aim of this study was to develop devitalized cartilaginous scaffolds that could enhance EBR in vivo. Additionally, the influence on EBR of chondrogenic or hypertrophic differentiation prior to devitalization was evaluated.

Allogeneic mesenchymal stromal cells (MSCs) were embedded in collagen and chondrogenically or hypertrophically induced prior to devitalization. It was confirmed that the devitalization procedure did not affect matrix composition (total protein, glycosaminoglycan, collagen) or ALP activity. Devitalized and vital chondrogenic or hypertrophic constructs were implanted in a critical-size rat femur defect. New bone formation was measured by micro-CT (4, 8, and 12 weeks) and confirmed with histology at 12 weeks.

Full bridging of all defects was observed for the devital chondrogenic (DC) constructs, already after 4 weeks. After 12 weeks, bone volume observed in the DC implants was superior compared to their living counterparts (97.4±11.2mm3 versus 38±26 mm3) and to both hypertrophic groups. Histological analysis displayed remodeling into cortical and cancellous compartments, only in the DC group. No adverse immunological reactions against the allogeneic DC implants were observed.

Here, we present for the first time MSC-derived devitalized cartilage constructs that go beyond the state-of-the-art and outperform their living equivalent in reproducibility and rate of bone regeneration. Their allogeneic origin and devital state are highly attractive for off-the-shelf clinical application.

Mesenchymal Stromal Cells (MSCs) are effective therapeutic agents enhancing the repair of injured tissues mostly through their paracrine activity. Although MSCs are found in virtually all organs, bone marrow (BM)-MSCs and adipose tissue (AD)-MSCs are most commonly used in clinical practice. Increasing evidences show that besides the secretion of soluble molecules, the release of extracellular vesicles (EVs) represents an alternative mechanism adopted by MSCs. Within this, we aimed to characterize EVs released by both human AD-MSCs and BM-MSCs to investigate their involvement as modulators of MSC paracrine effects. EVs have been isolated from the conditioned media of AD- and BM-MSCs by serial differential centrifugations in order to collect both medium-sized and small-sized EVs. EV morphology has been characterized by transmission electron microscopy (TEM), while their size and concentration by tunable resistive pulse sensing (TRPS). The expression of the tetraspanin family members was evaluated using a non-conventional flowcytometry approach. The role of both medium and small-sized EVs in the different phases of the endochondral ossification process has been evaluated by ex vivo mouse metatarsal culture model. A human protein cytokine array was used to define the profile of the EVs secreted by MSCs. Although EVs derived from AD and BM-MSCs present similar characteristics in terms of size, concentration and marker expression, they possess significant differences in their protein content that are reflected in their functional effects. Taken together, these results indicate that EVs released by AD- and BM-MSCs present functional differences which should be taken into consideration when planning EV-based therapies.

Cleft lip and palate (CLP) is the most common orofacial birth defect with a prevalence of about 1:1000 newborns causing problems mainly for suctioning and later for speaking[1]. About 45% of patients with CLP have a cleft in the soft palate. After surgery, dysfunction persists in around 30% of cases due to fibrosis[2]. The soft palate is formed by five different skeletal muscles of which the major one is the levator veli palatini (LVP)[3]. Our group established a model for muscle regeneration consisting of a biopsy wound in the LVP of the rat that shows fibrosis and impaired soft palate regeneration[3]. Yet, functional analysis of the rat soft palate has never been done up to now. Therefore the aim of this study is to establish a model to analyze the function of the normal and the wounded soft palate. Through wireless telemetric electromyography (EMG) the muscle electrical activity was measured while the rat is eating, drinking or grooming. While EMG signals are taken, the behavior of the rats is being video-recorded. The EMG signals and the videos were compared to analyze the muscle activity during these behaviors. Parameters such as train duration and peak amplitude were analyzed. The train duration did not show significant differences before and after surgical wounding while the peak amplitude was lower after wounding that indicates the function is affected in the wounded soft palate. This model for functional analysis will be useful to measure the muscle activity during regeneration after the application of muscle constructs.

Keywords

method development; cleft palate; electromyography

Scaffold-free regenerative approaches have captivated the interest of clinical stakeholders due to promising results achieved by pioneering strategies. However, biomaterial-free structures are often assembled either as thin two-dimensional cell sheets or spherical microaggregates, both limited on their ability to be deposited in a free-form manner, and dependent on complex processes for macroscale 3D upscaling. The shape of a fiber favors architectural free form positioning, and may be adapted to textile or printing technologies.We recently reported the rapid one-step fabrication of centimeter-long cellular fibers made of human mesenchymal stem cells derived from the adipose tissue (hASCs) [1]. A hanging column device enabled cells to be pulled to the apex of a stable liquid column, resulting in cell aggregation. Living hASCs fibers showed high cell viability, and were non-toxic in an ex vivo chick embryo chorioallantoic membrane (CAM) model. Cells could also invade simplified in vitro ECM-mimetic hydrogel models, while keeping the secretion of pro-regenerative and immunomodulatory factors overtime. The malleable character of the hASCs fibers enabled injecting them through needles and using them as shape-adaptable fillers in model defects. Despite their easy handling, the application of cell fibers in complex surgical procedures or as implantable living devices in tissues continuously subjected to mechanical stimulation justifies the development of tougher structures. By adjusting cell medium composition during cell assembly, we expect to develop cellular fibers with increased robustness, along with unaltered biological function.Acknowledgement: This work was supported by the POCI, component FEDER, and national funds through FCT/MCTES, project PTDC/BTM-ORG/30770/2017.

Background

Sarcopenia is the progressive generalized loss of skeletal muscle mass, strength, and function which occurs with aging. This study was undertaken to identify new biomarkers of sarcopenia by proteomics analysis of female sera.

Methods

A case control study was set-up, for which 19 sarcopenic subjects and 20 control subjects, according to the European Working Group on Sarcopenia Older People criteria published in 2010 (EWGSOP1), were enrolled. All the subjects being at least 65-year old and in majority female. Biomarker screening was done by a comparative mass-spectrometry analysis. Protein expression levels between the two groups were compared. One of the identified biomarkers, cathepsin D was measured by immunoassay on the serum of the full sample set (n=39). Its diagnostic performance was evaluated with a Receiver Operating Characteristic curve (ROC curve).

Results

Two biomarkers were identified: fructose-biphosphate aldolase A ($p \leq 0.05$) and cathepsin D ($p \leq 0.05$). The levels of all of them being higher in sarcopenic patients. It was confirmed by immunoassay that Cathepsin D levels in serum was significantly higher in the sarcopenic group of patients ($p = 0.038$). An inverse correlation (-0.385) was observed between cathepsin D levels in serum and gait speed. The area under the ROC curve measurement (AUC= 0.696) demonstrated that cathepsin D levels could discriminate between sarcopenic and non-sarcopenic subjects. A predictive model including cathepsin D, age and Body Mass Index was established to improve the diagnostic performance (AUC = 0.908).

Conclusions

Cathepsin D has been identified as a diagnostic biomarker of sarcopenia.

Intervertebral disc(IVD) herniation is the leading cause of spine surgery, in which failure of annulus fibrosus(AF) allows nucleus pulposus(NP) extrusion. During degeneration/herniation, IVD extracellular matrix(ECM) is remodeled, undergoing fibrosis, but this process is still under investigated, namely in the AF.

Samples (n=39) of human AF(hAF) collected from patients who underwent surgery for lumbar IVD and controls (n=6) of hAF from adolescent scoliosis patients were processed for histological analysis. ECM ultrastructure was evaluated by transmission electron microscopy(TEM), while biochemical content (sulphated glycosaminoglycans(sGAG), collagen 1(Col1)), fibronectin(FN)) and fibrotic markers (alpha-smooth muscle actin(αSMA+) and matrix metalloproteinase-12(MMP12)) were analyzed by histology, as well as collagen fibers distribution by Picrosirius Red. Uni-/Multivariate regression analysis was conducted to identify any association between ECM content/fibrotic markers with aging or IVD herniation progression.

For herniated patients, no association with Pfirrmann grade was found for the fibrotic markers. With aging, sGAG and Col1 decrease, while αSMA+ cells increase in young adults (22-40 age) and senior patients (>65). Independently of the age, the AF of patients with IVD herniation revealed structural changes, decrease in sGAG and Col1 content and increase of FN and αSMA+ cells with herniation progression (no significant interaction with age was found,$p<0.05$). Moreover, MMP12 and macrophages(CD68+) did not exhibit differences with aging or herniation progression.

hAF ECM content and fibrosis markers reveal differences with aging and herniation progression, that might be associated with an increase in αSMA+ cells, but not macrophages or MMP12. These findings reveal new insights about AF failure in IVD herniation.

Cardiovascular disease (CVD) accounts for nearly one third of mortality in the aging population. Mortality is even higher in patients with chronic kidney disease (CKD). Phosphate retention in CKD is a major driver of endothelial damage, cardiovascular morbidity and mortality. Vascular calcifications in CKD patients are mainly located in the tunica media of a vessel, yet it is the endothelial cells (EC) that are especially vulnerable to phosphate-associated toxicity. Indeed, endothelial dysfunction is one of the earliest manifestations of vascular disease in CKD and other vasculopathies. To date however, the cellular cross-talk between EC and vascular smooth muscle cells (vSMC) have not been systematically studied in cell cultures, because suitable models are missing.

Cell monocultures fail to reflect the complex calcification pathology in the cardiovascular system. Cell culture medium is usually static and without flow. Cellular cross-talk as well as barriers between cell layers are missing and calcification media are unphysiologically supersaturated. We aimed to analyze vascular wall calcification using a more physiological dual-cell model. We developed a vessel-on-a-chip comprising endothelial cells cultured under flow next to smooth muscles cells cultured in a separate compartment without flow, while retaining the ability for cellular cross-talk. We employed established supersaturated simulated body fluids as well as protein-mineral complexes / calciprotein particles (CPP) as the calcification agent. The chip is suitable for live imaging and for testing biomimetic barrier materials separating the cells. At the endothelial cell side, we reached flow rates that produce around 10 dyn/cm2 shear stress simulating arterial blood flow.

COMPARATIVE STUDY OF DECELLULARIZATION METHODS FOR PORCINE SKELETAL MUSCLE

Charlot Philips$_P$[1], Lisanne Terrie[1], Lieven Thorrez[1]

Skeletal muscle is of high clinical importance due to its role in metabolism and movement. A wide range of causes for muscle injury can have a debilitating effect on a person's life. However, current treatment strategies for volumetric muscle loss are limited to transfer of autologous muscle tissue, which is associated with donor site morbidity and incomplete functional recovery.

The development of acellular matrices through decellularization offers a promising approach to create scaffolds which retain the complex hierarchical structure of skeletal muscle tissue. Moreover, the preservation of the extracellular matrix (ECM) components could enhance the regeneration process. Challenges remain in finding the optimal balance between removal of cellular content without causing significant damage to the ECM and in the translation of effective decellularization protocols to skeletal muscle tissues of clinically relevant dimensions.

In this study, we compare different decellularization protocols to obtain acellular matrices of porcine skeletal muscle tissue with dimensions of 2 x 0.5 x 0.5 cm. Either the detergents Triton X-100, sodium deoxycholate or sodium dodecyl sulfate were employed, alone or in combination with enzymes such as trypsin and DNase I. We present both qualitative and quantitative data on the content of DNA, collagen and glycosaminoglycans. Furthermore, mechanical analysis reveals differences in viscoelastic properties of decellularized constructs.

We conclude that different combinations of decellularizing agents result in a different decellularization efficiency. However, it is feasible to achieve an acceptable decellularization of porcine skeletal muscle tissue with the proposed dimensions, which opens perspectives for further upscaling towards larger scaffolds.

Introduction: Bone formation is a complex process. Understanding the associated cascade of cellular events would help the design of grafting material capable of inducing effective regeneration. Immunodeficient mice (IC) are standard for assessing the regenerative capacity of bone-grafts, despite their lower preclinical relevance. Here, we aim at investigating the impact of the immune cells on the bone formation capacity of our graft, in both immunocompetent (IC) and ID mouse models.

Method: Our graft consists of in vitro engineered cartilage tissue produced by human mesenchymal stromal cell (hMSCs) lines. This cartilage is subsequently devitalized by apoptosis induction, resulting in a cell-free graft aiming at instructing bone formation by endochondral ossification. The devitalized cartilage is implanted subcutaneously in the back of IC and ID animals for a maximum of 12 weeks. Recruitment of immune cells is investigated at day-3/7/10 post-implantation.

Results: Following in vivo implantation, a complete remodeling into bone was achieved in ID, whereas only minor calcification was observed in implants retrieved from IC mice. We further established a correlation between early immune cell recruitment (“immune prints”) and outcome of bone formation in ID and IC settings.

Conclusion and discussion: Our study illustrates the significance of the initial immune response during bone formation, especially macrophage recruitment and polarization. Ultimately, compiling such immune prints may not only be essential for assessing bone grafts immunogenicity, but also towards tuning their composition to activate/inactivate key immune pathways and ensure effective bone formation in clinical setting.

Currently, efforts to reduce osteoporotic fracture risk include systemic anabolic treatments to promote bone formation or anti-catabolic therapeutics to prevent bone resorption, but these do not sufficiently repair and restore bone structure and function[1]. However, local delivery strategies of these therapies has yielded promising results boosting local bone repair with potential to mitigate osteoporotic fracture risk at clinically relevant sites[2,3]. We are interested in simvastatin (SVT) as a novel anabolic treatment to augment bone repair[4]. The aim of this project is two-fold: 1) Develop a thermoresponsive methylcellulose-collagen hydroxyapatite hydrogel that offers the potential to fill complex geometries found in osteoporotic bone, and provide a surrogate extracellular matrix to promote cellular infiltration and proliferation. 2) Investigate the release and osteogenic potential of SVT from the developed hydrogels. To date we have shown that the hydrogels are easily extruded from various needle gauges due to shear thinning properties at room temperature, undergo sol-gel transition upon approaching 37°C, resist degradation over 4 weeks when gelated and can support MC3T3-E1 (pre-osteoblast) cell viability and proliferation. These results demonstrate the suitability of the hydrogel for minimally invasive applications and site retention. The challenge remains to evaluate the osteogenic potential of this biomaterial and thereafter improve this by functionalizing with currently licensed anabolic or anti-catabolic therapies. Therefore, we further aim to harness the anabolic effects of simvastatin (SVT) to support osteoblast viability, facilitate osteogenesis and encourage mineralization. In parallel, the effect of SVT loaded hydrogel on osteoclast differentiation and bone resorptive activity will be determined.

INTRODUCTION: Tubular structures (TS) are present in blood vessels, the urinary and respiratory tracts, and the gastrointestinal system. In the body, these structures are found mostly in the millimetric (>1mm) or centimetric (>10mm) scale. Still, coaxial bioprinting techniques currently available focus largely on producing micrometric (<1mm) TS. To produce clinically relevant TS, approaches focused on layer-by-layer deposition of bioinks require long bioprinting time. We propose a new method for fast 3D bioprinting of clinically relevant TS. METHODS: We developed an adapter to be attached to the extrusion unit of a 3D bioprinter and redirect the flow from two syringes towards a single coaxial channel. The adapter can be customized to have the inner and outer diameters ranging from 1mm to 10mm (or more, if desired). We fabricated TS using an alginate-based bioink and a Pluronic F-127/CaCl2 fugitive/crosslinking hydrogel. TS were produced using the conventional layer-by-layer method for comparison. RESULTS: TS of 1.5/5.0mm and 3.0/9.5mm (inner/outer) diameter and tunable length were produced. The printing time using our technique is standardized at 2s/mm, irrespective of the construct size. Using the conventional method (1mm/s flow rate), the printing time for the 1.5/5.0mm construct was 240s/mm and 900s/mm for the 3.0/9.5mm construct. Our method was 120x faster for the small construct and 450x faster for the large construct. CONCLUSION: 3D TS can be fabricated hundreds of times faster using our novel method of coaxial bioprinting.

The increasing research interest on injectable hydrogels in tissue engineering and regenerative medicine is related to their ability to be used as cell-laden injectable scaffolding materials and compatibility with minimally invasive surgical techniques. Despite these advantages, large-scale bulk hydrogels are reported to hinder molecule and gas diffusion over large distances. This disadvantage associated with the poor solubility of oxygen in aqueous liquids[1] has led to the development of strategies for the production of microporous hydrogels[2] or the inclusion of oxygen-generating species[3] to enhance cell survival in such structures. We recently reported the development of cell-laden injectable gelatin methacryloyl (GelMA) foams, produced through a straightforward method based on the injection of air into a GelMA solution through the pull/push motion of a syringe plunger[4]. After 14 days of cell culture, human adipose-derived mesenchymal stem cells (hASCs) were found throughout the foam's whole volume, while GelMA bulk hydrogels showed uneven cellular distribution (hollow core without cells). Additionally, hASCs present in bulk hydrogels stained for hypoxia-inducible factor 1-alpha (HIF-1α), while such behavior was not observed in GelMA hydrogel foams. Therefore, we hypothesize that the oxygen present in the foam's air pockets may be slowly released and used by the cells, while on bulk hydrogels cells seem to migrate towards an oxygen-rich surface. To conclude, these results indicate that GelMA hydrogel foams may be advantageous for tissue engineering applications, particularly when homogenous tissue deposition in constructs with relevant sizes is required.

Introduction

This exploratory, monocentric, placebo-controlled, double-blind study aimed to study the effects of a Pomegranate extract (PE) on muscle recovery after anterior cruciate ligament plasty.

Patients and methods

One week after surgery, twenty-eight men received two food bars per day containing either PE/L-leucine/creatinine/vitamin D3/protein (n=14) or a placebo (n=14) for 12 weeks. The parameters studied were: pain at rest during the last 24 hours (Visual Analogue Scale (VAS)), disease activity assessed by the patient (AMP-EVA), physical performance by the "International Knee Documentation Committee (IKDC)" index, the peak torque of quadriceps and hamstrings using an isokinetic dynamometer and body composition by bio-impedancemetry (BIODY XPERT ZM®).

Results

There was no significant difference between the groups in pain, disease activity evaluated by the patient, physical performance (IKDC) and parameters of isokinetic exploration before and after 12 weeks of treatment. The lean mass decreased after surgery in the placebo group, while it remained stable in the PE group. However, the difference between groups was not significantly different. The lean mass compared to baseline was significantly higher in the PE group than in the placebo group after 2 (p=0.004) and 14 weeks of treatment (p=0.006). Finally, PE did not significantly alter basal metabolism compared to placebo. Compared to reference values, basal metabolism was lower in the PE group than in placebo group after two weeks.

Conclusion

Pomegranate extract had no significant effect on algo-functional status immediately after surgery for anterior cruciate ligament plasty but improve body composition by limiting the reduction in lean mass.

INTRODUCTION: Polysaccharides are extensively used in bioink formulations for extrusion-based 3D bioprinting due to their biocompatibility and processability. However, their low bioactivity is a major drawback. Tissue-specific decellularized extracellular matrices (dECMs), in turn, contain biochemical components that provide the ideal microenvironment for cellular attachment, proliferation, migration and differentiation. Herein, we combined the viscoelastic behavior of xanthan gum and the fast cross-linking ability of alginate with the unique bioactivity of dECM to achieve a bioink with good printability and superior biological performance. METHODS: Alginate-xanthan solution (1:3) was mixed with a lung dECM hydrogel at 75:25 (A), 85:15 (B) and 90:10 (C) weight ratios. Bioink viscosity at increasing shear rates and viscosity recovery were determined using a rotational viscometer. Printability was assessed by filament fusion and collapse tests using a 3D bioprinting system. RESULTS: The bioinks presented a shear-thinning behavior and their viscosity decreased with increasing dECM proportion. At high shear rates, viscosity of C was 1.7 and 1.1 times higher than A and B, respectively. Viscosity recovery was lower for bioink A than for B and C, reaching up to 98.5%. The printability is higher for C, with minimum material spreading. Filament of bioink C did not collapse between two consecutive pillars of up to 5 mm distance, while the filaments of B collapsed at 3 mm and of A at 2 mm. CONCLUSION: Bioinks with a range of rheological properties and good printability were obtained from the combination of polysaccharides and dECM.

Corresponding author's email: d.gawlitta@umcutrecht.nl

An essential step in endochondral bone regeneration (EBR) is to ensure an appropriate chondrogenic differentiation state prior to in vivo implantation. Vitreous humor (VH), the gelatinous mass between the lens and the retina, has emerged as a cell-instructive substrate that promotes mesenchymal stromal cell (MSC) chondrogenesis (1). The aim of this study was to establish the suitability of VH to support MSC progression towards a hypertrophic phenotype in vitro and EBR in vivo.

MSCs embedded in VH hydrogels were stimulated to achieve an early (chondrogenic medium only) or late (chondrogenic + hypertrophic medium) hypertrophic phenotype. After 31 days, the presence of chondrogenic (glycosaminoglycan and collagen type II) and hypertrophic (collagen type X and mineralization) markers was evaluated. Chondrogenic or hypertrophic MSC-laden VH hydrogels were implanted in a subcutaneous rat model for 8 weeks. Bone formation was evaluated by micro-CT (2,4,6 and 8 weeks), fluorochrome injections (2,4 and 6 weeks) and histological analysis (8 weeks).

VH supported a reproducible differentiation, as chondrogenic and hypertrophic markers were present in all samples from 3 different MSC donors. Once implanted, chondrogenic and hypertrophic MSC-laden VH constructs induced comparable neo-bone formation. However, a later onset of bone formation, larger portion of non-remodeled cartilage and smaller bone marrow cavities were observed in the hypertrophic group, compared to the chondrogenic one.

VH hydrogels effectively support MSC chondrogenesis and hypertrophy in vitro. Irrespectively of the culture conditions prior to implantation, EBR was observed in vivo. This indicates that VH is an ideal biomaterial for EBR-based regenerative approaches.

The 3D bioprinting enables to prepare skin tissue engineered grafts for non-healing chronic wounds or skin defects leading to effect on patients quality life1. Fibrin structural composition and binding to cells highly determine wound healing process2.

The aim is to develop a fibrinogen-based bioink with addition of alginate for skin constructs printing followed by fibrin cross-linking using a thrombin–calcium chloride (CaCl2) solution.

Several concentrations of bovine fibrinogen and sodium alginate were dissolved in deionized water. These solutions were semi-crosslinked by mixing with 100mM CaCl2 solutions at varying volumetric ratios. The crosslinking-solution has bovine thrombin (50 UT/ml) dissolved in 50mM CaCl2 solution.

The solutions printability and biocompatibility were characterized by: homogeneity test; spreading ratio; SEM; compression test; water uptake; degradation and cell viability/proliferation test on L929 mouse fibroblasts using LIVE/DEAD and XTT assay at 0-7 days3,4.

The bioink with the lowest spreading ratio and water up-take values, slower degradation rate and better cell proliferation was mixed with human dermal fibroblasts (6x106 cells/ml) and human epidermal keratinocytes (8x106 cells/ml) to print a bilayered skin constructs using a 25G conical nozzle, 12mm/s of speed and 10KPa of extrusion pressure. The bio-printed constructs were cultured up to 14 days and evaluated through histological analysis by H&E staining and Masson's trichrome.

The developed bioink is composed by semi-crosslinked alginate (25:9 as volumetric ratio) and 30 mg/ml of fibrinogen. The bio-printed constructs showed homogeneous viable cells distribution and collagen deposition.

These preliminary results showed that the fibrinogen-based bioink developed enabling cells proliferation post-printing and tissue maturation.

Development of multifunctional surfaces has drawn great attention over the years. Surface properties like antibacterial activity and biocompatibility are highly desired to allow tissue integration of biomedical implants.[1] Medical devices can undergo nosocomial infections caused by bacterial attachment and their growth into undesired biofilm formation, making them exceedingly resistant to antibiotic treatments.[2] In Europe, 1 patient out of 20 develops a nosocomial infection during hospitalization, posing a huge burden on the healthcare facilities and economy.[3] Prevention of the early attachment and proliferation of bacteria has gained popularity and led to the development of antibacterial coatings. Among several routes to modify surfaces, layer-by-layer (LbL) is a versatile method to design biocompatible and antibacterial coatings to prevent infections. Tannic acid (TA), a natural polyphenol, is known to inhibit the growth of several bacteria. Herein, we developed TA/collagen (TA/COL) LbL films built in acetate or citrate buffers at pH 4. Surprisingly, the used buffer impacts not only the physicochemical but also the antibacterial properties of the films. When incubated in physiological conditions, both types of TA/COL films released approximately same amount of TA depending on the last layer and showed an antibacterial effect against Staphylococcus aureus only for citrate-built films, without cytotoxicity towards human gingival fibroblasts. ITC and XPS demonstrate that the complexation strengths between TA and COL are different in the presence of both buffers that modifies the amount of TA immobilized. This work constitutes an important step toward the use of polyphenols as an antibacterial agent when incorporated in LbL films.[4]

Osteoarthritis (OA), there is more pronounced cartilage damage in the medial compartment ('lesion zone') than the lateral compartment ('remote zone'). This study fills a gap in the literature by conducting a systematic comparison of cartilage and chondrocyte characteristics from these two zones. It also investigates whether chondrocytes from the different zones respond distinctly to changes in the physical and mechanical microenvironment using three-dimensional porous scaffolds by changing stiffness and pore size. Cartilage was harvested from patients with end-stage varus knee OA. Cartilage from the lesion and remote zones were compared through histological and biomechanical assessments, and through proteomic and gene transcription analyses of chondrocytes. Gelatin scaffolds with varied pore sizes and stiffness were used to investigate in vitro microenvironmental regulation of chondrocytes from the two zones. Cartilage from the lesion and remote zones differed significantly ($p<0.05$) in histological and biomechanical characteristics, as well as phenotype, protein, and gene expression of chondrocytes. Chondrocytes from both zones were sensitive to changes in the structural and mechanical properties of gelatin scaffolds. Of interest, although all chondrocytes better retained chondrocyte phenotype in stiffer scaffolds, those from the lesion and remote zones, respectively, preferred scaffolds with larger and smaller pores. Distinct variations exist in cartilage and chondrocyte characteristics in the lesion and remote zones of knee OA. Cells in these two zones respond differently to variations in the physical and mechanical microenvironment. Understanding and manipulating these differences will facilitate the development of more efficient and precise diagnostic and therapeutic approaches for knee OA.

Background and Aim - Due to its structural and functional complexity, the heart imposes immense challenges on engineering a biological replacement, therefore we propose a simpler biological assist device for future support or replacement of failing human hearts. Our goal is to generate a 3D-perfused heart tube (3D-Heart-2B) based on human induced pluripotent stem cell-derived cardiomyocytes (iPSC-CMs).

Methods – 3D-Heart-2B is designed as a modular system based on the following components and strategies: Highly compacted fibrin-based myocardial-like tubes generated from iPSC-CMs for contractile function and iPSC-derived vascular cells for de novo vessel formation; novel strategies for instant perfusion; decellularized heart valves to direct medium and ultimately blood flow in bioreactors and mock circulation models; in vitro maturation and testing; surgical strategies in animal models for in vivo testing.

Results and Conclusions – We have generated highly compacted fibrin-based tubes containing up to 200 x 106 iPSC-CMs with a length of 10 cm, a diameter of 5-6 mm and an initial wall thickness of 0.6 mm. Cellular distribution and vitality in the 3D-Heart-2B construct was assessed by live cell imaging and immunohistological staining. Contractile function was demonstrated after 4 and 5 weeks of cultivation (d28 and d35). Implantation of the 3D-Heart-2B tube in an ex vivo perfused pig heart mounted in the Organ Care System (OCS) as a bypass graft demonstrated suturability but so far limited mechanical stability. Following scale-up to clinically relevant dimensions, the 3D-Heart-2B construct will fulfill key criteria of an implantable biological cardiac assist device for failing hearts.

Vascular access is considered the Achilles' heel of hemodialysis, resulting in frequent and recurring inverventions1. Autologous options are limited by pre-existing disease, previous interventions, and/or unsuitable vessels. Synthetic alternatives are susceptible to infection, intimal-hyperplasia, and/or thrombosis2. We aimed to create an off-the-shelf, porous, biodegradable, self-healing vascular access graft by means of in situ tissue engineering that in vivo gradually transforms into a living vascular graft. Our biodegradable supramolecular elastomeric materials-platform enables us to modulate the mechanical properties and biofunctionalise our graft to maximise (intended)cellular integration. We investigated the remodelling and functional capacity of these arterio-venous(AV)-grafts and the contribution of SDF1α bio-functionalisation in a large animal model.

Electrospun, porous, biodegradable, vascular scaffolds(6mm-diameter) made of supramolecular polymers, reinforced with a PCL 3D-printed coil to prevent kinking, were bilaterally implanted in goats(approx.65kg) as AV shunts, connecting the carotid artery and jugular vein. A subset was functionalised with SDF1α linked to the polymer material3. Patency was monitored by ultrasound. Grafts were explanted after 3months and analysed for mechanical properties, material breakdown, cellular infiltration, ECM deposition and tissue architecture.

After 3months 50% of the grafts remained patent, showed remodeling, and bore no signs of deformations. The synthetic material was resorbed and replaced by autologous tissue consisting of vascular cells and ECM. SDF1α functionalisation showed no effect. Our first implantations of an off-the-shelf, biodegradable, porous, non-kinking vascular scaffold in a goat model showed clear remodeling, gradually replacing the scaffold by autologous vascular tissue. This shows great promise for off-the-shelf in situ tissue engineered vascular access grafts.

Organoid systems represent an alternative approach for studying human organism and modeling human tissues and diseases (1), allowing the development of targeted therapies for individual patients (2). In contrast to traditional 2D in vitro and animal models, organoid cultures provide a more careful study of cell-cell and cell-matrix interaction mechanisms (3). These systems could be a valid tool for studying tumor microenvironment by using 3D biomaterial such as hydrogels, which imitate the tissue microenvironment and facilitate patient tumor cultures. To this aim, we developed an innovative thermo-sensitive hydrogel based on naturally derived polymers such as chitosan (CH) and pectin (PEC), which weakly interact to form polyelectrolyte complex (4). We exploited the characteristic of CH to crosslink with β-glycerophosphate (BGP) to form a stable polymeric network incorporating PEC into the system, thus originating a semi-Interpenetrating Polymer Network (semi-IPN). The developed PEC/CH semi-IPN resulted thermoresponsive at 37°C, injectable at room temperature, suitable for cell-encapsulation (pH=7.4), stable in vitro up to 3 weeks, a super-absorbent material with highly interconnected porosity and permeable to small-large nutrients (3-5 to 70 KDa). Tunable mechanical properties (around 1-4 kPa) and permeability, could be reached by varying the CH/PEC content. Finally, the PEC/CH semi-IPN was successfully used to induce human colorectal cancer cell (HCT116) spheroids formation up to 45 days of culture. The CRC-like spheroids dimension and density were influenced by the PEC/CH semi-IPN stiffness and permeability. These encouraging results would allow the implementation of faithful 3D tumor models for the study and development of personalized oncological treatments.

Advances in tissue engineering and manufacturing technologies have led to the rapid production of hundreds of biomaterials. The informational deluge generated from sources such as scientific articles, news, social media, etc. have created a technological challenge related to identifying, monitoring, and communicating potential risks.

As part of the risk pre-assessment, horizon scanning can capture early notions that are potentially associated with emerging risk (ER) that may develop into fully born risks over time. Horizon scanners such as the Risk Radar, conceptualised in the EU project, iNTeg-Risk [1] offers an organised and formal process of gathering, analysing unstructured big-data and disseminating value-added information to support decision making.

The Radar uses a bipartite network of documents and words extracted from splitting each document to individual words using word bagging [2]. The document sources include openly accessible abstracts of scientific publications, blogs, news articles, etc. Two parameters, Relevance and Novelty are defined and measured. While the former quantifies how central the documents are positioned in the term-document network, the later calculates the number of different topics a given document covers and is related to its expected impact. The parameters are combined to form a composite indicator "Criticality" based on the EU JRC COIN methodology [3].

The Risk Radar allows identification and monitoring of ERs, along with interconnectedness and quantification of the systemic importance of ERs. The Radar is developed as a practical web-based tool and is further developed for early recognition of new, emerging risks in biomaterials for the EU project PANBioRA.

Mathematics is used to describe, predict and optimize the world since milleniums. It has evolved from simple counting to complex topics beyond most of our imagination. The development of computers enabled the efficient use of numerics to solve problems where the effort was too high to be accomplished by pen and paper. A “natural” area of applying mathematics is technical engineering. But mathematics is universal so that using simulation in the fields of biology and medicine also got more and more common.

One application for the benefit of regenerative medicine can be using generative design. Designing artificial body parts can be based on the real loads and material strength thus delivering the optimal geometry and weight. Mimicking only the mechanical function of a body part can lead to unneccesary weight or too less strength and endurance. A new approach is presented where even non-simulation experts can quickly and reliably generate such parts.

These complex shapes can thankfully be produced by 3D printing nowadays. Nevertheless it is advisable to simulate manufacturing to predict and mitigate problems like distortion or failures. This enables a faster and less costly production at a higher quality. The current capabilities and limitations are presented.

Patients as well as implants are often examined by imaging technology like CT and MRT. The raw data obtained gets most of it meaning first after processing this data and making available all the possibilities of image evaluation. An overview on how mathematics powers the measurement data processing is given.

Abstract **#1443**

DEVELOPMENT OF A PIPE-LINE TO CREATE AND CHARACTERIZE CANINE AND FELINE ORGANDIES; LIVER AND PANCREAS AS EXAMPLES

Louis C. Penningp[1]

[1] *Utrecht University, Faculty of Veterinary Medicine*

Corresponding author's email: l.c.penning@uu.nl

Companion animals, like dogs and cats, can be instrumental in preclinical studies. However, both for preclinical and clinical studies, species differences must be taken into account in order to appreciate the true value of the measurements. To create a balance between in vivo studies with obvious animal welfare issues, and cell line measurements, with obvious physiological limitations, in vitro cultured mini-organ, so-called organoids, can provide a best-of-both-worlds situation.
After the creation of canine liver organoids, we developed feline liver organoids, and rapidly afterwards canine intestinal organoids, bovine liver organoids, porcine liver organoids, and canine pancreas organoids. All of these models had specific research questions to be answered. E.g. canine liver organoids were created as alternative for whole liver transplantation (pre-clinical model) (1,2), whereas feline liver organoids were used to screen for drugs affecting feline hepatic lipidosis (3,4).
The knowledge acquired during these 5 years of organoid technology in veterinary medicine has let to the development of a rapid method to create and characterize organoids from other organs.
The very recent development of canine pancreas organoids will be presented as an example how efficient this pipe-line is and (to be honest with you) the drawback of this technology and hurdles to expect will be described too.
The experience with organoid cultures clearly highlights the difference between species, even at in vitro culture level.

Abstract **#1444**

PROTEOMIC CHARACTERISATION OF EQUINE PLATELET-RICH PLASMA FROM ADULT PERIPHERAL BLOOD

Aggie Turlo$_P$[1], Aibek Smagul[1], Peter Clegg[1], Mandy Peffers[1]

[1] *Department of Musculoskeletal and Ageing Science, Institute of Life Course and Medical Sciences, University of Liverpool, UK*

Corresponding author's email: a.turlo@liverpool.ac.uk

Platelet-rich plasma (PRP) is used extensively in human and veterinary medicine to enhance tissue repair, however, its mechanism of action remains unclear. This study aimed to comprehensively profile the proteome of equine PRP to provide insights on potential mechanisms of tissue healing and compare it with existing human data.

PRP was obtained through double centrifugation method [1] from blood samples collected from four adult healthy horses culled at a commercial abattoir (PLT 441 x 103/µl ± 187, WBC 17 x 103/µl ± 5). Liquid chromatography-tandem mass spectrometry was used for global proteomic profiling of PRP following high abundant protein depletion (ProteoMiner). Proteins were identified with a 1% false discovery rate and minimum of two unique peptides per protein. Equine protein identifications were converted to human orthologs for bioinformatic analysis.

238 proteins were identified across all samples. Core dataset including 193 proteins found only in 4/4 and 3/4 biological replicates was generated and functionally characterized by gene ontology terms. Enrichment analysis (STRING) indicated ‘extracellular region’ and ‘secretory granule’ as the main cellular components, ‘vesicle-mediated transport’ as biological process and ‘protein binding’ as molecular function. Searching against Vesiclepedia database showed that 76% of proteins were found in human extracellular vesicles. 67% of proteins were previously identified in human PRP proteome [2].

Extracellular vesicles and their cargo constitute a major part of equine PRP proteome and may be responsible for mediating biological effect of PRP. Equine PRP studies may be useful to inform human application of PRP due to similarities in protein composition.

Bone defects and impaired healing of fractures are an increasing public health burden and represent an unmet clinical need. Gene therapy has been investigated as a promising approach to improve or augment bone healing with the potential to provide true functional regeneration. While large numbers of studies have been performed in vitro or in vivo in small animal models that support the use of gene therapy for bone repair, these systems do not recapitulate key features of a critical/complex fracture environment. An overview of preclinical studies in large animal models, ongoing clinical work and a technology readiness assessment (TRA) are presented to identify potential translational bottlenecks and provide recommendations to overcome them. The current state of orthopaedic gene therapy research in preclinical large animal models was systematically reviewed. Whilst the results and outlook in the current preclinical research literature are generally positive, inconsistent methodologies across studies were a limitation in addressing factors vital for translation and risk of bias with regards to study design was observed. Systematic analysis suggests that most preclinical approaches tested in large animals currently sit within technology readiness level (TRL) 4. A comprehensive overview of clinical studies and the status of translation is provided in the context of the regulatory environments in the EU, US and Russian Federation. This work aims to provide a robust basis and outlook for continued, standardised and translation-tailored development of gene therapy for orthopaedic indications and beyond in regenerative medicine.

Introduction. Whereas healthy human adult vasculature is quiescent, the development of new capillaries from the existing vasculature (angiogenesis) constitutes a critical step for regenerative medicine and tissue engineering. Recent evidence suggests that circadian rhythms (CR) are involved vascular physiology, particularly angiogenesis, whilst the 3D-microenvironment of the vasculature is critical for the spatiotemporal maturation of capillaries and the regulation of endothelial cells (EC) and pericytes (PC). This study aims to evaluate the effect of circadian clock on angiogenesis in a 3D-environment.Methods. Tube formation was evaluated in a 3D-Matrigel assay. Highly-porous polyurethane (PU)-scaffolds, fabricated by Thermal-Induced Phase Separation [1], were surface modified with fibronectin/gelatin to mimic the extracellular matrix. Primary human EC and PC were cultured in PU-scaffolds either individually or co-cultured together. Stack images were acquired using confocal laser-scanning microscopy.Results. Multicellular Matrigel assay showed a clear influence of CR on the organisation and conformation of capillary-like structures, especially when EC and PC were both synchronised. Alongside our results showing PC circadian rhythmicity for the first time in vitro, these indicate a role for CR during angiogenesis. Multicolour confocal imaging revealed that EC and PC organise in vascular-like structures around pores in polymeric 3D-scaffolds over 2 weeks of culture. Discussion/Conclusions. This preliminary data provides the basis for future advanced study of circadian regulation of angiogenesis in 3D tissue-engineered scaffolds. This would offer a reliable in vitro platform for chronobiology applications, recapitulating the complex spatial distribution of cells in their natural environment, while maintaining the tuneable characteristics of a tissue-engineered microenvironment.

The thin and concave tissue of tympanic membrane (TM) captures sound pressure waves from the environment and transforms them into mechanical motion [1]. The successful transmission of these acoustic vibrations is attributed to the intricate three-dimensional (3D) architecture of the TM, consisting of radially and circumferentially aligned collagen fibrils [2, 3]. In this work, we investigate the influence of this precise geometrical construction on its mechano-acoustic response by applying relevant computational and biofabrication approaches.

A Python script was developed for generating 3D models highlighting the key anatomical features of the human TM. Three test designs along with a plain control were chosen to decouple some of its dominant structural attributes. A dual-scale fabrication strategy combining electrospinning and additive manufacturing was carefully optimized to manufacture scaffolds within the dimensions of the native TM. Preliminary in silico modeling performed in COMSOL Multiphysics suggested a geometrical dependency of their mechanical and acoustical responses, where the presence of radially aligned fibers was observed to have a more prominent effect as compared to their circumferential counterparts. The experimental characterizations conducted using macro-indentation and laser Doppler vibrometry confirmed similar mechano-acoustic results. Finally, human mesenchymal stromal cells and human dermal fibroblasts cultured on the TM scaffolds demonstrated a desirable alignment and collagen deposition along the fabricated patterns.

This work synergizes theoretical and experimental approaches toward understanding the significance of geometry in tissue engineered TM scaffolds. Furthermore, with the optimized biofabrication strategies, a radical improvement has been achieved in the previously reported limits for manufacturing alloplastic TM replacements.

Colonies of induced pluripotent stem cells (iPSCs) are heterogeneous and their subsets organize towards the outer rim. To gain better insight into this self-organization we used either an array of PDMS pillars or micro-contact printing (µCP) to geometrically confine the growth of iPSCs. Subsets with higher expression of the pluripotency markers OCT4, E-cadherin, and NANOG progressively segregated to the outer 50-70 µm of the colonies. After 5 days the self-organized colonies were analyzed with single-cell RNA-sequencing (scRNA-seq) and the OCT4high subpopulation revealed most prominent upregulation of NODAL and its inhibitor LEFTY. In fact, these proteins were also higher expressed at the outer rim, whereas intermittent disruption of calcium-dependent cell-cell interaction abrogated this self-organization and resulted in uniform expression of OCT4 and NODAL. After 5 to 7 days the self-organized iPSC colonies spontaneously detached from their µCP substrates to form three-dimensional (3D) aggregates. This new method facilitates robust generation of embryoid bodies (EBs) of controlled size, without enzymatic or mechanical treatment. The procedure could even be implemented on a semi-automatic liquid handling unit and the resulting EBs could be differentiated towards all three germ layers. Notably, early 3D aggregates revealed similar self-organization as observed in 2D colonies with marked upregulation of OCT4, E-cadherin, and NODAL at the outer layer. Furthermore, scRNA-seq demonstrated progressive upregulation of similar genes in the OCT4high subpopulation, particularly of LEFTY1, TDGF1, NODAL, and genes of the TGF-ß/SMAD signaling pathway. Our results demonstrate that the spatial self-organization of iPSC colonies continues at their transition into EBs.

Therapeutic solutions for osteochondral defects using an endogenous approach are emerging. Osteochondral defects are often accompanied by synovial inflammation. We investigated how synovial inflammation influences mesenchymal stromal cell(MSC) migration, and whether modulation of inflammation improves migration.

Osteoarthritic synovial tissue explants were cultured with/without 1µM triamcinolone acetonide(TAA) for 24h to obtain synovium-conditioned medium(SCM). The effect of 6 SCM donors on migration of passage 3 BMSCs was examined in Boyden chamber assays. Inflammation of the synovial explants was assessed with gene expression analysis and flow cytometry for macrophage subtypes. Human peripheral blood monocytes were stimulated with TNF-α/IFN-γ towards pro-inflammatory-, with IL-4 towards repair-, and with IL-10 towards anti-inflammatory macrophages. After polarization they were cultured with/without 1µM TAA for 24h, the conditioned medium was used to assess BMSC migration.

Modulation of synovium with TAA significantly decreased expression of TNFA, IL1B, and IL6, genes associated with inflammation, and increased gene expression of CD163, associated with anti-inflammatory macrophages. The percentage of CD14+/CD80+($p<0.001$) or CD14+/CD86+($p<0.001$) pro-inflammatory macrophages was lower, whereas the percentage of CD14+/CD163+ anti-inflammatory macrophages was higher($p<0.001$) in samples treated with TAA than without TAA. Modulation of synovium with TAA resulted in a 1.5-fold increase($p<0.01$) in migration of BMSCs. Moreover, BMSC migration increased 3.1-fold($p<0.001$) in response to medium conditioned by repair macrophages, and 2.3-fold($p=0.02$) by anti-inflammatory macrophages when these macrophages were exposed to TAA.

Decreased synovial inflammation increased BMSC migration. Modulation of inflammation and macrophage phenotype in synovium using TAA might be promising to enhance BMSC migration in osteochondral defect repair.

Mechanobiological cues are proposed to encourage tumor cell invasion [1, 2], however, the specific biomechanical cues that govern metastasis to bone are not understood. Although in vitro models have been developed to study bone metastasis [3, 4], these have not incorporated mechanical cues that occur in vivo. The objectives of this study were to (1) develop an engineered biomimetic 3D in vitro multicellular model system that replicates in vivo mechanical cues and (2) investigate the biophysical regulation of bone metastasis. Gelatin-nHA (Nano hydroxyapatite) encapsulated OCY454 osteocytes and MC3T3 preosteoblasts were layered and cultured in the presence of osteogenic factors for 21 days to allow mineralisation. Next, gelatin-nHA encapsulated RAW264.7 preosteoclasts (Healthy model), or RAW264.7 and 4T1 adenocarcinoma cells (Metastatic model), were added to the mineralised constructs. The constructs were mechanically stimulated (0.5Hz, 0.5% strain 1h/day) within a custom bioreactor and cultured without osteogenic factors for 3 and 7 days. Static controls were included. In the healthy model, osteoclast activity (CTSK positive multi-nucleated cells) was confirmed under static conditions at day 7. Mechanical stimulation reduced this osteoclast activity and maintained already deposited mineral. In the metastatic model, positive IL-6 staining increased under static conditions, when compared to healthy conditions. Interestingly, the addition of mechanical stimulation reduced IL-6 staining in the metastatic model relative to the healthy counterpart. These results confirm the establishment of an engineered biomimetic 3D in vitro multicellular model system with confirmed osteoblast, osteoclast and metastatic activity and thereby provides an advanced model for studying bone metastases.

Although fracture treatment improved over the last decades, a substantial part of all fractures shows delayed healing and complications such as non-union(1,2). Fracture healing is a complex process, involving cell-cell interactions, various cytokines and growth factors(1,3,4,6,8). Although the fracture hematoma (FH) is known to have a relevant role in this process, the exact mechanisms are poorly understood(1,2,3,5-7). To improve strategies in fracture treatment, regulatory pathways in fracture healing need to be investigated. Lipids are important structural components of the cell and function as messenger compounds, therefore this study initiates with lipid spectra analysis.

The aim of this study is to identify lipid spectra in FH over time with matrix assisted laser desorption/ionization mass spectrometry imaging (MALDI-MSI). MALDI-MSI enables analyses of lipids and their spatial distribution without prior knowledge, biological- or chemical labeling. Therefore, this method is more time-efficient and requires less tissue than conventional methods.

For this study, fourteen FH samples were surgically removed, snap frozen, sectioned, washed and analyzed at different timepoints after fracture injury (1-19 days). Principal component analysis and discriminant analyses identified three groups based on distinctive m/z values which were associated to FH age; early (1-3 days, n = 4), middle (6-10 days, n = 6) and late group (12-19 days, n = 4). This shows that MALDI-MSI is well capable of making clear distinctions in lipid spectra between the early, middle and late FH group. These findings warrant further research into FH analysis by means of MALDI-MSI and its possible clinical implications in fracture treatment.

Infertility is the main obstacle to achieve pregnancy naturally for women. The current treatments for infertility can not be applied for women who are suffering from uterus malfunction. Regenerative medicine and tissue engineered organ is a promising solution, which scaffold plays an important role for tissue regeneration. In this research, we developed a combination method to fabricate decellularized scaffold by using enzyme and high hydrostatic pressure. The enzymatic high hydrostatic pressure method can fabricate uterine scaffold within 40 minutes. Results showed cells were removed from native uterine tissue while preserving the natural macro- and microstructure of extracellular matrix. For in vivo, scaffold showed tissue regeneration in murine model. Moreover, pregnancy test was successfully achieved. Thus, the enzymatic high hydrostatic pressure showed a promising solution for uterine tissue engineering.

Bioassembly of microtissues has the potential to meet the difficulties of creating complex osteochondral tissues. Microtissue bioassembly relies on the development and progressive fusion of the microtissue modules. In this study, we investigated in vitro microtissue fusion and demonstrated that bioassembled constructs preserved their spatial properties in vivo. This was shown for both human adult periosteum derived cells (hPDC) as well as human induced pluripotent stem cells (hiPSC) as cell source.

hPDC microspheroids were created in agarose microwells and differentiated towards the chondrogenic lineage. A hierarchical construct was formed by assembly of three hPDC-derived cartilaginous microtissue intermediates of progressive maturity from i) early day 7, ii) mature day 14 to iii) (pre)hypertrophic organoids day 21. Upon ectopic implantation in nude mice, the formation of a hybrid tissue with bone, mineralized cartilage and fibrocartilage was observed. To engineer more stable articular-like cartilage, hiPSC-derived hyaline cartilage microtissues (iCMT) were introduced in combination with the pre-hypertrophic cartilage organoids (day 21) to create dual structures. iCMT fused slower during dual assembly and were therefore incubated longer to allow formation of a stable construct. Both tissue zones revealed their biological potency upon ectopic implantation, corresponding to the pre-engineered zonal pattern.

The assembly of functional building blocks as presented in this work, opens possibilities for the production of complex tissue engineered implants by embedding zone-specific functionality through the use of properly pre-programmed living building blocks.

Neutrophils play a pivotal role in orchestrating the immune response to biomaterials, the onset and resolution of chronic inflammation and macrophage polarization. Neutrophil response can be described by: survival, neutrophil extracellular trap (NET) formation, and release of granules with immunoregulatory factors. We investigated the processes in human primary neutrophils exposed to different biomaterial surfaces.

Human primary neutrophils of five healthy donors were seeded at a concentration of 1.0*106/mL in wells coated with a panel of hard and soft biomaterials. Cell-survival and metabolic activity were determined after 1,3,5,7, and 24 hours. Formation of reactive oxygen species(ROS) and NET components myeloperoxidase and elastase were assessed after 3 hours. Secretion of inflammation-related factors was evaluated biochemically.

Neutrophil survival was 90-100% after 24 hours on the soft hydrogel surfaces, but was lower than 50% on tissue culture plastic(TCP) and polycaprolactone(PCL). Metabolic activity after 1, 3, 5, and 7 hours was 2-3-fold higher on TCP and PCL than on soft materials. MPO and elastase levels were 3-10-fold higher on TCP, PCL, and polyvinyl alcohol(PVA) surfaces than on hyaluronan-and collagen-containing hydrogels. In contrast, ROS production was higher on soft hydrogels than on TCP and PCL. MMP9 secretion was significantly higher on TCP, PVA and PCL surfaces than on hyaluronan-and collagen-containing hydrogels.

Biomaterials deriving from natural proteins resulted in higher levels of ROS, whereas neutrophils respond with more NET formation on synthetic materials. Stiffness and composition of substrates play a role in neutrophils responses suggesting the ability to be potential characteristics to modulate the inflammatory response.

Plant-derived biomaterials hold promise as regenerative materials for wound healing applications. Using electrospinning as a platform, we developed and tested soy-based wound dressings that entail a biomimetic nanofibrous network ideal for cell interaction, growth, and differentiation.[1] Using a pig model, we previously demonstrated that electrospun soy protein isolate (SPI) can enhance the healing in both the wound bed and the epithelium.[2] Similar results have also been found when comparing electrospun SPI side-by-side to a commercial acellular matrix, Oasis.[3] In order to improve cellular infiltration into the scaffolds, we modified the electrospinning process creating a gradient porous fibrous (GPF) scaffold, with pore sizes ranging from 7.8 ± 2.5 µm on the small pore side to 58.0 ± 23.6 µm on the large pore side.[4] In order to avoid toxic solvents, we began using a water-soluble soy protein isolate (WSsoy) and combined electrospinning and electroblowing for a methodology termed “electroprocessing”. Electroprocessed WSsoy scaffolds exhibit smaller diameter fibers (200 ± 20 nm)[5] and are formed more rapidly than by electrospinning alone. Both GPF and WSsoy scaffolds showed enhanced wound healing in a rat model. As electroprocessing is less sensitive to the distance from the needle to the target, we developed a hand-held device for applying electroprocessed biomaterials directly to a wound, with improved healing both in terms of gross wound healing and at the deeper, cellular architecture level. Taken together, electroprocessing is a promising technology for advancing wound healing and the field of regenerative medicine.

The biobank's tasks are not only collecting, processing and storage of biological samples and connected with them information, but also developing technology and commercial solutions.In 2016, Poland as BBMRI.pl Consortium joined the European biobank's network BBMRI-ERIC. The Consortium consists of highly specialized units, which professionals are working on the development of broadly understood biobanking in Poland. The main task of BBMRI.pl is to create Polish Biobanking Network (PBN) which aim is to join Polish biobanks and optimize their work. This is supposed to lead to the advancement of science, medicine, pharmacy, and related fields.There are many biobanking entities in Poland. PBN has already joined 50 units. Most of them declare specialized, clinical, or mixed (specialized-population) character. There are also some population biobanks in Poland. The material collected in biobanks is various types, mainly of human origin. Due to its diversity, it can be used in many preclinical studies. The quality standards that biobanks care about and advancement of used technology ensure the credibility of the biobanked material and obtaining reliable results of research in which it was used.Biobank's resources are often associated with rare, genetic, or oncological diseases. Thanks to the use of biobanked material, the acceleration and reduction of research costs at the preclinical stage is observed. That is why biobank can be named as an institution of a new type, combining the interests of independent entities.Key words: biobank, Polish Biobanking Network, BBMRI.pl This work was supported by MNSW, grant DIR/WK/2017/2018/01-1

We present a scaffold-based in vitro platform to create a 3D biomimetic sensory nerve model with applicability for pathology modelling, drug testing, tissue innervation and patterning. Starting from an optimized high throughput 3D differentiation protocol, we first generate uniform and homogenous human iPSC-derived nociceptive sensory neurons and validate based on marker expression and electrophysiology. To recreate the three-dimensional (3D) anisotropy and myelination of native neural tissue, we seed primary rat schwann cells (SCs) seeded onto an electrospun scaffold and embed in a fibrin hydrogel to provide three-dimensionality. The versatility of this scaffold was shown using the PC12 cell line, rat dorsal root ganglions (DRGs), human IPSC-derived nociceptors as possible different neural cells. All neurite growth was well aligned and maintained mature myelin segments. Fibrin provided a 3D environment with increased outgrowth compared to 2D cultures, with over 6.5 mm of axonal growth densely packed within a 3D matrix. Consistent anisotropic neurite growth was observed throughout the gel, suggesting a unique indirect ‘at a distance’ guidance mechanism. Using this 3D co-culture platform to model diabetic neuropathy, the demyelinating effects of hyperglycemia were shown and therapeutic drugs were evaluated to prevent or counter demyelination. We further show the versatility and utility of this platform by demonstrating the introduction of pancreatic pseudoislets and endometrium organoids, to create target tissue innervation models. Finally, we incorporate a vascular network to investigate neurovascular (NV) interactions and show, for the first time, the impact of SCs on in vitro vascular networks formation and vessel orientation.

The human eardrum or tympanic membrane (TM) is a thin, concave tissue located at the end of the ear canal [1]. It is responsible for receiving sound vibrations from the outer air and transmitting them to the middle ear. Perforated TMs are the most common injury to the human ear, resulting in a partial or complete hearing loss due to inept sound transmission [2]. In this work, we investigate the integration of tissue engineering approaches with targeted drug delivery for a complete reconstruction of the damaged eardrum.

Ciprofloxacin-encapsulated poly(D,L-lactide-co-glycolide) (PLGA) nanoparticles were synthesized with two distinct approaches, namely double-emulsion and nanoprecipitation, by applying an automated microjet reactor technology. A co-electrospinning/electrospraying strategy was implemented to incorporate these drug-loaded nanoparticles within an electrospun mesh of poly(ethylene oxide terephthalate)/poly(butylene terephthalate) [3]. Subsequently, a three-dimensional pattern mimicking the microanatomy of the native TM was deposited over it using additive manufacturing. Homogeneous distribution and adhesion of the PLGA nanoparticles was confirmed on the fabricated scaffolds; following which, the release kinetics of ciprofloxacin was evaluated. Optimization of the loading parameters are currently under investigation to ensure a sustained drug delivery, capable of preventing all on-site infections upon transplantation. Finally, preliminary cytocompatibility studies performed with human mesenchymal stromal cells revealed no noticeable effect of the ciprofloxacin-encapsulated nanoparticles on cellular attachment and proliferation.

This work introduces a combination of hierarchical biofabrication strategy with nanoparticle drug delivery systems to conduct a full eardrum reconstruction. The nano-biofabricated TM scaffolds will be ultimately validated based on their antimicrobial and anti-inflammatory responses.

Effects of mechanical stiffness in the cell niche has typically been evaluated via modulating ECM stiffness. However, cellular stiffness may also play an important role in various cellular processes, as cell junction proteins such as beta-catenin can function both as a mechanosensor and a signalling protein.

Using multiphoton fabrication, we studied the effects of modulus and 3D mechanical confinement with E-cadherin coated substrates on cell fates. Cells were seeded onto two types of structures: flat matrix structures which presented E-cadherin only, or a 3D checkerboard structure with laminin on the base and E-cadherin on the sides to observe monolayer formation and fidelity.

On the E-cadherin coated flat matrix structures, beta-catenin spreading was observed to correlate with F-actin differently in low- and high- modulus conditions. On high-modulus E-cad substrates, diffuse beta-catenin was observed and actin localization was observed at protrusions. On low-modulus E-cad substrates, cells exhibited sporadic spikes or puncta of beta-catenin that co-localized with actin spikes.

On the checkerboard structures, cells spread and were rounded, filling up the space on the structures. Compared to laminin-only controls, E-cadherin and beta-catenin staining had lower intensity. This suggests that cells may regulate cadherin expression when exposed to 3D mechanical confinement with apicobasal cues.

Combined, these results improve our understanding of mechanosensing at E-cadherin junctions, as a first step to understanding the role of cell stiffness in processes such as EMT and epithelial cell development.

Introduction: Routine cardiovascular interventions such as balloon angioplasty, cardiac bypass and stenting, provoke vascular activation and remodelling often requiring further interventions(1). Current models fail to account for physical stimuli such as flow and the interaction between cells and the extracellular matrix, which are essential for vascular tissue maintenance and function(2). Methods: MultiJet Fusion 3D-printing technology was used to create our novel bioreactor insert (EasyFlow) conveniently fitted on a 50ml centrifuge tube. Porcine carotid arteries were excised and cultured at different flowrates using EasyFlow for up to 7 days. Control tissue was cultured under static conditions. Some vessels underwent injury using balloon catheter at day 0. Tissues were collected at different time points and analysed by immunofluorescence and confocal microscopy.Results: We have successfully designed and manufactured a cost-efficient and versatile perfusion system. The EasyFlow perfusion adaptor takes advantage of 50ml centrifuge tubes isolating the reaction space from the environment and reducing the culture volume. The adaptability of our design accommodates vessels of different sizes and origins while the self-contained nature of EasyFlow allows efficient parallel-cultures and minimal media consumption, ideal for pharmacological studies. Culture of porcine arteries in EasyFlow preserve the endothelial coverage and the smooth muscle organisation, as compared to static culture. Upon balloon injury, tissues cultured in flow recapitulated the hallmarks of remodelling, such as intimal denudation, smooth muscle cell disarray and activation.Conclusions: This work lays the basis for ex-vivo future investigations into how vessel wall resident cells contribute to the pathological remodelling of blood vessels.

SINGLE WALL CARBON NANOTUBE REINFORCED COLLAGEN-CHITOSAN HYDROGELS: PROMISING APPROACH FOR BONE TISSUE REGENERATION

Kulwinder Kaur[P][1], Ciara Murphy[1]

[1] *Department of Anatomy, Tissue Engineering Research Group, Royal College of Surgeons in Ireland, 123 St. Stephens Green, Dublin 2, Ireland*

The development of highly biomimetic scaffolds in terms of composition and mechanical structure is particularly relevant for bone tissue engineering. Carboxylated single walled carbon nanotubes (SWCNT) are attractive for use due to their high aspect ratio combined with outstanding mechanical properties. This project investigates the use of mechanically robust SWCNT to reinforce collagen-chitosan hydrogels, to develop thermoresponsive hydrogels with appropriate mechanical properties and bioactivity, for use in load-bearing bone applications. Hydrogels comprising of a collagen-chitosan polymeric matrix, incorporating SWCNT, were prepared by mixing solubilized type I collagen and medium molecular weight chitosan with solutions of SWCNT at concentrations of 0, 0.5, 1 and 2 wt% in presence of β-glycerophosphate. The effect of SWCNT composition on the chemical, mechanical and thermoresponsive properties of the hydrogels was investigated using different physiochemical techniques including UV-visible spectroscopy, rheology, FTIR, Raman Spectroscopy, SEM and TEM analysis. It was determined that increasing concentration of SWCNT led to increased mechanical strength. Furthermore, the strong molecular interactions formed between polymeric matrix and SWCNT led to increased porous interconnectivity. The degradation ratio was varied by changing the concentrations of Collagen/ Chitosan and SWCNT. Thermoresponsive properties were achieved in all hydrogel groups by adjusting pH~7.4 with β-glycerophosphate, gelation occurs at ~36-37 degree Celsius within 5 minutes. Ongoing work is investigating the bioactivity of the hydrogels in terms of human mesenchymal stem cell viability, proliferation and osteogenic differentiation. These results demonstrate the potential of the hydrogels for minimally invasive applications in the field of bone tissue engineering and regeneration.

BACKGROUND: Biomaterials can be functionalized using nanomagnetic particles (NMP) able to increase the biomechanical and functional properties of bioartificial tissues (1). However, the in vivo biodistribution of NMP used in tissue engineering are not fully understood.

METHODS: Fibrin-agarose tissue-like substitutes containing magnetoferric NMP with a diameter of 70-80 nm were generated and subcutaneously grafted in Wistar rats. Biodistribution was assessed by magnetic resonance imaging (MRI) and histology, and major biochemical parameters were quantified in peripheral blood.

RESULTS: MRI and histological analyses showed that NMP stayed at the grafting site after 3 months and did not migrate to distal organs. In addition, a biochemical analysis of relevant parameters in blood revealed that all hepatic and renal function parameters were within normal values and were not altered by the bioartificial tissue implant.

CONCLUSIONS: These results suggest that the biomagnetic bioartificial tissues used in this work were safe for the animals and tended to stay at the implant site, while providing novel functions and properties to the fibrin-agarose tissue-like grafts.

COMPRESSION LOADING INDUCED FORMATION AND MATURATION OF 3D-MATRIX ADHESIONS (3DMAS) IN HUMAN MESENCHYMAL STEM CELLS

Barbara Mechanical Chan[P][1], CW Li[1], YT Lau[1], KL Lam[1]

[1] *Tissue Engineering Laboratory, Department of Mechanical Engineering, The University of Hong Kong*

Corresponding author's email: bpchan@hku.hk

Cells are known to sense and respond to mechanical signals including substrate compliance and mechanical loading. Cell-matrix adhesions are important molecular mechanosensors at the interface between cells and the matrix microenvironment. However, how external mechanical force affects the cell-matrix interactions particularly with the formation and maturation of cell-matrix adhesions is largely unknown.

Here, using a previously developed mechanical loading device [1], human mesenchymal stem cells (hMSCs)-collagen microtissues [2] were subjected to compression loading for both short term and long term, while the formation and maturation of integrin-based cell matrix adhesions were investigated.

Specifically, we found that integrin αV binding, focal a¬¬dhesion formation, and subsequent FAK activation were upregulated upon short-term dynamic compression. This compression-induced FAK signaling also leads to YAP activation. While long-term compression induced the formation and maturation of α5-integrin based adhesions, which are characterized as elongated 3D-matrix adhesions (3DMAs) with composition and morphology different from that of the 2D focal adhesions. Most importantly, compression loading-based pre-conditioning of hMSCs in the 3D micro-tissues induced the formation of mature integrin α5-dependent 3DMAs and potentiated the osteogenic differentiation of hMSCs. Collectively, this work demonstrated that active mechanical stimulation (compression) alters cell-matrix interactions at the cell-material interfaces in a dynamic manner and affects cell fate determination, demonstrating the significance of loading-based functional tissue engineering.

Introduction: Adipose tissue-derived mesenchymal stem cells (AT-MSCs) have received attention as a tool to enhance graft healing in ACL reconstruction. Nakayama developed a novel method to create scaffold- free tubular tissue from multicellular spheroids using a “Bio-3D printer”-based system. This system enables the creation of pre-designed three-dimensional structures using a computer robotics system. With this system, we created a tubular AT-MSCs constructs and studied its effect on tendon-bone healing in a rabbit ACL reconstruction model.

Methods: 12 white rabbits were used in this study. Interscapular fat tissue was harvested and tubular AT-MSCs constructs were made using bio-3D printer. ACL reconstruction with semitendinosus tendon autograft was performed. In the right knee, AT-MSCs constructs were implanted into the femoral bone tunnel (implantation group). In the left knee, only ACL reconstruction was performed (control group). Each 6 rabbits were sacrificed at 3 and 6 weeks postoperatively. 5 of the 6 rabbits were used for biomechanical and μCT analysis, remaining 1 were used for histological observation.

Results: On biomechanical analysis, the ultimate failure load of implant group at 3 and 6 weeks were significantly greater than those of control group. On μCT analysis, the volume of bone formation in the femoral bone tunnel in implant group was significantly smaller than control group at 3 weeks, but increased significantly at 6 weeks and showed no significant difference with control group.

Conclusion: Implantation of AT-MSCs constructs into femoral bone tunnel enhanced early pull-out strength of tendon graft, and promoted osteogenesis after 3 weeks.

MUSCADINE GRAPE EXTRACT IMPROVES SKELETAL MUSCLE REGENERATION THROUGH MACROPHAGE ATTENUATION

James M Poteracki$_P$[1], Yu Zhou[1], Patricia Gallagher[2], Ann Tallant[2], Tracy Criswell[1]

Introduction

Compartment Syndrome (CS) is a severe skeletal muscle injury requiring surgical intervention (fasciotomy). CS occurs after a primary injury to a muscle, resulting in increased intra-compartmental pressure (ICP), blood vessel occlusion, and tissue ischemia. Fasciotomy decreases ICP, but results in functional deficits and tissue fibrosis. Muscadine grape extract (MGE) is a mixed polyphenol compound with anti-inflammatory properties which may attenuate the macrophage response after injury and activate tissue regeneration.

Methods

In vivo: Using a rat model of CS with fasciotomy, MGE was administered in the drinking water 2 weeks prior to CS injury and throughout the experiment. Tibialis anterior (TA) function was measured pre- and post-injury and tissue collected for histological evaluation. In vitro: RAW 264.7 macrophages were cultured with MGE to determine if MGE could attenuate the inflammatory cytokine response, specifically through NF-κB inhibition. C2C12 myoblasts and primary muscle progenitor cells (MPCs) were cultured with MGE to determine if cell proliferation and myotube fusion were altered by MGE.

Results

Increased maximal force was detected in MGE treated rats pre and post CS injury. At 3 days post-injury, the number of Pax7+ satellite cells and CD68+ macrophages were decreased, while MyoG+ myofibers were increased compared to untreated controls. In vitro MGE treated macrophages decreased IL-6 mRNA expression compared to untreated controls.

Conclusion

These data suggest that MGE altered the macrophage phenotype and satellite cell response in vivo which may be due to altered cytokine production, as observed in vitro. MGE may be a novel therapeutic for skeletal muscle regeneration.

REMODEL is an H2020 project dedicated to building capacity to work with organoids and advanced 3D models in biomedical research. Biomedical research faces a need for replacement of animal experiments by reliable, safe and accurate in vitro models that better recapitulate the structure and function of human tissues than present 2D models. Among emerging in vitro models, organoids are especially interesting as they present the 3D organization that is characteristic for a certain tissue in vivo(1). Organoids bridge 2D cultures and in vivo models, providing a near-physiological model system for studying cells and tissues in a variety of contexts, e.g. patient-derived organoids for studying human diseases that are difficult to model in animals(2). While there is an enormous interest among scientists to access these model systems, the laboratory skills required to successfully develop organoids for different research purposes requires training. Existing training in model systems is focused either on animal use in research or non-animal models for toxicology testing. REMODEL aims to overcome the gap by developing advanced training in organoid and organoid-like systems for students and early researchers. Starting in 2020, we are organizing workshops and developing tools for blended learning to build a strong European network on 3D in vitro models for cancer, infection and tissue regeneration. Through research collaborations we also intend to tackle technical challenges such as the absence of an immune system and a vasculature within organoid cultures. Herein, we will present training models and outcomes based on the experience of the project first year.

Current bone tissue engineering (BTE) strategies are based on porous biocompatible scaffolds seeded with tissue-specific cells. The conventional approach involves seeding cells onto a macroporous scaffold and expects cell colonization to form composite tissue constructs. Many limitations have been observed using this approach, due to slow vascularization, limited diffusion of nutrients, low cell density and non-uniform cell distribution. Previous studies have shown that the Layer-by-Layer (LBL) fabrication approach, based on the assembly of small-seeded blocks, provided more efficient cell repartition in 3D compared to conventional methods [1,2].

The aim of this work was to evaluate the in vivo bone formation using cellularized macroporous scaffolds or LBL assembly of cellularized PLGA-HA membranes. We have developed a new material, made of medical-grade Poly(lactic-co-glycolic) acid (PLGA) mixed with 10% (w/w) hydroxyapatite nanoparticles (HA) for 3D printing by Fused Deposition Modelling (FDM) [3]. Materials were seeded with rat stromal vascular fraction isolated from adipose tissue. Both approaches demonstrated favorable tissue formation and relevant cellular responses for BTE applications. The results indicated that the LBL approach could be suitable for BTE, in order to promote homogenous cell distribution inside the scaffold.

A NOVEL SCAFFOLD WITH HIGH GLYCOSAMINOGLYCAN/HYDROXYPROLINE RATIO FOR INTERVERTEBRAL DISC REGENERATION

Xingxing YANGP[1], Barbara Pui Chan[1]

[1] *Tissue Engineering Laboratory, Department of Mechanical Engineering, The University of Hong Kong, Pokfulam Road, Hong Kong Special Administrative Region, China*

Corresponding author's email: bpchan@hku.hk

INTRODUCTION: In degenerated disc, nucleus pulposus (NP) lose its ability to maintain the cell function, followed by loss of glycosaminoglycan (GAG) content and reduction in disc height. It has been reported that the GAG/Hydroxyproline ratio in health young adult NP is 27:1 and decreased to 5:1 in aged [1]. Methods to enhance GAG incorporation has been intensively studied, but the GAG/HYP ratio of modified collagen-GAG scaffolds could not exceed to 4.5:1[2-3], which is below that of the NP of a young adult. Hence, development of scaffold with high GAG incorporation that mimic the native NP would be a useful strategy for disc regeneration. In this study, we report a novel scaffold, aminated collagen-aminated hyaluronic acid-GAG (aCol-aHA-GAG), with comparable GAG/HYP ratio and similar ultrastructure to native NP, good biocompatibility and cell phenotype maintenance ability.

EXPERIMENTAL METHODS: The aCol-aHA-GAG scaffold with different composition were fabricated before evaluating the GAG/HYP ratio, GAG release, ultrastructure, mechanical properties of the resultant coprecipitate structures. Bovine nucleus pulposus cells (bNPCs) were encapsulated into the aCol-aHA-GAG scaffold and cell viability, extracellular matrix deposition, cell phenotype maintenance as well as gene expression of phenotype marker was studied in detail.

RESULTS AND DISCUSSION: The GAG/HYP ratio of the scaffold was 20:1, approaching that of young adult native NP. SEM image showed bead-like and TEM image showed brush-like structure. Safranin-O staining of the bNPCs encapsulated scaffold showed extensive GAG distribution.

CONCLUSIONS: This study demonstrates that aCol-aHA-GAG structurally and functionally bio-mimic the native NP, would be an ideal scaffold for disc regeneration.

Introduction

Macrophages are immune cells able to polarize toward a pro- (M1) or anti-inflammatory (M2) phenotype, playing a key role in inflammation. The macrophage phenotype has been shown to change in response to biophysical cues. Here, we exploited melt electrowriting (MEW) to fabricate scaffolds with different 3D geometries to investigate the ability of scaffold architecture in modulating macrophage phenotype.

Methods

Polycaprolactone (PCL) scaffolds with different angles (90°, 60°, 120°) formed between adjacent fibers were fabricated by Melt Electrowriting (MEW). Unpolarized (M0) and polarized (M1, M2a, M2c) macrophages were cultured for 3 days on scaffolds (control groups: TCP and PCL films). To evaluate macrophage polarization, the release of pro- (TNF-α, IL-6, IL-1β, CXCL9, CCL5) and anti-inflammatory (IL-1RA, IL-10, IL-13, CCL22, CCL24) proteins was assessed.

Results

We selected three different pore geometries (square-, triangle-, and rhombus- grid) to obtain scaffolds with 90°, 60°, and 120° angles, respectively. The rhomboidal grid was more effective than the other configurations in promoting the release of all the analyzed anti-inflammatory factors, especially IL-10, by M0 and M2a macrophages and it was the only scaffold that significantly enhanced IL-10 secretion by M2a macrophages compared to PCL films.

Discussion & Conclusions

The rhomboidal architecture increased the secretion of anti-inflammatory factors, especially compared to PCL films without geometric cues, suggesting that rational scaffold design could be exploited to modulate the macrophage phenotype with the final aim of improving tissue healing.

Grafts produced by combining induced pluripotent stem cell (iPSC)-derivatives and tissue engineering (TE) are a promising therapeutic option for the replacement of cardiomyocytes (CM) lost due to myocardial infarction. Recent protocols allow for differentiating CMs in large scale and chemically defined (CD) manner [1]. However, most extracellular matrices used for TE in vitro are not suitable for transplantation due to immunogenicity, insufficient mechanical characteristics, or unreliable reproducibility. In search for CD substitutes of commonly used xenogeneic matrices, we disclose new dextran (Dex)-derived hydrogels with varying molecular weights suited for bioartificial cardiac tissue (BCT) development.

Dextran hydrogels were generated by an in situ gelation protocol [2] based on crosslinking via hydrazone formation. By varying the degrees of derivatization and the composition, material properties such as water storage capacity and mechanical strength could be flexibly adjusted. To modulate bioactivity, the cyclic pentapeptide RGD was coupled to the dextran backbone. A hydrogel blend with dextran and human collagen I (hColI) was added to iPSC-CMs and fibroblasts to generate BCTs.

Our results show that unlike collagen alone, Dex+hColI blends with or without RGD supported tissue formation and long term cultivation. The gel compaction, contractile strength and beating frequency of the formed BCTs were comparable to published TE constructs and transcriptome analysis revealed functional maturation of the CMs within the constructs. While, the presence of RGD did not show a beneficial improvement, we could demonstrate the feasibility of covalently crosslinked dextran hydrogels as matrix system in the field of cardiac regenerative medicine.

More than 42 million people worldwide suffering from heart valve disease could benefit from tissue engineered heart valves able to overcome the disadvantages of the available heart valve prostheses.[1] Utilizing highly resolved stereolithography we address the production of a scaffold for an advanced biohybrid heart valve implant with anisotropic mechanical properties mimicking those of the aortic valve. Specifically, we aim at replicating the properties of the three layers (i.e. ventricularis, spongiosa, fibrosa)[2] of the native heart valve tissue.

Polymeric scaffold structures were 3D printed using either a Caligma200UV from Cubicure employing a laser source with a wavelength λ=375nm with an acrylic photo resin or a custom-made stereolithography setup with a Nd:YAG laser source at λ=266nm and a self-developed thiol-ene-based photo resin[3]. Diverse unit cell designs were tested. Thoroughly cleaned scaffolds were mechanically characterized and tested for cytotoxicity. Finite element analysis was performed to optimize the scaffold architecture.

Mechanical properties of scaffold structures were investigated in respect of unit cell design, wall thickness and porosity, starting from a cubic lattice structure and moving to rhombohedral and Schwarz-P structures. The mechanical characterization reflected the material properties of the used polymers and of the 3D-architecture. From the aspect of material properties, polymer scaffolds from acrylic resin showed a higher Young's modulus but a lower ultimate strain than thiol-ene-based scaffolds. Furthermore, the ultimate mechanical properties of the scaffold depend on the unit cells used to construct the 3D-architecture. First cytotoxicity assessment on thiol-ene materials demonstrated that scaffolds can be used in combination with cells.

A physiologically relevant cell culture model is one that mimics the in vivo tissue organization and is physiologically relevant and/or patient-derived and meet the requirements of the pharmaceutical industry. We propose human-based biomaterials prepared from placenta and platelet rich plasma (PRP) to engineer humanized platforms for cell culture.(1,2,3) Human placenta based biomaterials result in non-immunogenic platforms with anti-inflammatory and pro-angiogenic properties. PRP is rich in growth factors and involved in tissue healing and angiogenesis that was herein explored to prepare bioactive hydrogels for cell culture.

Placenta was decellularized, solubilized, lyophilized, and milled. Platelet lysates (PLs) were prepared by exposing PRP to freeze-thaw cycles. The placenta extracellular matrix (hPECM)-proteins and PLs were chemically modified using a methacrylation protocol well established in our group. (1) Degree and local of modification were evaluated by mass spectrometry. The methacrylated proteins were processed in the form of a hydrogel upon irradiation with UV light.

The mechanical properties of the resulting gels can be easily tailored by varying the degree of modification and/or the concentration of the solution. The gels have proven to support distinct human derived cell cultures (stem cells, endothelial cells and cardiomyocytes), furthermore, the cells acquired an in vivo-like cell polarity and were able to invade the matrix, forming complex interconnected cellular networks.

We propose human based materials, as innovative, versatile platforms for cell culture, microtissue development and disease modeling. It offers the possibility to be personalised (using the patient's own proteins) according to the end-user needs with high potential for clinical translation.

Keywords

human protein biomaterals; 3d cell culture; personalized tissue engineering

NEW PHOTOCLEAVABLE HYDROGELS FOR HIGH-RESOLUTION SUBTRACTIVE BIOFABRICATION

Wanwan Qiu[P][1], Ralph Müller[1], Xiao-Hua Qin[1]

[1] *ETH Zurich, Institute for Biomechanics*

Corresponding author's email: wanwan.qiu@hest.ethz.ch

Phototunable hydrogels are important materials for tissue engineering and regenerative Medicine [1]. Recent advances have enabled researchers to grow functional tissues in 3D hydrogels with fine-tuned biochemical and biophysical properties. The integration of these materials with additive manufacturing techniques such as two-photon polymerization (2PP) allows 3D construction of complex structures. However, low throughput of 2PP remains a major challenge for scaled biofabrication at high spatial resolution.

To address these limitations, we seek to combine photocleavable hydrogels with subtractive two-photon photolithography to fabricate biomimetic microstructures during 3D culture. So far, the o-nitrobenzyl ether [2] and coumarin derivatives [3] are often used to prepare photocleavable hydrogels. However, these compounds suffer from rather limited efficiency for two-photon absorption. As a result, very high laser dosage and long irradiation times are required for photoscission parameters at which living cells are prone to be damaged [4].

In this contribution, we will present the design and synthesis of novel photocleavable hydrogels and their applications for photodynamic 3D culture. To improve the efficiency of these materials, we employ new concepts in photochemistry by introducing chemical groups with large two-photon absorption cross sections such as the long-conjugated oxime-ester derivatives [5] to cell-compatible polymers such as polyethylene glycol and hyaluronan. The mechanical properties of these gels are studied by in situ photo-rheology, while two-photon hydrogel degradation is investigated on a confocal laser scanning microscope. Preliminary results of subtractive high-resolution biofabrication will be presented in a 3D bone cell culture. The promise and challenge of this platform will be discussed.

Instructive tissue engineering biomaterials provide a vascular niche and protect oxidative stress in injured tissue. In this study, we exploited bioinspired bacteriophage nanofibers, previously recognized by their biochemical and structural cues inducing angiogenesis, as an antioxidant tissue engineering material. We demonstrated that topological cues of Arg-Gly-Asp (RGD)-engineered bacteriophage nanofibers provide angiogenic niches and cytoprotective functions against cellular oxidative stress with increased expression of antioxidant enzymes heme oxygenase-1 (HO-1) and NAD(P)H-quinone oxidoreductase 1 (NQO1) via the extracellular-signal-regulated kinase (ERK)−nuclear factor erythroid 2−related factor2 (Nrf2)-mediated signaling pathway, where a high density of RGD cues on the phage body support efficient interaction of cells with phage cues.

In cardiovascular tissue-engineering applications, many tissues and organs require long maturation times in bioreactors, where different physical, biochemical and cell-source related effects influence the proliferation of cells and extracellular matrix formation of the construct. In case of heart valves, the conditioning phase includes a mechanical stimulation through an increasing pulsatile flow that needs different sensors and actuators for adjustment and monitoring. The aim of this study was to develop a centrally organized control unit for the experimental equipment that autonomously controls the conditioning process without the need of manual intervention.

Therefore, the software-controlled maturation process was elaborated using the example of an aortic heart valve. The experimental setup includes a feedback-controlled software that is fed by sensor data including pressure transducers, a backflow measurement unit, a highspeed-camera and an ultrasound probe as well as a multi-photon endoscope. Pulsatile movement of the heart valve was provided by actuators controlling medium flow and the compliance volume.

The conditioned heart valves reveal a more homogeneous tissue and, among the experimental batches, less variation of the tissue development. The majority of previously manual steps were implementable in an autonomous-working process control that reduced the required working times. Besides, the current maturation state of the heart valve was transparently traceable at every point through the logged sensor data. In summary, the study showed that the dynamic conditioning of tissue-engineered heart valves is automatable. The experimental setup may be also suitable for other bioreactor applications in tissue engineering.

Osteoarthritis (OA) is a common chronic joint disease and cause of disability worldwide. MSCs-derived extracellular vesicles (EVs) showed ability in modulation and treatment of OA. Nevertheless, a key obstacle to clinical acceptance of EV-based therapies is the uncertainty surrounding their distribution after transplant.

In this scenario, we developed a novel tool for tagging EVs, using nanostars (NS). NS are gold nanoparticles with branching arms (like a star), thanks to which they can be detected by optoacoustic imaging (OAI). OAI utilises the optoacoustic effect: nanosecond pulses of laser light illuminate the tissue; the resulting pressure wave is detected using ultrasound sensors and converted into an image. NS were carboxylated (NS-COOH), to enhance their binding ability, and chitosan-coated (NS-COOH-CHS) to avoid their clustering.

We isolated human MSCs and cultured them in a heparin-free human platelet lysate (PL), allowing their future use for clinical intent. We isolated EVs and characterized for size, morphology and content by non-conventional flow cytometry, TEM and western blot. NS-COOH and NS-COOH-CHS were added at 400pM and 800pM to EVs for different exposure time. The labelling was investigated by TEM to optimize the tagging protocol. In vitro analyses were performed to assess the functionality of MSC-EVs and NS-tagged MSC-EVs in an in vitro OA model. MSCs derived EVs are indeed able to revert the IL-1α-induced inflammation in human articular chondrocytes.

All these strategies could finally represent a novel tool for regenerative medicine, allowing to follow cells and EVs in vivo in small and large animal models.

Hepatocyte-like cells derived from human induced pluripotent stem cells (hiPSC-HLC) hold great promise as a new cell source of hepatocytes for preclinical drug development and regenerative medicine (1). Nonetheless, the generated hiPSC-HLC are still immature when compared to their adult counterparts. Recapitulating liver maturation in vitro is complex, as this physiological process takes approximately 2 years after birth and involves a wide range of biological events. The human gut microbiome, which is thought to be established early in the fetal stage, has been strongly associated with the acquisition of hepatic functionality (2). Herein, we developed a nature-inspired protocol to generate more mature hiPSC-HLC through the use of human microbiome.

hiPSC were differentiated into HLC using a 3D culture strategy in stirred-tank bioreactors (3). After differentiation, hiPSC-HLC were treated for 6 additional days with intestinal microbiota secretome generated from neonatal or adult samples. Our results showed that HLC generated in 3D culture exhibited higher expression of some hepatic hallmarks (CYP3A4, A1AT, HNF4a, ALB), an increase in the albumin production, higher uptake and release of indocyanine green when compared with the HLC generated in 2D monolayers. Treatment with microbiome secretome induced upregulation of CYP3A4, CYP2C9, HNF4a and ALB in HLC, which was not verified in cells cultured in medium only or supplemented with secretome from a donor under antibiotic treatment. Interestingly, the secretome from neonatal origin showed to be more efficient in driving HLC maturation than the adult formulation.

HUMAN ARTICULAR CHONDROCYTE RE-DIFFERENTIATION IN 3D-PRINTED PLATELET RICH PLASMA (PRP) AND ALGINATE BASED BIOINK

Tissue engineering strategies for clinical treatments of cartilage defects are mainly based on transplantation of in vitro expanded autologous chondrocytes in the patient damaged tissue. However, their dedifferentiation during in vitro expansion often leads to suboptimal therapeutic outcomes [1]. Three dimensional (3D) culture systems can revert this dedifferentiated state and re establish chondrogenic phenotype [2]. In this scenario, 3D-bioprinting technology allows to create a patient-shaped grafts starting from cell-laden bioink, obtaining a more physiological environment for transplanted cells, promoting tissue regeneration. Thus, human articular chondrocytes (hACs), isolated from patient tissue biopsies and expanded in vitro in monolayer, were 3D-bioprinted in alginate or alginate Platelet Rich Plasma (PRP)-mixed bioinks. In vitro cell morphology, viability, growth and chondrogenic differentiation were investigated. 3D culture in both cases significantly increased the expression of chondrogenic markers compared to 2D condition. Furthermore, the addition of PRP to alginate up-regulated the expression of these markers. PRP functionalization increased hACs viability and growth compared to alginate alone. 3D constructs were implanted in nude mice to analyze the chondrogenic differentiation in vivo, showing a slight cartilage tissue-like organization after two months. Finally, 3D-bioprinting of hACs allowed them to recover chondrogenic phenotype and the embedding in PRP supplemented bioink supported chondrogenic culture inside the printed constructs. In view of future clinic translation, the choice of cell source for 3D-bioprinting of patient-specific grafts will have to be oriented towards cell types with higher potential, such as chondro progenitors, than mature hACs in order to ensure a successful cartilage regeneration and repair.

Developing miniature bone cell models is key to tissue engineering and disease modelling. Bone has a sophisticated internal architecture across several length scales. Recapitulating the structural complexity in bone requires the development of high-resolution biofabrication techniques that faithfully recreate tissue architecture down to the micrometer-scale accuracy. One promising approach is to combine computer models derived from biomedical imaging data with light-based additive manufacturing (AM) techniques. Using light as the stimulus, photopolymer solutions can be locally solidified through lithographic voxel-by-voxel patterning in accordance with computer models. However, existing high-resolution AM techniques by means of two-photon polymerization often suffer from lengthy fabrication process and poor cell-compatibility.

Here, we present an image-based subtractive manufacturing process for creating cell guidance cues in biocompatible hydrogels. To this end, new computer models that mimic the topology of lacuno-canalicular network (LCN) in bone are developed by sequential immunostaining and confocal microscopic imaging of osteocytes in mouse bone specimen. These models are processed into stereolithography files through image processing with MATLAB. Using two-photon subtractive 3D microprinting, we demonstrate the fabrication of LCN-mimicking microstructures inside a photodegradable polyethylene glycol hydrogel at high spatial resolution. The structure fidelity is highly dependent on the laser processing parameters such as laser power and writing speed, whereas permeability assays with fluorescently labelled proteins shows that the printed microstructures are accessible to fluid transport. Lastly, preliminary data on subtractive 3D microprinting in the presence of living bone cells and guided 3D cell growth will be presented.

Particle size in free-packed systems has been overlooked as a possibly relevant parameter to control cell response. We here explore the hypothesis that there is a lower limit of the traction force necessary for cells to adhere, effectively spread and move, which could be controlled by microsphere size. We aimed at understanding how cells sense and respond to those forces and how that drives cell fate, using a quasi-3D free-packed microparticle system in a liquid medium.

We used commercial polystyrene microspheres coated with type I collagen and assessed the adhesion and phenotype of human adipose tissue-derived mesenchymal stem cells (hASC). By focusing on different size ranges of microparticles - 14-20 µm, 38-45 µm, 85-105 µm -, we evaluated the metabolic activity, cell adhesion and morphology, besides focal adhesion formation after stipulated incubation timepoints (4 hours, 1, 3 or 4, 7 days).

Metabolic activity quantification suggested that initial cell adhesion to particles is not hampered in any microparticle size. Nonetheless, after 4 hours, microscopy data showed different cytoskeletal rearrangement profiles with intermediate and higher diameter microspheres presenting higher numbers of adhered cells with stretched actin fibers. Metabolic activity assessment corroborated that increasing microsphere diameters promoted cell proliferation over time (7 days), while detachment from smaller (~14 µm) microparticles explains the detected decline of observable cells and metabolic activity.

We hypothesize that higher and intermediate dimension spheres benefit long-term cell adhesion, whereas smaller microparticles may be an unsteady substrate for cell survival, due to the movement created by cells' pulling forces.

BACKGROUND: Treatment of severely damaged corneas affected by trophic ulcers and other conditions is challenging. In this regard, a clinical trial to evaluate the clinical usefulness of a model of bioengineered lamellar human cornea generated as an advanced therapy medicinal product (ATMP) (1) is being currently implemented. The objective of this work is to evaluate the expression of relevant tissue molecules in these clinical-grade bioartificial corneas as compared with human native corneas.

METHODS: Human bioengineered corneas generated as ATMP were analyzed by immunohistochemistry using specific primary antibodies anti-cytokeratin and anti-plakoglobin and connexin, relevant cell-cell junction proteins in cornea.

RESULTS: The bioartificial cornea was biomimetic of the native cornea, although the differentiation level of the cornea epithelium was lower as compared to the human organ. Expression of the epithelial markers plakoglobin, connexin and cytokeratin was similar to control corneas.

CONCLUSIONS: These results imply that bioengineered human corneas are able to synthetize some of the proteins involved in human cornea differentiation and function and, therefore, fulfill the requirements for clinical use.

BRIDGING THE GAP BETWEEN THE MECHANICAL AND METABOLIC ACTIVITY IN MSC DIFFERENTIATION

Ana San Felix$_P$[1], Sara Trujillo Muñoz[1], Matthew Dalby[1], Manuel Salmeron-Sanchez[1]
[1] *Centre for the Cellular Microenvironment (CeMi), University of Glasgow,*
Corresponding author's email: a.san-felix.1@research.gla.ac.uk

Cells are in constant communication with their surroundings and every information gathered from their vicinity is used to generate an ultimate response(1). To do that cells exert forces of different magnitude depending on how they sense the extracellular matrix(2). We hypothesise that every mechanical modification that cells undergo during their attachment, migration, proliferation and differentiation has a direct impact in their metabolic activity(3). This study aims to fill the existing gap between cell mechanical and metabolic activities, providing a better understanding on how microenvironmental cues can be used to control cell fate.

In this study, mesenchymal stem cells (MSCs) are seeded on full-length fibronectin(FN)-PEG hydrogels(4) with different stiffness and degradability. By using traction force microscopy (TFM), we observed that cells exert higher forces on degradable gels compared with non-degradable, and on stiffer gels compare with soft. When cytoskeleton contractility was inhibited, cells exerted lower forces on the surfaces. Looking at the mechanotransduction factor YAP, its nuclear location was higher on non-degradable surfaces compared with degradable ones. However, there were no significant differences when cytoskeleton contractility was inhibited using blebbistatin.

These experiments suggest that cell behaviour can be regulated by substrate's rigidity and degradability. In addition, cytoskeleton contractility has a great importance in force generation. It was interesting to see that YAP results differ from what we saw in TFM. Finally, based on these results, we are investigating how the cellular metabolic profile will change under these same properties of the environment.

FUNCTIONAL MODIFIED COLLAGEN GEL PROMOTED THE RECOVERY OF MYOCARDIAL FUNCTION AFTER ISCHEMIA REPERFUSION INJURY

Tzuhsuan Chan[P][1]

[1] *Affiliated Drum Tower Hospital, Medical School of Nanjing University*

Corresponding author's email: zxzhan2018@sinano.ac.cn

Myocardial ischemia reperfusion injury happens at left anterior descending artery which branch from left coronary artery belongs to coronary artery disease (CAD). In China, CAD is the major cause of cardiovascular disease (CVD) with a proportion higher than 40%, while CVD is the leading cause of death in non-communicable diseases in the 2019 world health statistics. Angiogenesis therapies that decrease the death of cardiomyocytes by promoting the formation of new vessels restoring myocardial function are required for CAD patients' better quality of life.

Basic fibroblast growth factor (bFGF) is a well- known angiogenic stimulators which plays an important role in the angiogenesis process of migration, proliferation, and vascular tube formation directly. While stromal cell derived factor-1α(SDF-1α) stimulate the happening of angiogenesis by guiding artery cell's migration during collateral development. However, the combining effect of bFGF and SDF-1α on angiogenesis after ischemia reperfusion injury is unknown. Collagen gel is considered because of its well-known biocompatibility, low antigenicity, and its safety and feasibility, as the myocardium ECM is mostly comprised of collagen.

In this study, an injectable collagen gel modified with bFGF and SDF-1α was injected into the hearts of rats after induced ischemia reperfusion injury. Our results showed that the combined injectable collagen gel significantly promotes neo-vasculature forming and lessens fibrosis degree. In addition, it shows great enhancement in the functional restoration after heart ischemia reperfusion injury. Therefore, the combination of two factors, bFGF and SDF-1α, with injectable collagen gel provides a promising outcome after ischemia reperfusion heart injury.

Sensorineural hearing loss is a pathology that affects the inner ear [1]. It is characterized by a lack of signal transduction, from the mechanic (fluid waves) to electric (depolarization of spiral ganglion neurons, while the nerve still maintains its function [2]. To date, the therapeutic option for patients suffering intense SNHL is the cochlear implant (CI), a high-tech electronic device replacing the entire cochlear function. Piezoelectric materials can play an important role in SNHL treatment by simply mimicking the function of the cochlear sensory epithelium. We aimed at developing significant advancements about piezoelectric biomaterials for cochlear implants as an innovative technology to aid hearing loss. Lithium niobate (LiNbO3), a piezoelectric ceramic, has been investigated as a potential candidate material for next-generation CIs. Lithium niobate nanoparticles resulted otocompatible with inner ear cells in vitro, had strong immunomodulatory activity and enhanced human defensin in epithelial cells, and also showed direct antibacterial activity against P. aeruginosa. Moreover, the electrospinning technique was used to produce LiNbO3-loaded polyvinylidene fluoride-trifluoro ethylene [P(VDF-TrFE)] composite fiber mesh. Aligned composite fibers containing 20% w/w% of LiNbO3 showed an enhanced piezoelectric response. These composite fibrous structures also supported human neural-like cell growth in vitro. Development of high-performance electroactive biomaterials via a combination of nanotechnology and tissue engineering opens new opportunities for cochlear stimulation and otoprotection, and would improve the quality of life of deaf people since they are cost-effective, simple, biomimetic, water and magneto-compatible.

Elastin-like recombinamers (ELRs) have gained increasing interest because of their widespread application in drug delivery and tissue engineering.[1,2] Here, antimicrobial peptides (AMPs) have been co-produced with ELRs in a modular design in order to combine the antimicrobial potential of the AMPs with the stimuli-responsiveness of the ELRs for the development of antimicrobial and self-assembling biomaterials.

We investigated two different approaches: (i) L- and D-enantiomers of a designer AMP were incorporated in a low-fouling ELR[3] (AMP-ELR1). ELR1 remains unfolded at physiological conditions and a C-terminal grafting domain was incorporated. (ii) Self-assembling AMPs were cloned on the hydrophilic block of an amphiphilic ELR (AMP-ELR2) in order to assess their use as self-assembling domains to drive hierarchical organization of intrinsically-disordered proteins.

We developed an innovative and scalable method for the bioproduction of antimicrobial polypeptides. When AMP-ELRs were tethered on metal surfaces and the AMPs forced to be exposed (AMP-ELR1), ELR low-fouling activity seemed to converge synergistically with the antimicrobial properties of the AMP providing safe nanocoatings with strong antibiofilm properties.[4,5] In contrast, the ability of AMPs and ELRs to self-assemble in solution led to hierarchical architectures by way of a dual-assembly process (AMP-ELR2). First, the AMPs triggered the formation of nanofibers; then, the thermoresponsiveness of the ELR2 enabled assembly into fibrillar networks with potential application as molecular nanoreservoirs and physically crosslinked three-dimensional scaffolds for tissue engineering applications.[6] Our findings evidenced that the combination of AMPs and ELRs is a promising tool for improving the properties of the AMPs controlling their supramolecular assembly.

MICROFLUIDIC SELF-ASSEMBLY OF CELL-LADEN MICROGELS INTO CLUSTERS, CHAINS AND ARRAYS: FROM ORGANOIDS TO VASCULATURE NETWORKS ENGINEERING.

Jan Guzowski[P][1], Katarzyna Rojek[1], Marco Costantini[1], Monika Ćwiklińska[1], Robert Buda[1]

We report microfluidic generation of a variety of compartmentalized cell-laden hydrogel structures ranging from hydrogel bead-clusters and quasi-1D granular threads to 2D granular arrays and demonstrate that such types of tailored complex structures can be used to impose spatial cell-patterning in various types of biomaterials. We adopt the idea of capillary self-assembly of hydrogel beads inside a non-crosslinked hydrogel-precursor liquid layer, a method originally proposed over a decade ago by Du et al. [1]. Here, we propose a way of manipulating the capillary-arrested microbeads with unprecedented precision, throughput and reproducibility using microfluidics [2], which opens new perspectives in tissue engineering.
Our approach allows for directed self-assembly of hydrogel microbead clusters and we demonstrate possible applications of such structures in formulation of organoids such as artificial pancreatic islets or microtumors. We also demonstarte deposition of bead-chains and multi-chains, as well as perturbed quasi-1D structures at a substrate. The quasi-1D structures remain regular, yet stochastic; this allows encoding of the information about the encapsulated biomaterial and unique 'labeling' of the microbioreactors. We discuss potential applications of the technology in high-throughput drug screening.
Finally, we also report microfluidic assembly of endothelial-cell coated microbeads into regularly-spaced 2D arrays embedded in external fibrin matrix. The beads serve as angiogenic 'seeds': we observe outgrowth of capillaries, branching and finally anastomosis of microvessels coming from the neighboring beads indicating formation of a complex vascular network. We discuss the perspectives of the system in organ-on chip studies on vascular diseases.

Melt electrowriting (MEW) technique is a relatively new manufacturing technology used to fabricate scaffolds through the deposition of polymeric fibres according to a user-oriented design. Polymer melts, hydrogels and bioinks have been successfully spun via MEW, with both hydrogels or bioinks undergoing crosslinking by controlling the temperature at the nozzle section or by applying a post-process such as UV curing. In this work, we develop an inline photocrosslinking approach via laser irradiation within the nozzle section. Polyethylene glycol diacrylate (PEGDA) of Mw 3k and 6k are used as a material with two different photoinitiators, i.e. Irgacure and LAP. Melt rheology is performed under various conditions to determine pot life, processing temperature window and crosslinking parameters. A conceptual model is described based on rheology date to facilitate the choice and design of a laser module and finally integrated into custom-made MEW system. MEW of the PEGDA is successfully done at a melting temperature of 60°C and by crosslinking with a laser. While changing the laser intensity, the filament stiffness is successfully tuned inline, making it possible to control the stiffness of the filament at the desired time/location. Due to greater control over stiffness compared to other methods of crosslinking, this technique is useful for creating anisotropic scaffolds without changing the design patterns. Mechanical tests have been performed to show the different anisotropic behaviour of identical square pattern scaffolds.

Reconstructing auricle resulting from trauma, neoplasm, or congenital defects is one of the most challenging and diverse tasks in aesthetic and reconstructive surgery due to the highly complex three-dimensional anatomy of the outer ear [1]. We aimed at providing alternatives to overcome the shortcomings of the standard surgical reconstructive procedures using tissue engineering. Emulsion and freeze-drying were used to produce poly(vinyl alcohol)/gelatin (PVA/G) sponges at different weight ratios (100/0 - 50/50 w/w%), which were cross-linked by exposure to glutaraldehyde vapors. PVA/G sponges with highly round-shaped interconnected pores, highly swelling capacity (> 200%), and an essentially elastic mechanical behaviour were obtained. Different culture conditions were applied to obtain elastic cartilage: , undifferentiated versus chondrogenic pre-differentiated bone marrow derived human mesenchymal stromal cells (hMSCs), commercial versus hand-made chondrogenic differentiation medium and static versus dynamic culture [i.e. ultrasound (US) or bioreactor stimulation] were used. After three weeks, the constructs were analyzed via immunohistochemistry (IHC). Intense glycosaminoglycan, glycoprotein and collagen syntheses by hMSCs were most frequently observed using the commercial medium, while round morphology was observed when pre-differentiated hMSCs were seeded. The application of US stimulation during the culture on cell/scaffold constructs enhanced extracellular matrix deposition and led to 30% higher collagen type II expression at gene level. However, at protein level, collagen type II, aggrecan and elastin formation were observed via IHC only by using bioreactor culture. Results showed that 70/30 (w/w%) PVA/G sponge is a suitable scaffold for auricle reconstruction.

UNIAXIAL CYCLIC STRAIN TO RESTORE THE ANISOTROPY OF CARDIAC CELLS AND ECM IN 2D AND 3D IN VITRO MODELS OF MYOCARDIAL INFARCTION

The human myocardium is a mechanically active tissue typified by its anisotropic organization of cells and extracellular matrix. Upon injury, the myocardium undergoes dramatic alterations, resulting in disruption of anisotropy and loss of coordinated contraction. Moreover, loss of anisotropic organization hampers the differentiation, matrix production, and mechanotransduction of resident and newly injected cardiac cells. Therefore, restoring the anisotropic organization in the injured myocardium could greatly benefit myocardial regeneration.

In this project, we studied the effect of mechanical and structural cues, inspired by myocardial biology, on the organization of cardiac cells. We showed that uniaxial cyclic strain, mimicking the local deformation of cardiac beating, led to anisotropic organization of cardiac fibroblasts (cFBs), but not of cardiomyocytes (hiPSC-CMs). Next, we reconstructed the cellular compositions of normal and pathological myocardium using co-cultures with varying cell ratios. Surprisingly, contrary to the response of the hiPSC-CM monoculture, the co-cultures adopted an anisotropic organization under uniaxial cyclic strain, regardless of the co-culture composition. These data suggest that the mechanoresponsiveness of cFBs may be critical in determining myocardial tissue structure and function.

To further investigate the relevance of these mechanical and structural cues in vivo, we developed 3D myocardial micro-tissues, consisting of cell-laden collagen I/Matrigel constructs within flexible micropillars. Using this model, we successfully imposed mechanical constraints to tune the degree of microtissue organization and allow measurement of tissue contraction. We will discuss how uniaxial cyclic strain can be used to induce anisotropy in a 3D myocardial micro-tissue and how this effects tissue contraction and function.

Mesoporous nanoparticles (MSNs) constitute promising carriers for the adsorption and local control release of biological active agents that promote bone regeneration. Doping MSNs with cerium ions could contribute to control over bacterial contamination and enhance the capability of vascularization, eliminating the chance of bone loss1. The aim of this study was the evaluation of the antioxidant agent artemisinin2 loading/release profiles, biocompatibility and hemolytic activity of different Ce-doped MSNs (1, 2.5 and 5%). MCM-41 mesoporous nanoparticles were synthesized via sol-gel and had either neat siliceous or metal (Ca and Ce) substituted walls. X-Ray Diffraction analysis and N2 porosimetey were used to determine their structural characteristics. Their drug loading and release profiles were assessed with Liquid Chromatography–Mass Spectrometry (LC-MS) and their cell viability with the MTT assay on human periodontal ligament cells (hPDLCs). Their hemolytic activity was evaluated in contact with human red blood cells at various concentrations (12.5-500μg/ml). A high loading capacity was recorded for all Ce-doped MSNs (73-85%) that was higher compared to pure silica (64%). Artemisinin release was verified after sonication for 40 min, without significant differences among MSNs. At low concentrations MSNs presented no hemolytic activity, while at high concentrations the lowest hemolytic activity was recorded for the MSNs with the highest amount of cerium. The 1 and 2.5% Ce-doped MSNs significantly promoted mitochondrial activity and proliferation of hPDLCs. In conclusion, cerium can be incorporated in MSNs to improve their performance in terms of biocompatibility, hemolytic activity and loading of artemisinin.

Traumatic chondral lesions are common in the young and active population, and if left untreated can evolve towards osteoarthritis. The inflammatory response initiated as a consequence of tissue damage imposes a major challenge in cartilage repair. The released pro-inflammatory factors induce a shift in chondrocyte activity towards catabolism and promote further tissue degradation (1-2). Several anti-inflammatory drugs have been successfully tested (2), and we propose ibuprofen-loaded poly(lactic-co-glycolic acid) (PLGA) nanoparticles as a strategy to locally deliver an anti-inflammatory treatment.

Here, we aimed to evaluate the chondroprotective and chondrogenic effects of ibuprofen-loaded PLGA nanoparticles. To achieve this, human chondrocytes were cultured as 3D pellets, submitted to a pro-inflammatory environment (stimulation with 100ng/mL of IL-1β), and treated with PLGA nanoparticles loaded with 15 or 30 μg/mL of ibuprofen. Analyses were performed 3 and 7 days after nanoparticles addition.

Our results show that 3 and 7 days treatment with ibuprofen-loaded nanoparticles (15 or 30 μg/mL of ibuprofen) leads to a decrease in both IL-1β protein release and metalloproteases mRNA expression (MMP1 and MMP8) by human chondrocyte pellets cultured under a pro-inflammatory stimulus. Moreover, under similar conditions, 3 days treatment with these nanoparticles induced an increased production of extracellular matrix (ECM) components (collagen type II and aggrecan). Altogether the obtained data indicate that treatment with ibuprofen-loaded PLGA nanoparticles mitigates chondrocytes' pro-inflammatory response and ECM degradation activity induced in an inflammation scenario. Therefore, this is a promising strategy to overcome catabolic effects of post-traumatic inflammation on cartilage.

For a viable and compliant clinical translation of tissue engineered products, the adoption of automated technologies has been acknowledged as a prerequisite. Recently, the use of chondrogenic microtissue and organoid assemblies has shown promising results in long-bone defect regeneration through endochondral ossification[1]. Hence, automated biomanufacturing technologies able to culture and handle these tissue building blocks are of great interest. Here, we present an automation strategy through the use of different robotics for (i) media change during differentiation and (ii) image-based picking of microtissues for enabling spheroid-specific QC.

Media change of microtissues in microwell platforms requires controlled pipetting to avoid microtissue displacement and suspension leading to uncontrolled fusion. A first design of experiment (DoE) revealed that dispensing speed and its interaction with pipetting needle depth during dispensing affected microtissue displacement the most. Conversely, aspiration speed within the predefined ranges had less impact. A second DoE was created to improve protocol parameters for microtissues of different sizes (250/1000 cells). Smaller microtissues moved more than large, especially at higher aspiration speeds. Subsequently, the automatic cell-screening and -picking system CellCelector™ was used to select and transfer single spheroids in a controlled manner. Spheroids were automatically selected based on the presence of only 1 spheroid/well and/or size via image-based analysis. The aspirated spheroid was subsequently deposited in a pre-defined receiver-microwell for further analysis.

We demonstrate the development of an integrated bioprocess for culturing and manipulation of cartilaginous spheroids. We anticipate the progressive substitution of manual operations with automated solutions for manufacturing of microtissue-based living implants.

Several diseases affecting the musculoskeletal compartment (e.g. bone tumors, muscle fibrosis) involve the interplay among tissue-specific cells, vascular cells and extracellular matrix [1]. Currently available models are too simplified to address such a complex scenario and alternative systems able to recapitulate the native human tissue complexity are required.To overcome limitations of microfluidic models (e.g. limited tissue thickness, availability of biological material) we biofabricated mm-scaled models of bone and muscle tissues which are compatible with proteomics and gene expression analyses. Bone models included osteoblasts, osteoclasts, vascular cells and macrophages in a fibrin matrix with or w/o hydroxyapatite nanoparticles. The muscle model embedded aligned human muscle fibers wrapped by endomysium and surrounded by vascular network. To analyze the behavior of healthy and pathological cells we combined immunofluorescence, flow cytometry and qPCR analyses. Exploiting microfluidic models we reproduced the higher extravasation rate of breast cancer cells (bCCs) in the bone compared to the muscle model [2]. This increased bCC affinity towards the bone was also demonstrated in the mm-scale models. We thus exploited our bone model as drug screening platform showing that doxorubicin and rapamycin reduced bCC proliferation while inducing vascular damage. The mm-scale muscle was evaluated as fibrosis model employing diseased human fibroblasts, showing its ability in replicating typical fibrosis features compared to standard 2D models [3].The generation of complex biological environments in our models allowed to replicate disease hallmarks and to investigate the effects of drugs more reliably than current standard models.

INTRODUCTION: Cartilage is responsive to mechanical stimulation, with the potential for exploitation in tissue engineering for reconstructive surgery. The aim of this study was to determine the role of dynamic culture conditions on cell growth and chondrogenesis independent of mechanical stimulation through the use of an orbital shaking system.

METHODS: Human nasal septal cartilage was acquired from septal surgery. Human nasal chondrocytes were seeded into 100ul nanocellulose and alginate hydrogels, crosslinked with calcium chloride and incubated at 37oC for 14 days in either static or dynamic conditions (orbital plate shaker, 500 rpm). Cell growth and chondrogenesis was confirmed using quantitative polymerase chain reaction, histological stains of cartilage extracellular matrix and cell proliferation assays. Relative gene expression was compared between static and dynamic groups using unpaired t-tests. Computational analysis was used to determine the degree of shear stress experienced by cells in the biomaterial in the orbital shaking conditions.

RESULTS: In nasal septal chondroprogenitor cell populations, dynamic conditions induced marked increases in the gene expression of chondrogenic genes COL2 (7.28-fold increase, $p<0.001$), aggrecan (10.26-fold increase, $p=0.001$) and SOX9 (2.34-fold, $p=0.002$). Histological analysis demonstrated increased matrix formation and superior biomaterial integrity in dynamic conditions. Computational modelling confirmed the shear stress exerted by orbital shaking was inadequate to directly affect chondrogenesis.

CONCLUSIONS: The use of an orbital shaking system exerts biologically relevant effects on human nasal chondrocytes independently of mechanical stimulation. We postulate this mechanism is through enhancing growth media perfusion and has implications for in vitro cartilage tissue engineering for reconstructive surgery.

Oligomers have potential application for printing and as adjuvants for vaccines. Preparing oligomers is especially worthwhile for stereolithography. So one gets materials in the needed viscosity range. Oligomers are favourable as adjuvants for vaccines, as they facilitate renal clearance. Methacrylic polymers known to be widely tolerated in vivo, so they are widely used in biology and medicine. So, to prepare the oligomers mainly methacrylic monomers were used.
The oligomers were prepared by catalytic chain transfer polymerisation (CCTP). Cobalt macrocycles are effective and mostly used catalysts for the CCTP. This is disadvantageous for medical applications, as cobalt is toxic. Iron has higher biocompatibility and is also abundant in nature, so it is additionally more sustainable. The catalysts were prepared in situ. For that iron bromide and dimethyl glyoxime or diphenyl glyoxime were added as ligands. Different catalyst concentrations were used. The reactions were made in bulk and with toluene as solvent.
The reaction conditions and monomers influenced the level of control. For reactions using diphenyl glyoxime as ligand it was preferable to prepare the oligomers in bulk. In contrast to that dimethyl glyoxime as ligand could control reaction better in solvent. To control the reactions higher concentration of iron catalysts were needed than in case of cobalt catalysts.
Iron catalysts are a possible replacement for cobalt catalysts for the CCTP. This allows to prepare reproducible, biocompatible oligomers. Further work will be done to optimise the conditions.

Studies on the cardiac repair potential of Extracellular Vesicles (EV) traditionally use mesenchymal or cardiac progenitor cell-derived EV [1,2], overlooking the potential of human induced pluripotent stem cells (hiPSC) and hiPSC-derived cardiomyocytes (hiPSC-CM) as alternative EV sources.

In this study, we characterized EV derived from key stages of the hiPSC-CM differentiation and maturation, i.e. from hiPSC (hiPSC-EV), cardiac progenitors (CPC-EV), immature (CMi-EV) and mature (CMm-EV) cardiomyocytes, with the goal of studying their potential role as therapeutics, and whether their yield and function was influenced by the state of their parent cell.

Two hiPSC lines were differentiated into hiPSC-CM and cultured as 3D spheroids in a fatty acid supplemented medium to improve CM maturation [3,4]. EV were isolated using density separation and characterized in terms of yield, particle size distribution, and bioactivity. EV yield varied along CM differentiation stages. Specific EV markers (CD63, CD81, TSG101) were present and the typical cup-shaped morphology was confirmed by TEM analysis.

Bioactivity assays with human umbilical vein endothelial cells (HUVECs) showed that uptake of PKH26-labelled EV could be blocked by dynasore. Increased migration was observed in HUVECs treated both with hiPSC and cardiomyocyte-derived EV, but angiogenic properties were only found for hiPSC-EV (fold change of 11.2 ± 4.59 in total segment length vs. control, $p<0.001$).

Ongoing work will elucidate the differences in the small RNA cargo and identify the regenerative functions associated with EV from each cell source.

[2] *IRCCS Istituto Ortopedico Galeazzi*

Corresponding author's email: Matteo.Moretti@eoc.ch

Microfluidic models can be precious tools in orthopedics, to study diseases such as bone metastases but also for osteoarthritis (OA), in which extravasation of cancer cells and immune cells is involved. Thus, in our lab we generated microfluidic models of bone, muscle and joint tissues, to study the preferential extravasation of cancer cells into bone and of immune cells into the synovium. Bone, muscle or synovial cells together with vascular cells were embedded in 3D fibrin matrices, generating tissue-specific compartments with perfusable microvascular networks. In joint models, a channel with chondrocyte in fibrin and a channel with synovial fluid were also present. Our models demonstrated how muscle-secreted adenosine and inhibition of key phosphorylation events of focal adhesion proteins impaired the process of cancer cell extravasation. Furthermore, we showed that the presence of blood cells and the features of surrounding tissue environment influenced the process. In the joint models, the addition of OA synovial fluid or inflammatory cytokines increased endothelium activation and monocyte extravasation. Furthermore, inflammation modulated MMPs expression and angiogenesis, whilst the injection of bMSCs and ASCs modified cellular morphology and secretion of inflammatory cytokines. In conclusion, the use of microfluidic models of bone and muscle tissues allowed to replicate the mechanism of preferential metastatization of breast cancer to bone, indicating possible mechanisms involved. On the other hand, the generation of a joint-on-a-chip model allowed to study inflammatory processes in OA and to simulate the administration of injective therapies to OA patients, evaluating their effects on joint tissues.

Treatments for bone diseases that specifically target the individual's bone phenotype do not yet exist. Development of a human 3D-bioprinted bone model using patient-derived bone cells may represent an attractive approach to further our understanding of the pathomechanisms behind the genetic heterogeneity of bone diseases offering a platform to explore personalized therapies. However, tissue harvesting, cell isolation procedures and culture conditions influence the osteogenic potential of cells. Here, the influence of media compositions with (+) or without (-) bFGF and NEAA on osteogenic gene expression was investigated in patient-derived osteoblasts. Enhanced growth rates and upregulation of osteogenic markers (BGLAP and E11) similar to bone biopsies were only observed in cells cultured in medium +bFGF +NEAA. 3D bioprinting of patient cells expanded under these conditions had high cell viability (>90%). Similar to bone biopsies, PHEX (early osteocyte-related gene) was upregulated in organoids compared to 2D patient cells. Sirius red staining showed organoids were able to produce a collagen I matrix and micro-CT images revealed an average mineral volume of 53.6 ± 4.3 mm3 after 42 day-culture in osteogenic media. Osteocalcin immunohistochemistry staining indicated the presence of mature osteoblasts. Fluorescence imaging revealed osteocyte-like cell connections, reminiscent of the lacunar-canalicular network of bone. We have established the culture conditions that support the formation of a mineralized bone organoid with an osteoblastic and early osteocytic phenotype similar to in vivo bone tissues. In the future, these bone organoids may open new possibilities for personalized medicine to study and identify potential therapeutic targets.

Background: Surgery is the most common treatment of carpal tunnel syndrome (CTS). The increased recurrence of clinical and electrophysiological findings and absences of their regressions were reported in some cases after surgery. In this study, we aimed to see the effect of Matriderm and platelet-rich plasma (PRP) on the clinical and electrophysiological findings in patients with secondary CTS.
Methods: Seven patients with secondary CTS were included in our study. PRP and Matriderm were applied to the patients as an adjuvant to the surgery. Patients were administered Q-DASH and Visual Analogue Scale (VAS) and underwent electrophysiological tests such as; compound motor action potential (CMAP), motor nerve conduction latency (ms), motor nerve conduction velocity (m/s), sensory nerve action potential (SNAP), sensory nerve conduction latency (ms), and sensory nerve conduction velocity (m/s) in the preoperative period and the postoperative twelve months both after primer and revision operation.
Results: After revision surgery: No significant difference was found in terms of CMAP(compound motor action potential). ($p>0.05$) However, Q-DASH, Visual Analogue Scale (VAS), and other electrophysiological parameter values varied significantly different from preoperative and primary surgery values.($p<0.05$)
Conclusions: As a result, it can be concluded that the use of Matriderm and PRP together in the surgery for CTS treatment increases neural regeneration and reduces scar formation and the recurrence of symptoms, thus improving the recovery after revision of the surgery.

For a successful translation of tissue engineered implants to the clinic, non-destructive monitoring of differentiation status of cells in microtissues is of paramount importance.

We aimed at tracking the secretome of human periosteum derived microtissues during in vitro chondrogenic differentiation in relation to their in vivo endochondral bone forming potency. For that, we cultured microtissues from six donors in a serum-free chondrogenic medium which enabled proteomics characterisation of the supernatant. Microtissues were monitored with brightfield microscopy, and samples were taken for DNA quantification. Additionally, conditioned media was collected for high-throughput LC-MS/MS secretome identification. Microtissues showed an increased expression of chondrogenic markers (SOX9, COL2, COL10). On average, DNA content increased in the first week (158% of the starting amount), followed by a decrease to 92%. After 3 weeks of culture, 600 microtissues were fused over 24 hours and implanted ectopically in nude mice for 4 weeks. Bone ossicles containing bone marrow compartments were found for 4 out of 6 donors as shown by nano-computed tomography. Conditioned medium from the first donor contained 731 proteins, of which 278 are secreted. Of these, we identified 10 proteins that were significantly elevated between week 1 and 3.

In conclusion, we carried out a series of orthogonal quality characterisation studies and used high-sensitivity proteomics for mapping the secretome during chondrogenic differentiation. This is promising for the identification of biomarkers that will enable the implementation of quality-by-design strategies by predictively controlling the microtissue differentiation processes in vitro as to ensure skeletal defect regeneration upon implantation.

The use of Cold Atmospheric Plasma in oncology is an emerging field due to its huge potential as novel anti-cancer therapy [1]. Plasma chemistry leads to the generation of an abundance of reactive species (RONS) which are suspected to play a key role in selective cancer cell death without damaging surrounding healthy tissues. Such effects have also been observed in plasma conditioned liquids (PCL), opening the door for minimally invasive therapies. However, the beneficial effects of plasma and of plasma-treated liquids for treating cancer have mostly been demonstrated in 2-dimensional cultures of cells [1, 2, 3], which do not mimic the complexity of the 3-dimensional (3D) tumor microenvironment.

To evaluate the effects of plasma in a relevant context o, we developed a 3D tissue-engineered model of osteosarcoma using a bone-like scaffold made of collagen type I and hydroxyapatite nanoparticles. Different human osteosarcoma cells were cultured within the scaffold showing high capacity to infiltrate and proliferate and to exhibit osteomimicry in vitro. Significantly different functional behaviors were observed between monolayer and 3D cultures when treated with PCL. Our data reveal that the 3D environment protects cells from PCL-induced lethality by scavenging and diminishing the amount of reactive oxygen and nitrogen species generated by plasmas, but also favours the stemness phenotype of osteosarcoma cells, demonstrating for the first time the negative effect of PCL on cancer stem-like cell subpopulations in a 3D biomimetic cancer model. These findings may allow to suitably re-focus research on plasma-based therapies in future.

Corneal mesenchymal stem cells (CMSCs) have demonstrated great anti-inflammatory potency, making them ideal candidates as therapeutic agents for ocular surface inflammatory disorders. Previous phenotypic analysis has been used to demonstrate the expression of classical MSC markers by the cells, however phenotypic profiling has not been carried out. In this study, we aimed to identify key phenotypic markers of CMSCs and compare these with previously identified MSC markers from alternative sources. Additionally, we aimed to develop an understanding of any CMSC phenotypic and behavioral changes following activation with a pro-inflammatory inflammatory cytokine 'cocktail'.

The BD Lyoplate™ Human Cell Surface Marker Screening Panel was utilised with flow cytometry to assess CMSC expression of 242 markers of unstimulated cells, cells stimulated with pro-inflammatory cytokines and stimulated cells with a recovery period. Cell behaviour, viability and morphology was also assessed.

Following activation with the cytokine 'cocktail', a subpopulation of cells remained viable, with reversible inhibition of proliferation. The remaining population of cells also demonstrated increased potential for release of anti-inflammatory factors compared to unstimulated CMSCs. CMSCs displayed a similar phenotypic profile to bone marrow and umbilical cord derived MSCs depicted in the literature [1], with CD140a, CD49d, CD26 and CD95 identified as specific to CMSCs. Furthermore, significant phenotypic changes were observed in the cells following stimulation and recovery.

Here, we have developed a phenotypic and behavioural profile of CMSCs, which is vital for safe and effective translation of the cells as a clinical cell therapy.

Titanium, a popular material used for bone implants due to its bioinert and strength. The poor cell attachment and osteointegration properties, and stress shielding effect associated with its motivated the exploration of the titanium-ceramic composite. Titanium-ceramic composite has enhanced bioactivity and a mechanical property closer to bone. This study was conducted to investigate the affinity of mesenchymal stem cells towards both titanium-hydroxyapatite and titanium wollastonite. Surface characteristics through scanning electron microscopy show that both the composite materials exhibit rough surfaces which portents good cell attachment. This has been also confirmed through the use of atomic force microscopy to give a quantitative assessment of the materials concerned. Titanium ceramic showed enhanced mesenchymal stem cell attachment, cell proliferation, and osteogenic gene expressions compared to titanium. MSCs seeded on titanium ceramic maintains their immunomodulatory property in terms of activated T-cell suppression. Compared to titanium-hydroxyapatite, titanium-wollastonite showed greater bioactivity. Wollastonite is lower in cost compared to hydroxyapatite and can be derived from natural resources. Hence, the prospect of titanium-wollastonite as a scaffold for tissue engineering scaffold or bone implant material should be explored further. Finally, the safety and osteointegration properties of titanium vs titanium ceramic in vivo are currently being investigated.

Though a large number of bioinspired and synthetic tissue adhesives have been developed, none have been granted approval by the US food and drug administration (USFDA) for use as a calcified tissue adhesive[1-6]. In fact, a comprehensive set of preclinical evaluation criteria does not exist, as there is no existing device predicate for comparison. Herein we review recently developed, novel adhesives that have been proposed or evaluated for bonding calcified tissues, and suggest potential evaluation criteria for specific clinical applications (e.g. fracture fixation). Comparisons are made between published data on modern synthetic adhesives, biomimetic adhesives, and a newly discovered class of phosphoserine cement adhesives, which appear suitable for calcified tissue reconstruction. Finally, the current preclinical standards (ISO) (e.g. lap shear testing) will be compared with cutting edge experimental test methods (e.g. in vivo adhesive-augmented screw pull-out testing in femur, combined with microcomputed tomography imaging of mechanical failure), to identify whether new preclinical evaluation methods are warranted.

ASSESSMENT OF IN VITRO AND IN VIVO ASSAY TO EXPLOIT THE POTENTIAL OF CELLS AND TISSUE-ENGINEERED MEDICAL PRODUCTS: ACCELERA'S EXPERIENCE.

Simona Marzorati[P][1], Alberto Ghiglieri[1], Guido Di Gallo[1], Claudio Bernardi[1]

[1] *Accelera Srl*

Corresponding author's email: simona.marzorati@accelera.org

Due to their intrinsic variability, cells and tissue-engineered medical products require tailored and flexible preclinical safety assessment. In Accelera, the assessment of toxicity, and when required, ADME properties, of different tissue engineering and regenerative medicine products, are usually carried out adopting Good Laboratory Practice (GLP) standards. Evaluation of the stability of cellular phenotypes, delivery, and treatment localization and of cell fate is usually performed combining in vitro testing via cell culture assay and in vivo assessment in appropriate animal models. Fine-tuning and a modular strategy allow to exploit the characteristic of each component of the candidate product. For example, molecular biology tools (e.g., qPCR), integrate microscopy (e.g., Immunofluorescence), ELISA, and cytofluorimetric analysis are combined to allow the monitoring of the biodistribution of therapeutic cells or cell products. Tissue absorption, distribution, metabolism, and excretion of cellular and non-cellular materials are also exploited using autoradioluminography techniques and HPLC-MS/MS approach. Biomaterials must fulfill some requirements to be safely implanted into the human body, for this reason, when is required, radiolabeling techniques are used to improve research for regenerative medicine and prosthetic devices. With the aim to apply the 3 R principle, that promotes replacement, refinement, and reduction of animal experiments, thanks to numerous collaborations, promising new in vitro tools (e.g., organ-on-chip) are eventually explored to compare data obtained with animal models, such as the absence of toxic events (e.g., by assessing cardiovascular or liver toxicity).

Introduction: 3D bioprinting technology holds exciting promise for reconstructive surgery. Our previous work has shown Nanocellulose (NC) bioinks have promising biological and mechanical properties for 3D bioprinting. The aim of this project was to combine nanocellulose with hyaluronic acid for 3D bioprinting cartilage to further optimise its biomechanical strength and chondrogenicty with a view to 3D bioprint cartilage.

Methods: Hyaluronic acid (HA) powder was gelated to make a 30mg/ml hydrogel. NC and HA were blended to make composite NC-HA bioinks ranging from 100% HA to 20% HA, with NC-alginate as a control. Human nasoseptal chondrocytes were cultured in the biomaterial, crosslinked with 5µM hydrogen peroxide, for 21 days. Chondrogenicity was determined with PCR and histology. Printability was assessed using an AR-G2 Controlled Stress Rheometer. Cell viability and proliferation within the biomaterial was demonstrated with Live-Dead and AlamarBlue assays.

Results: Instant crosslinking of NCHA was achievable at concentrations of 5µM hydrogen peroxide with no detriment to cell survival. NCHA was noted to be up to 10-fold more chondrogenic ($p<0.0001$) than NC-Alginate and HA alone ($p<0.0001$). Histologically, NCHA demonstrated more intensely stained extracellular matrix than NC-Alginate and HA. Of the NCHA mixtures, 20%HA -80%NC ($p=0.0001$) was the most chondrogenic blend. Rheologically, all hydrogels demonstrated appropriate mechanical properties for 3D printing. Cell viability and proliferation was sustained over 21 days.

Conclusions: NCHA bioinks demonstrate superior chondrogenicity, favourable mechanical properties and excellent biocompatibility for bioprinting cartilage for reconstructive surgery. We explore the impact of these findings and suggest the potential long-term clinical impact.

Spinal cord slice (SCS) cultures enable physiological study of complex CNS microenvironments and have been used to model neuroinflammatory responses associated with nociception. Mesenchymal stem cells (MSCs) are thought to reduce neuroinflammation and pain signalling due to their paracrine activity within the injured spinal cord. Here, explants of mouse SCSs were cultured in canine MSC conditioned medium (cMSC CM) versus control medium. There were significantly increased levels of glial fibrillary acidic protein (GFAP) immunoreactive astrocytes, reduced levels of βIII tubulin immunopositive nerve fibres and increased calcium transients in the dorsal horn of SCSs in MSC CM versus control medium. The up-regulation in GFAP in astrocytic cells was confirmed by Western blotting of cell extracts from cMSC CM treated U-87MG glioblastoma cells (versus control medium), which is indicative of reactive astrocyte hypertrophy. These results contrast with previous studies of MSC transplants after spinal cord injury (SCI), where decreased astrocytic reactivity and increased axonal growth were reported. Hence, this study shows: i) that different experimental model systems elicit important differences in response to MSC activity; ii) suggesting that wound responses seen within the CNS are complex, and; iii) that MSC-secreted factors may reduce inflammatory responses after SCI via their effects on infiltrating inflammatory cells, rather than directly on cells within the spinal cord itself.

Due to the limited regenerative capacity of cartilage, patients that develop severe osteochondral (OC) defects require surgical intervention to restore the natural biomechanics of the joint. However, current graft treatments rely on donor tissue availability and regenerative therapies such as autologous chondrocyte implantation (ACI) and matrix-assisted ACI (MACI) require costly in-vitro cell expansions. Gene-activated matrices (GAMs) are a promising, graft-free and acellular alternative to current treatments for OC defects that use spatially controlled vectors encapsulating gene-encoding therapeutic payloads to instruct stem cell differentiation. Recently, a novel electrophoretic platform technology has been developed to produce anisotropic gradient mineralised hydrogels as GAMs for in-situ OC defect regeneration at low cost. This approach spatially controls coprecipitation of plasmid-DNA- (pDNA) loaded calcium phosphate nanoparticles (pDNA-CaP-NPs) and pDNA-loaded magnesium phosphate nanoparticles (pDNA-MgP-NPs) as osteogenic and chondrogenic layers respectively. The GAM therefore spatially controls nucleic acid drug delivery, cell transfection and biomineralisation of the gel matrix in-vivo. The bioactivity and pDNA release kinetics of monolayered and anisotropic bi-layered matrices in simulated body fluid were measured using appropriate assays and SEM imaging. Osteoconductive properties were demonstrated in the pDNA-CaP-NP layers of monolayer and bi-layer matrices due to Ca2+ and PO43- ion absorption and hydroxyapatite- (HAp) like particle precipitation. Meanwhile, pDNA-MgP-NP layers demonstrated a comparatively reduced mineralisation. The anisotropic HAp-like mineral precipitation in bi-layer matrices indicates their potential for OC tissue regeneration. Further development of the novel electrophoretic platform will allow manipulation of nanoparticle nucleation and growth mechanisms to modulate particle sizes for optimal in-vitro transfection efficiencies.

Corresponding author's email: gabriel@tissuelabs.com

INTRODUCTION: The use of 3D bioprinters with multiple printheads has been proposed for the fabrication of complex tissues. The use of multiple extrusion heads requires the constant switch among the different extrusion heads, reducing print speed and efficiency and ultimately leading to increased stress for the cells. Some alternatives for this problem are the use of microfluidic systems and systems composed of multiple reservoirs connected to an extrusion unit by a tubing system. This approach, however, can either lead to material loss or restrict the use of hydrogels with high viscosity. A different approach to allow the 3D bioprinting of multiple biological materials is desirable. METHODS: We developed a 3D bioprinting system containing a syringe adapter designed to be attached to its extrusion unit. This adapter allows the extrusion of two (or more) materials, each of them flowing from a different syringe. This syringe adapter can be designed in different ways. RESULTS: Three distinct designs were proposed and carried out. The first, to extrude two or more materials, flowing from two or more syringes, as a parallel multi material flow. The second, to extrude two or more materials, flowing from two or more syringes, as an homogeneous, mixed, single material flow. The third, to extrude two or more materials, flowing from two or more syringes, as a coaxial multi material flow. We successfully 3D bioprinted tissue constructs using these different approaches. CONCLUSION: Low-cost multi-material extrusion 3D bioprinting systems can be achieved with the use of customized adapters.

The role of Bone Morphogenetic Protein (BMP) signalling in triggering hypertrophy during embryonic cartilage development has been demonstrated. BMP has been also recently postulated to contribute in the onset of cartilage hypertrophy during osteoarthritis (OA) pathogenesis. Our recent findings demonstrated that selective inhibition of BMP signalling contributes in counteracting hypertrophic differentiation of adult human mesenchymal progenitors (1). Motivated by this finding, we hypothesized that selective inhibition of BMP signalling by targeting ALK2 and ALK3 with LDN-193189, a commercially available BMP type I receptor kinase, would also revert hypertrophic features in OA cartilage. To test this hypothesis, we first developed a 3D in vitro OA micro-cartilage model using minimally expanded OA chondrocytes cultured in poly-2-hydroxyethyl methacrylate coated 96-well plate (2). This 3D in vitro OA micro-cartilage model reproducibly captured OA-like hypertrophic features, as demonstrated by upregulation of hypertrophy-related genes (e.g. COL10A1, MMP13 and IHH) and presence of clustered cells positive for Collagen type X. Inhibition of BMP signalling pathway by means of LDN-193189 then resulted in a reduction of such OA hypertrophic features (reduction of Collagen type X positive cell clusters, reduced expression of COL10A1,MMP13 and IHH), while maintaining the capacity of the cells to produce cartilage specific proteins. Our findings open potential pharmacological strategies to counteract cartilage hypertrophy in OA and support the broader perspective that key signalling pathways comprehended from developmental processes can guide the understanding, and possibly the counteraction, of adult pathological traits.

THE EFFECT OF LOW-ENERGY EXTRACORPOREAL SHOCKWAVE TREATMENT (ESWT) ON THE FUNCTIONAL, MORPHOLOGICAL AND MOLECULAR LEVEL IN SUB-ACUTE AND CHRONIC PHASES OF TRAUMATIC SPINAL CORD INJURY

Mohamed Ashmwep[1]

[1] *Ludwig Boltzmann Institute for Experimental and Clinical Traumatology in AUVA Research Center, Vienna, Austria*

Corresponding author's email: alexander.ruehrnoessl@gmail.com

Extracorporeal shockwave therapy has proven to be effective for treating various pathologies of soft tissues, bone and the peripheral nervous system.

We investigated effects of ESWT in sub-acute (2 weeks after injury) and chronic (5 weeks after injury) settings in a rat contusion model at the 11th thoracic vertebra, at clinically relevant time points regarding secondary spinal damage. Functional outcome was assessed using BBB-Score, Ladder rung walking test and Catwalk®-analysis at different time points. Lugol-stained spinal cords accessed by µCT imaging provided insights into morphological changes after ESWT. Numerous systemic microRNAs were screened to explore therapeutic effects and underlying mechanisms of injury.

In Open Field-testing animals in both treatment settings (n=12 and n=15) showed significant improvement regarding their functional outcome in contrast to untreated rats (n=24) after SCI. However, Catwalk®-analysis did not show statistical differences between therapy and control groups in initial experiments. Currently the range of methods has been extended by ladder rung walking test and retrograde labelling, however data obtained is still being analysed.

Development of an automated computational algorithm to measure parameters of injured spinal cord, such as remaining spinal cord at lesion, revealed significant correlation between higher BBB scores at the end of observation time and a greater rate of spared white matter compared to controls. Finally, we were able to identify miRNAs (e.g.miR-375) showing significant treatment effects after ESWT.

We provide evidence for ESWT efficacy in treatment of subacute and chronic spinal cord injuries, and allow further insights into secondary mechanisms of damage after SCI.

THE TEMPORARY APPROACH IN THE MANAGEMENT EPIDERMOLYSIS BULLOSA RELATED SQUAMOUS CELL CARCINOMA: IS IT EFFECTIVE TO USE MATRIDERM(DERMAL SUBSTITUTE) AND SUPRATHEL(DL-LACTIDE ACID POLYMER) ?

Mehmet Bozkurt[P][1], Burak Ergün Tatar[1], Percin Karakol[1], Can Uslu[1], Melihcan Sezgic[1]

[1] *Bagcılar Training and Research Hospital Department of Plastic Surgery*

Corresponding author's email: drmbozkurt@yahoo.com

INTRODUCTION:

Epidermolysis bullosa (EB) is a genetic disease. Skin cancer may develop in EB patients due to skin sensitivity. As a surgical treatment, it is treated with an appropriate reconstruction method after excision.

In this case, we present our patient whose temporary treatment was performed using Suprathel(DL-lactide acid polymer) and dermal substitute Matriderm in EB related SCC(Squamous Cell Cancer) in the dorsum of the right hand and left foot.

CASE:

A 26-year-old EB male patient presented with skin lesions on the dorsum of his right hand and left foot. The biopsy results are SCC. After oncology and orthopedic consultations, tumors in the foot and hand were excised under general anesthesia in accordance with the clean surgical margin. A partial-thickness skin graft was taken from the right thigh. Suprathel dressing was applied over the donor area with cell-spray also Matriderm and graft were inset on the foot and hand. It was covered with dressing.No complications were seen in the donor site and grafts in postoperative period.

CONCLUSION:

Skin lesions in EB increase the possibility of infection and, therefore, the possibility of mortality. The incidence of skin cancer increases in long-term skin lesions. In our patient, the suprathel used to prevent a second defect in the graft donor area in SCC treatment, and the matriderm used for the inset of the graft provided a suitable wound healing environment. Matriderm had a positive effect in terms of the use of suprathel and graft inset as temporary wound care in patients with EB.

Differentiation of stem cells into mature tenocytes using biophysical signals has been interested in recent years. In this study, we used human tenocytes and sections of tendon tissue as a positive mold to make a polydimethylsiloxan-based patterned substrate for the induction of tenogenic differentiation in mesenchymal stem cells.

For making patterned sheets, PDMS were cast on fixed tenocytes and longitudinal sections of human tendon. Adipose derived mesenchymal stem cells were cultured on patterned sheets (including tenocyte imprinted PDMS; that called cell replica group and tendon imprinted PDMS that called Tissue replica group) and after 7 and 14 days the expression of tenogenic markers including Scleraxis (SCX), Tenomodulin (TNMD) and Tenascin C (TNC) were evaluated using real time RT-PCR.

On the seventh day after culture, only TNC marker in the Tissue replica group showed a significant increase compared to the control group. Although TNMD and SCX expression increased in both groups, this increasing did not reach a significance level. Also, on the fourteenth day after culture, the expression of TNMD and SCX markers showed a significant increase only in the cell replica group compared to the control group.

The results of this study showed that a proper surface topography can induce tenogenic differentiation in stem cells. Oue findings also suggest that induction of adult cell morphology in stem cells can be considered as a way to induce differentiation and can be used as a strategy for tissue engineering purposes.

Development of biomaterials aimed for biomedical utilization requires extensive physico-chemical characterization followed by in vitro and in vivo functional evaluation. This process is long and expensive imposing the need for methods for quick and reliable selection of the most promising candidates. Biomimetic bioreactors are recognized as valuable tools that can provide evaluation of biomaterial functionality under physiologically relevant conditions, biomechanical properties, and cell–biomaterial interactions. In the present study, we address all of these three aspects by utilizing two bioreactor types: perfusion and a bioreactor with dynamic compression. Specifically, we evaluated bioactivity of porous composite scaffolds based on hydrogels (gellan gum and alginate) and hydroxyapatite (HAp) precursor particles (bioactive glass and beta-tricalcium phosphate) aimed for bone tissue regeneration. Perfusion of simulated body fluid at superficial velocities in the range 100-500 µm/s relevant for osteogenesis was shown to significantly enhance HAp deposition revealing mass transfer limitations in traditional static tests. The bioreactor with dynamic compression applied in the regime relevant for articular cartilage (5 % deformation, 0.68 Hz frequency, 337.5 µm/s loading rate) was utilized to monitor biomechanical properties of scaffolds over time revealing slight composite weakening at lower mineral contents while an increase in dynamic compression modulus at pronounced HAp deposition. Finally, the same bioreactors were utilized for cytotoxicity evaluation of nanocomposite Ag/alginate hydrogels as potential antimicrobial cartilage implants as well as cultivation of osteosarcoma cell line in a bioactive osteogenic environment. These studies confirmed advantages of biomimetic bioreactors in providing consistent results corresponding to those found in vivo.

Traumas can cause complex wounds require tissue regenerative scaffolds1. Scaffold design requires optimization of mechanical strength, biodegradability, porosity, interconnectivity, and antigenicity2. The project aims to develop biodegradable, regenerative soft tissue scaffolds for reconstructing acute and chronic wounds. A unique high internal phase macro-emulsion(HIPE) scaffold formulation was developed in our lab, providing a hierarchical microporous nanostructure scaffold based on native proteins3. Oil-in-water emulsions were prepared with protein and polymer components, cast at 37ºC fallowing crosslinking, reducing, washing, and lyophilisation steps. The resulting product provides angiogenic properties due to fibrin`s binding sites for ECs resulting high cell response4.Natural and synthetic polymers give finely distributed fibrin meshes with high porosity/interconnectivity, and controllable pore void diameter of 100-200µm, shown by SEM images. Cytotoxicity assay using the PBS extract of scaffolds revealed that the crosslinking step does not cause cytotoxicity and the viability is around 65%-73%. Mechanical analysis shows that the scaffolds have storage modulus between 0.30-0.56 MPa while young's modulus between 0.065-0.090 MPa, suggesting polymer addition provides higher young's modulus and higher elasticity. These preliminary results show that the scaffolds yield encouraging visco-elastic properties for surgical handleability and the polymer composites can provide control over the mechanical properties. These results demonstrate the potential for optimisation of mechanical properties, biological response, degradation kinetic and interior structure as the crucial design parameters. The synthetic and natural polymer/protein blends effect in HIPE scaffolds will enable the creation regenerative scaffolds with novel properties and will be an important milestone in the pursuit of a next-generation skin scaffold.

TWO-PHOTON MICROPATTERNING OF 3D BONE CELL NETWORKS IN PHOTOSENSITIVE HYDROGELS

Christian Gehre[P][1], Ralph Müller[1], Xiao-Hua Qin[1]

[1] *Institute for Biomechanics, ETH Zurich*

Corresponding author's email: cgehre@ethz.ch

Crucial for the structural integrity of bone – and thus vertebrate survival – is a functional cellular network throughout the bone matrix. To form this network, mechanosensing cells called osteocytes are deeply embedded inside the bone, creating an interconnected cellular system [1]. It is recognized that the microarchitectural environment of these networks influences the osteocytes' ability to orchestrate the dynamic process of bone remodelling [2]. However, osteocyte mechanotransduction inside the complicated lacuna-canalicular-network (LCN) remains poorly understood. To overcome the inaccessible nature of dense bone in order to access osteocytes, we combined multiphoton-based laser ablation with 3D bone cell culture in photodegradable hydrogels [3, 4]. With this approach, we were able to embed human mesenchymal stem cells (hMSC) in gelatin methacryloyl (GelMA) hydrogels and perform subtractive multiphoton patterning of microchannels. Patterning in the presence of bone cells lead to the outgrowth of cellular protrusions into the artificial canaliculi, similar to osteocyte dendrites in bone. Despite the invasive process of 3D subtractive laser printing, the cells showed remarkable cell viability and could be kept under osteogenic culturing conditions for at least 14 days. To confirm the cellular phenotype, the expression of differentiation biomarkers will be investigated alongside utilization of other photodegradable materials, such as polyethylene glycol diacrylates. Taken together, these results show the promising effect of multiphoton based laser ablation of photosensitive hydrogels towards the formation of 3D osteocyte networks in vitro.

Bioresorbable stents (BRS) are designed to overcome perceived limitations of drug-eluting stents (DES) by providing temporary support to the vessel wall [1,2]. Herein, we developed 3D printed BRS by solvent-cast direct-write technique as a multifunctional scaffold able to encapsulate drugs and/or to attach peptides and/or to be radiopaque to overcome coronary problems. 3D printed stents were obtained with a modified fused deposition modelling (FDM) 3D printer (BCN 3D). The ink was a solution of poly-l-lactic acid (Purasorb) in chloroform (3.7%v/v). Inks were modified: (i) with iodine to render radiopacity (0.1-1% w/v) or (ii) with antithrombogenic drug aspirin (0.2% w/v).REDV and YIGSR peptides were synthesized by solid-phase and covalently attached to the surface using EDC/NHS. Printed stents were characterised by SEM and DSC and evaluated with expansion and compression mechanical tests. Radiopacity of iodinated stents was assessed in a µ-CT scanner. Aspirin release was characterised by spectrophotometry. Thrombogenicity was tested into a prefusion chamber with volunteer donnor's blood. PLLA biodegradable stents of 3 mm diameter were obtained with struts of 130 µm or 80 µm and different peaks. Iodinated stents manifested radiopacity at the expense of a decrease in radial strength. Aspirin-loaded stents showed an initial burst and posterior steady release of the drug. Average breaking pressure was between 15-17 atm and a good stent deployment was observed into the simulated artery. Biological tests confirmed that 3D printed stents were not cytotoxic independently of the number of peaks. Finally, functionalization enhanced HUVEC migration and did not increase thrombogenicity. Cardiac patches consisting of induced pluripotent stem cell-derived cardiomyocytes (iPSC-CMs) show beneficial effects when placed on the infarcted heart and the first human clinical trials have been approved. However, current patches do not replicate myocardial tissue, lacking 3D organization, mechanical properties, cellular maturity, and relevant thickness, and thereby fail to provide real contractile support to the failing heart.

Previously, we have shown that melt electrowritten (MEW) hexagonal fiber scaffolds can be used to generate contractile cardiac patches that mimic native mechanical properties, thereby inducing iPSC-CM maturation and tissue organization.[1] Although a huge step forward, these constructs do not yet fully replicate myocardial cellular and ECM composition and organization, and myocardial 3D fiber alignment.

To tackle these hurdles, we have investigated the incorporation of additional cardiac cell types like iPSC-derived cardiac fibroblasts (cFBs) and endothelial cells (ECs), the use of various myocardial and EC-optimized bioinks for extrusion-based bioprinting to allow for strategic cell-type arrangement, and introducing 3D myocardial fiber-angle orientation by stacking hexagonal MEW scaffolds.

We found that the addition of cFBs, the optimization of hydrogel/ECM composition and stiffness (Collagen-GelMA), and increasing thickness (1cm) and fiber organization by strategically stacking hexagonal meshes, led to the formation of a thick synchronously contracting myocardial tissue-like construct. Our constructs showed a multi-layered 3D fiber organization, with cells aligning with the hexagonal microarchitectures and an increase in maturation.

Taken together, we have developed a next-generation bioengineered myocardium with a more native-like muscle structure and the potential to provide real functional support to the injured heart.

Approximately 200 million people worldwide are suffering from osteoporosis[1],a metabolic bone disease characterized by low bone density and deterioration of bone architecture that increases the risk of fracture[2].Vertebral compression fractures are extremely frequent in osteoporotic patients, resulting in back pain and immobility. In the frame of the H2020 GIOTTO project, an innovative composite cement was developed to stabilize these fractures and to stimulate bone regeneration. The cement was prepared by combining a mixture of inorganic phases in dry powder form with an aqueous phase to obtain a paste-like material, directly injectable into the fractured vertebral bodies. The powder component consisted of α-calcium sulphate hemihydrate as resorbable matrix, mixed with strontium and zirconium containing mesoporous bioactive glasses to impart pro-osteogenic abilities and radiopacity, respectively. The effects of liquid-to-powder ratio on cement's injectability and setting time were investigated. Furthermore, to confer anti-osteoclastogenic properties to the final device, ICOS-Fc molecule able to inhibit the osteoclast activity was incorporated into the final formulation.The injectability was tested in a human vertebral body model obtained from human tomography images. The setting time of the developed paste and the related rheological behavior along setting were evaluated. The imparted radiopacity and the presence of residual porosity, detrimental to the cement mechanical properties, were examined using micro-computed tomography. In vitro release of Sr2+ions and ICOS-Fc, as well as the degradation kinetics of the cement were investigated under simulated physiological conditions. Static mechanical testing under compressive loading was also conducted. The GIOTTO cement overall properties were compared to commercial references.

Although bioactive glasses (BGs) are being increasingly explored for various applications in tissue engineering and regeneration [1], the effects of ions released by BGs on the immune system, surprisingly, have not been investigated in detail so far. In this presentation current understanding about the effect of BG dissolution products on cell biology markers characterising the immune system response will be summarized. The results of recent investigations involving silicate and borate bioactive glasses with tailored delivery of biologically active ions will be discussed. Dendritic cells, being the most potent antigen-presenting cells of the immune system, were investigated in their interaction with different concentrations of ionic dissolution products from ion-doped borate BGs [2]. The borate BGs were based on the well-known silicate 13-93 composition and additionally doped with copper and/or zinc. A dose-dependent effect on the viability and expression of surface markers of dendritic cells was found by cultivating dendritic cells in the presence of different concentrations of BG dissolution products. Moreover, by co-cultivating dendritic cells and T-cells, a composition and dose-depending effect of the investigated BGs was found on the capability of dendritic cells to induce T-cell proliferation. The effect of the relative ion concentration was specially considered taking into account different degradation rates of BGs. Therefore, the results of this study showed the immune modulating effects of BGs, and open an important area of research anticipating that the response of the immune system can be greatly affected by the type and concentration of metallic ions released from BGs.

DYNAMIC OXYGEN PRE-CONDITIONING OF MESENCHYMAL STROMAL CELLS TO ENHANCE THERAPEUTIC ANGIOGENESIS FOR REGENERATIVE MEDICINE PURPOSES

Jasmine Ho[P][1], Martin Birchall[1], Mark Lowdell[1], Umber Cheema[1]

[1] *University College London*

Corresponding author's email: jasmine.ho@ucl.ac.uk

INTRODUCTION:

Hypoxia is a key factor for the up-regulation of angiogenic factors in mesenchymal stromal cells (MSCs).1 Our aim is to determine the exact in vitro oxygenation conditions through dynamic pre-conditioning in 2D and 3D settings, which can help further potentiate the angiogenic pathway for therapeutic in vivo applications.

METHODS:

MSCs were pre-conditioned in normoxia (21% O2) and physiological hypoxia (1% and 5% O2) and subsequently seeded into Type I collagen hydrogels. These cell-loaded 3D hydrogels were subjected to three different oxygen conditions (1%, 5% and 21%). Media from different time points were collected and analysed for VEGF levels and RNA from cells were extracted for qPCR of HIF1a and stemness markers. Viability and proliferative capacity were also determined.

RESULTS:

Cells pre-conditioned in 2D in physiological hypoxia (5% O2) prior to being seeded did not exhibit increased VEGF production when compared to cells pre-conditioned in normoxic (21% O2) conditions. Cell viability between cells grown in 21% and 5% were not significantly different, but proliferative ability decreased when cells were cultured in 1% O2. Normoxic pre-conditioned cells produced more angiogenic factors and HIF1a gene upregulation when subsequently placed in 3D hypoxic conditions (5% and 1%), than if they were pre-conditioned in hypoxia and then cultured in 3D hypoxia. Hypoxia enabled maintenance of stemness markers.

CONCLUSION:

Our results offer an insight into cellular behaviour of MSCs within their 2D and 3D settings in dynamically changing oxygen environments. This could help guide pre-conditioning of cells in the pre-clinical stages for therapeutic angiogenesis purposes.

Nitric oxide (NO) is a useful endogenous agent for its potential to promote angiogenic activity that is one of the essential requirements for the healing of wounds. The beneficial effect of exogenous NO for facilitating faster healing of acute and chronic wounds have been demonstrated by earlier works [1-3]. There are several biopolymers that can be used in drug delivery applications. One of them is Gelatin methacryloyl (GelMA) hydrogels which is highly favorable to physiological ECM conditions leads to rapid wound healing. GelMA was crosslinked using a cell-friendly ruthenium based crosslinker.In this context, we developed a GelMA based hydrogel patches containing a nitric oxide donor (SNAP) at an optimum level to promote cell proliferation, migration, and viability.

The NO-releasing GelMA hydrogels showed a prolonged and sustained release for a time of 120 hours. The results showed a greater number of live cells in NO-releasing GelMA hydrogel as compared to control and blank GelMA hydrogel. A higher level of NO help in promoting enhanced cell remodeling and proliferation as observed in earlier studies [1].

Our results invariably demonstrated that the incorporation of NO loaded GelMA hydrogel promoted cell proliferation, migration, and viability. The presence of NO at an optimum level promoted angiogenesis and wound healing. Initial results are highly promising towards the development of a clinically relevant GelMA based wound healing patch for the treatment of chronic diabetic wounds.

Intestinal ischemia-reperfusion (IR) is a potentially life-threatening condition. Although previous animal and human in vivo studies have provided important insights in IR pathophysiology, the inability to translate findings to effective therapies contributes to its continued high mortality rates. A physiologically relevant in vitro model is crucial to thoroughly investigate mechanisms of IR-induced epithelial injury and test potential therapies. In this study we demonstrate the use of human small intestinal organoids to model IR injury by exposing organoids to hypoxia and reoxygenation (HR). A mass-spectrometry-based proteomics approach was applied to characterize organoid differentiation and decipher protein dynamics and molecular mechanisms of IR injury in crypt-like and villus-like human intestinal organoids.

We showed successful separation of organoids exhibiting a crypt-like proliferative phenotype, and organoids exhibiting a villus-like phenotype, enriched for enterocytes and goblet cells. Functional enrichment analysis of significantly changing proteins during HR revealed enrichment of processes related to mitochondrial metabolism and organization, lipid metabolism, and immune response in both organoid phenotypes. Changes in protein metabolism, as well as mitophagy and protection against oxidative stress were more pronounced in crypt-like organoids, whereas cellular stress and cell death associated protein changes were more pronounced in villus-like organoids.

Our results demonstrate that the human intestinal organoid model allows separate investigation of the crypt- and villus response to HR, and findings recapitulate in vivo properties of the IR response. This model can be used for mechanistic studies to better understand IR pathophysiology as well as to test therapeutics to prevent IR injury and promote regeneration.

DEEP LEARNING AUGMENTED DIGITAL PATHOLOGY – TOWARDS COMPUTATIONAL PRECISION PATHOLOGY DIAGNOSTICS.

Peter Boor[P][1]

[1] *RWTH Aachen University*

Corresponding author's email: pboor@ukaachen.de

Pathology is essential for the diagnosis of plethora of diseases and a major read-out of experimental pre-clinical and clinical studies. The advancement in digital pathology , i.e. digitalization of histological slides, and the application of artificial intelligence, especially deep learning, has opened new research perspectives that have the potential to transform diagnostic pathology into quantitative “computational” pathology. This requires specific infrastructure, multidiscinplinary expertise and relevant large datasets. Proof-of-concept studies, including our own, open new frontiers in mining digital histology datasets. Given that pathology also provides the basis for development of in vitro models, the transformation of pathology towards a quantitative and reproducible precision medicine tool could also facilitate validation of such models.

To provide better regeneration in vivo bone bioengineering techniques are aimed on pre-vascularization of bioequivalents. However, the cooperation of molecular pathways regulating osteogenesis and angiogenesis in vitro is still poorly understood, with insufficient vascularization in artificial bone tissue still being one of the challenges in tissue engineering. Thus, this study set out to investigate the sequence of activation of angiogenic and osteogenic factors in human adipose-derived stromal cells (ADSCs) 3D culture during cell differentiation, induced simultaneously in two directions. Four groups of spheroids (intact spheroids, spheroids with osteogenic induction, endothelial induction, and double induction) were analyzed by qPCR and immunocytochemical staining. Complex analysis of expression of key factors in two experimental repeats indicated that ADSC spheroids were capable of spontaneous differentiation in both directions. The addition of exogenous inducing agents resulted in the modification of this process with the angiogenesis-related genes further promoting osteogenesis. The obtained experimental data suggested that the predominance of one differentiation direction and the maturity of the resulting types of cells were possibly dependent on the ADSCs subpopulations (CD90/CD105/CD73high and CD90/CD105/CD73low) randomly distributed in spheroids. The current study showed that ADSC spheroids were capable of spontaneous differentiation, while double-induction stimulated osteogenesis, also providing angiogenesis. These findings can contribute to a better understanding of the cross-talks of differentiation processes and open new approaches to the generation of vascularized bone tissue bioequivalents.

Introduction: Regenerative therapies targeting cardiac valves are a vibrant field of research. In attempts to stimulate tissue growth from tissue engineered heart valve (TEHV) scaffolds, taking cues from the native environment of heart valve tissue is vital. The relationship between mechanical loading and cellular activity is well-documented and represents a source of biological inspiration for TEHV design. This effort sought to analyze valve performance from tissue to organ-level scale under dynamic conditions.

Methods: TEHVs electrospun from blends of elastomeric poly(carbonate urethane)urea (PCUU) and polycaprolactone (PCL) meant to vary mechanical stiffness were placed into a mock circulatory system. 3D positions of markers placed on valve leaflets were acquired to map principal strains. In addition, the geometric orifice area (GOA) of the valves and pressure gradient during peak systole was determined.

Results: All valves were able to reproduce pressure and flow waveforms that are physiologically normal for the aortic valve. Valves were observed to coapt during diastole with no visual signs of regurgitation. Average principal strains of PCUU were 15.8% during peak systole while GOA = 1.4 cm2. By contrast, principal strains of stiffer 75%PCUU/25%PCL averaged 3.2%, with GOA = 1.1 cm2.

Conclusion: Strain magnitude was greatly reduced in the stiffer PCUU/PCL blend, demonstrating the effect of polymer choice on valve function. However, the reduction of strain also reduced movement of the valve and GOA. While TEHVs are currently made from a variety of materials, the stiffness of typical tissue engineering polymers may make them unsuitable for this application.

The purpose of this study was to develop a biomaterial in the form of a cone for endodontic regeneration based on cell homing (1). The cone could be inserted inside the main root canal of a tooth after preparation. It should support the formation of a stable blood clot which will act as a natural source of mesenchymal stem cells and growth factors (2).
Porous membranes made of polylactic acid and polycaprolactone were fabricated using electrospinning combined with electrospraying, and functionalized with tannic acid (TA) which bring antibacterial properties. Membrane sheets were rolled as a cone and stabilized with a gelatin coating. The biocompatibility was assessed by in vitro tests on dental pulp stem cells (DPSCs). The cones were inserted into newly designed micro-bioreactors mimicking the root canal space to study cell migration. Blood clot formation was evaluated by immersing the cone in blood from human donors.
The biocompatibility of the membranes has been demonstrated, DPSC could adhere, proliferate, differentiate in odontoblasts and colonize all the cone. TA, released in solution, showed antibacterial activity against bacteria as E.Coli. Blood coagulation with a dense fibrin network and platelet adhesion around the cone were observed by scanning electron microscopy.
Activation of platelets allowed the liberation of growth factors such as VEGF and PDGF which were detected by Elisa tests. The cones showed interesting capacities to promote cell differentiation, migration and to induce the formation of a stable blood clot. These results are promising for the regeneration of dental pulp by cell homing.

Efficient differentiation of pluripotent cells to alveolar epithelial cells and achieving to functional mature cells was usually poor. Interaction between cells and the extracellular matrix (ECM) provides a dynamic environment and mediates cellular responses during the development and tissue repair. ECM-derived hydrogel contains proteins and glycosaminoglycan components of the native matrix and provide familiar binding site for cell attachment and important cues to guide cell differentiation.

To explore the possibility of generation of mature alveolar epithelial cells in vitro, we compared the efficiency of differentiation cells grown on lung ECM-derived hydrogel (Gel) with cells those cultured on fibronectin-coated plates. We found that the percentage of cell viability showed no significant differences in both groups after 7 days. While, both procedures revealed differentiation to definitive endoderm by expression of SOX17 and FOXA2 markers and lung progenitors' differentiation by emerging of NKX2.1 and P63 expressing cells. Whereas, cells grown on lung ECM-derived hydrogel showed significant upregulation of SOX9 as distinct marker of distal airways epithelial and developing alveolar cells and SPC (AT2 marker) as well as upregulation of differentiated cells markers including ciliated (FOXJ1) and secretory (MUC5A) cells. We concluded that the culture of PSCs-derived lung progenitors on hydrogel resulted in high upregulation of AT2 genes in comparison with fibronectin.

SKIN REGENERATION USING XENOGENEIC ACELLULAR DERMAL MATRIX FROM ANIMALS OF DIFFERENT AGES

Amir Mellati[P][1]

[1] *Department of Tissue Engineering, School of Advanced Technologies in Medicine, Mazandaran University of Medical Sciences*

Corresponding author's email: amirmellati@gmail.com

Despite lots of attempts, wound treatment after deep trauma and severe burns remained a challenge so far. Among various approaches, acellular dermal matrix (ADM) from xenogeneic sources, including bovine ADMs are promising options. However, effects of the animal developmental stage on physical, biomechanical and biological properties of the ADMs as a skin substitute have not been fully addressed yet.

In this study, fetal (6 months) and cattle (12 months after birth) dermis were decellularized and the resulting ADMs were characterized in vitro and were evaluated in rat models.

Real-time RT-PCR analysis revealed that the ratio of collagen type III to collagen type I in fetal skin was 36.3 ± 2.1 % higher than cattle skins. Both fetal and cattle dermis were effectively decellularized through the selected protocol as confirmed by H&E staining and DNA quantification. Scanning electron microscopy of ADMs showed no significant morphological differences between fetal and cattle. Tensile strength and suture retention force were both beyond the acceptable limits (not less than 5 N per square mm and 5 N, respectively). Contraction of wounds covered with fetal ADMs was significantly faster than that of cattle ADMs during 14 days after implantation.

The results suggest that the animal age affects the performance of the ADMs in wound healing which can be correlated to their relative collagen type III content and consequently, fetal ADMs are more appealing candidates for skin regeneration.

THE IMPACT OF SPACE IN HUMAN BRAIN ORGANOIDS

Alysson Muotri[P][1]

[1] *UC San Diego*

Corresponding author's email: muotri@ucsd.edu

Gravity is an organizing force in the development of tissues that influence many interactions during tissue growth. Microgravity has been shown to evoke changes in cell growth, differentiation, cell communication, aging, and epigenetic/gene expression alterations in a variety of cell types including brain cells. Moreover, exposure to microgravity has an impact on the cognition of mice and humans, suggesting that the consequences of this environment to brain function could be significant. Importantly, no complex human model of neurodevelopment was ever exposed to microgravity. Brain organoids, a new class of brain surrogate generated from human pluripotent stem cells (hPSCs), have gained traction as a model for studying the intricacies of the human brain by using advancements in stem cell biology to recapitulate aspects of the developing human brain in vitro. Recent observations from our lab revealed the spontaneous emergence of neural oscillations from these organoids, suggesting this reductionist model can be used to measure the molecular, cellular, and network impact of the space environment in the human brain. I will present data on how human brain organoids were affected by growing at the ISS.

In recent years, an increasing rate of mortality due to myocardial infarction (MI), has led to the development of nanomaterials especially gold nanoparticles (AuNPs) as promising nanomaterials for diagnosis and treatment of MI. These promising NPs have been used to develop different nanobiosensors, mainly optical sensors for early detection of biomarkers as well as biomimetic/bioinspired platforms for cardiac tissue engineering (CTE). Therefore, in this review, we presented an overview on the potential application of AuNPs as optical (surface plasmon resonance, colorimetric, fluorescence, and chemiluminescence) nanobiosensors for early diagnosis and prognosis of MI. On the other hand, we discussed the potential application of AuNPs either alone or with other NPs/polymers as promising three-dimensional (3D) scaffolds to regulate the micro-environment and mimic the morphological and electrical features of cardiac cells for potential application in CTE. Furthermore, we presented the challenges and ongoing efforts associated with the application of AuNPs in the diagnosis and treatment of MI. In conclusion, this review may provide outstanding information regarding the development of AuNP technology as a new generation platform for current MI treatment approaches.

BACKGROUND: Different agarose types have been used in tissue engineering (1,2), but the specific properties of each agarose type have not been elucidated. In the present work, we evaluated the in vivo biocompatibility of 5 types of agarose for use in tissue engineering.

METHODS: Agarose hydrogels were generated at the concentration of 3% and 0.3% using agaroses LM, D2LE, D1LE, MS8 and D5, and each biomaterial was subcutaneously grafted in Wistar rats. Then, the implant area was analyzed after 3 months of follow-up.

RESULTS AND DISCUSSION: Agaroses D1LE, D2LE and D5 at 3% tended to remain unaltered after 3 months, whereas agaroses LM and MS8 were partially reabsorbed at this time. At 0.3%, most grafted materials became reabsorbed, especially LM and MS8. Histologically, all agarose types were very biocompatible, without inflammation or side effects. Whilst agaroses D1LE and D5 became encapsulated by fibrous tissue, agaroses LM, MS8 and partially, D2LE, were progressively replaced by the host fibrous tissue with abundant collagen and fibroblasts, especially at the lowest concentration.

CONCLUSIONS: These results suggest that all agaroses were very biocompatible, and that LM and MS8 should be used when a rapid effect is sought, whereas D1LE and D2LE would be preferable for a long-time duration effect.

To avoid the use of animals for drug and cosmetic testing, and to better model human skin diseases, numerous bioengineered human skin model in vitro were recently developed. In this study, we developed human skin tissue constructs (organoids) containing different skin cell types as a novel tool to recreate a human skin microarchitecture and restore native cell interactions. Cellular aggregates containing keratinocytes, melanocytes, fibroblasts, pre-adipocytes, endothelial and follicle dermal papillae cells self-organized into organoids and maintained long-term viability. Visual analysis demonstrated progressive maturation of the skin organoids towards uniform pigmentation up to day 21. Combined analysis of histology, scanning electron microscopy and immunohistology assay revealed the skin-specific organization of the organoids with layered microstructure, with a surface zone formed by epidermis cells (keratinocytes, melanocytes) and the central core formed by dermal (fibroblasts and follicle dermal papillae cells) and hypodermal cells (pre-adipocytes). The skin organoids also contained tubule-like structures in the central core formed by endothelial cells and showed high production of extracellular matrix proteins such as collagen III and laminin. Functional testing of the skin organoids in response of UVB exposure demonstrated converting retinol into retinoic acid and increased melanin synthesis. Ultimately, this technique provides an in vitro model of skin, and could be used as a platform for investigation of dermatopathologies, drug testing, and incorporation into body-on-a-chip platforms.

Chronic wounds are characterized by a highly inflammatory environment that prevents healing. Macrophages are the key players in the inflammation since they polarize into two main phenotypes, the pro-inflammatory M1 (secrete the TNF-α, IL1β cytokines), and the anti-inflammatory M2 which can be classified into three subtypes: M2a (lymphocyte response, secrete IL10, TGF-β1), M2b (immunoregulation, secrete IL10, IL1β) and M2c (matrix remodeling, secrete IL10, TGF-β1). Silica nanoparticles have been shown to regulate the inflammatory response of macrophages, with the nanoparticle's small size and the presence of silicon implicated in the Nlrp3 inflammasome activation. To address this, silicon nanoparticles (SiNps) were synthesized from N-(2-aminoethyl)-3-aminopropyltrimethoxysilane. The nanoparticle size obtained by electronic microscopy was smaller than 10 nm, and the nanoparticles produced fluorescence under UV light. The main peak of 29Si RMN spectra at -73 ppm indicated that SiNps are composed of Si(-Si)4 molecules. To evaluate the macrophage cytocompatibility and the inflammatory response, five concentrations were tested (5, 10, 20, 40, 80 µg SiNps /mL) obtaining that all groups produced a similar metabolic activity compared to control. A concentration of 10µg/mL of SiNps down-regulated the production of the pro-inflammatory cytokines TNF-α and IL1β, and up-regulated the anti-inflammatory cytokines IL10 and TGF-β1. The SiNps 10 µg/mL concentration produced cytokines comparable to the IL4-stimulated anti-inflammatory control. These results suggest that SiNps can regulate inflammation in macrophages and have the potential to promote wound healing by polarizing M2c macrophages.

The implementation of robust methods for in vitro differentiation of human induced pluripotent stem cells into cardiomyocytes (hiPSC-CM) which produce cells that truly recapitulate the adult heart counterpart is an unmet need of pharma industry. Here, we describe our strategy to obtain more mature hiPSC-CM by combining 3D cell aggregation with metabolic modulation in dynamic suspension cultures.

Aggregation of hiPSC-derived cardiac progenitors was done in a scalable differentiation protocol yielding highly pure hiPSC-CM cultures, followed by metabolic maturation, in a galactose and fatty-acid supplemented medium (GalFA-M) (1,2).

Whole-transcriptome analysis showed that 3D hiPSC-CM aggregates cultured in GalFA-M had down-regulated glycolysis and lipid biosynthesis-related genes and enhanced expression of oxidative phosphorylation genes, compared to onset maturation. Ultrastructure images obtained by transmission electron microscopy highlighted the significant increase of mitochondrial density and intercellular junctions in the GalFA-M group. Nonetheless, calcium handling assays showed no maturation signs in the GalFA-M group. Sensitivity to doxorubicin and menadione was observed in a dose-response manner in hiPSC-CM aggregates cultured in GalFA-M, a deleterious effect abolished by antioxidant agents. Lastly, patch-clamp analysis suggested an increase of both sodium and calcium currents, which was more pronounced in the GalFA-M matured cells.

Our work demonstrates that combinatorial approaches where metabolic modulation and dynamic cultures are driving forces, will be fundamental for the recapitulation in vitro of the highly complex and controlled cardiac maturation process.

While many studies have investigated the effect of topography and stiffness on neuronal differentiation independently, few have investigated the combined effect. In vivo, cells are exposed to both cues simultaneously. Independent investigations have offered a plethora of information on cellular responses to biophysical cues, but a systematic investigation into the combined response could be important to understand the mechano-sensing mechanism, and to better tailor biomaterials for more precise control of neuronal differentiation. To study the combined effect, we have used polyacrylamide – 6-acrylamidohexanoic acid (PAA) hydrogels of varying stiffnesses (6 kPa – 110 kPa). These gels were patterned with anisotropic micropatterns of various dimensions using soft lithography, with surface-immobilized laminin for cellular adhesion. Mouse neuronal progenitor cells (mNPCs) were differentiated for two weeks, and immunofluorescent staining for TUJ1, MAP2 and GFAP was performed. Their lineage commitment, rate of differentiation and morphology on the gels were assessed.

To further understand the mechanisms and forces involved in the grating-induced cell elongation and differentiation, 3-dimensional (3D) cell traction stress measurements were made on the soft elastic PAA hydrogels with grating substrates. Using fibroblasts as model, we observed the cells forming protrusions in the grating grooves, and elongating and aligning parallel to the grating direction. The 3D traction stress measurements revealed that elongated fibroblasts on grating substrates exert anisotropic traction stresses, in the direction parallel to the grating direction. We propose that the increased cytoskeletal tension in the direction parallel to the grating would lead to polarized traction stresses which drive cell elongation.

Bacterial infection is often a hurdle in chronic wound resolution. To mitigate infection, antimicrobial peptides (AMP) have been seen as a solution to minimize the induction of bacterial resistance often associated with traditional antimicrobial formulations[1,2]. Peptides should be shielded from the harsh proteolytic environment in chronic wounds, which may be achieved by covalent immobilization[3,4]. The antibacterial effect of covalently immobilized AMP Dhvar5 has already been shown by our group using copper catalyzed azide-alkyne cycloaddition (CuAAC) [5,6]. However, the high quantity of peptide used (4% yield) constituted a potential barrier for future industrial scale-up. Herein, Dhvar5 was covalently immobilized onto chitosan using the highly reactive thiol-norbornene photoclick chemistry (TNPC). The aim is to efficiently improve the natural antimicrobial properties of chitosan in wound dressing applications. Successful AMP immobilization was extensively monitored by several techniques (1H-NMR, XPS, FTIR and Amino Acid Analysis). Dhvar5-chitosan films were produced by spin-coating and the viability of Staphylococcus epidermidis (ATCC 35984) was assessed by staining with BaclightTM LIVE/DEAD® kit (Syto9/Propidium Iodide). Dhvar5-Chitosan by TNPC led to the immobilization of 34 µmol Dhvar5/g modified chitosan (18.5% yield). Results suggest that Dhvar5-chitosan films exhibit enhanced anti-adhesive properties when compared to chitosan films, while also reducing bacteria viability. Therefore, this strategy not only increased the efficiency of Dhvar5 immobilization, but also preserved the antibacterial properties already observed for this AMP. Overall, Dhvar5-chitosan synthesized using TNPC exhibited promising antibacterial activity that may be extremely useful for the fabrication of wound dressings with improved ability to fight bacterial infection. INTRODUCTION: The measurement of volatile organic compounds (VOCs) or drug concentrations in the exhaled air represents a promising approach in individualized medicine. The aim of the project is to establish a lung microchip for its use in preclinical respiratory gas analysis.

METHODS: Endothelial cells were cultured in MCDB131 medium and epithelial cells were cultured in RPMI medium, in cell culture dishes, ThinCerts™ and on PDMS. For chip fabrication, PDMS was poured into a 3D printed master with the negative chip structures. Alginate was covalently bound on the PDMS to create a hydrophilic surface. Barrier function was assessed via immunofluorescence staining, TEER measurement and via permeability assays. Propofol was sampled via solid phase microextraction (SPME). Subsequent analysis was carried out using GC-MS.

RESULTS: A lung-on-a-chip was constructed, consisting of a liquid and air microchannel, which are separated by a semipermeable membrane. Associated microfluidic was established. Propofol dissolved in medium could be detected in gas phase using SPME-GC-MS. Absorption of propofol by the lung-chip was reduced by alginate-coating. The alveolar-co-culture model was viable for two weeks in air-liquid-culture and sustained good barrier functions. Chip materials were biocompatible.

DISCUSSION & CONCLUSIONS: An air-liquid-co-culture model was successfully established representing key features of an alveolar barrier, enabling the investigation of alveolar drug passage. Proof-of-principle of respiratory gas analysis of a VOC, was shown by semi-quantification of propofol. This lung-on-a-chip model is highly relevant for many applications that include quantitative investigations using organ-on-a-chip systems.

ACKNOWLEDGEMENTS: Financial support was received from the Baden-Württemberg Stiftung gGmbH.

Osteoarthritis (OA) is a painful and disabling condition driven by degradation of articular cartilage and underlying bone. OA is a leading cause of painful disability and loss of work worldwide. The contribution of bone and cartilage phenotypes and exact mechanisms of degeneration are still being elucidated. In this study we used bioprinting to produce in vitro models of the human osteochondral interface with spatially defined bone-like and cartilage-like regions. Bioprinting has grown rapidly over the past decade and is a powerful tool for medium-high throughput production of 3D in vitro models. These enable more physiologically relevant environments to screen potential therapeutics compared to traditional 2D culture. Using an alginate-gelatin bioink (with nanocrystalline hydroxyapatite for the bone-like region) we printed constructs with patient-derived osteoblasts and chondrocytes for bone and cartilage-like regions respectively. As the materials used in both regions are similar, there was very good integration at the interface and they did not delaminate. Initial experiments showed that in appropriate culture media, tissue specific extracellular matrix was formed with high cell viability. Furthermore, using chondroadherin peptides specific for integrin α2β1 binding, in conjunction with TGF-B1, we found that production of proteoglycan-rich matrix was increased in chondrocyte pellet cultures and within the chondral region of the bioprinted model. Ongoing experiments are currently probing osteogenic and chondrogenic gene expression markers in respective compartments to assess stability of the model over 28 days of culture. This model may provide a novel, reproducible human tissue platform for screening therapeutics and assessing mechanisms of osteochondral pathology.

Objective: The aim of this work is to evaluate the angiogenesis and lymphangiogenesis potential of a fibrin-agarose model of bioartificial human (BHK) skin (1,2) once grafted in vivo.

Methods: First, BHK was generated fulfilling all requirements of the national medicines agency using nanostructured fibrin-agarose biomaterials containing dermal fibroblasts within and a stratified epithelium on top. BHK was grafted in vivo, and small tissue biopsies from the grafting area were taken after 1 month of follow-up. Then, the presence of blood and lymphatic vessels was assessed by CD31, SMA and Podoplanin immunohistochemistry.

Results and discussion: Results showed that the BHK became properly integrated at the host site. Grafted BHK was capable to regenerate mature SMA and CD31-positive blood vessels after 1 month. Podoplanin expression was found in some thin vessels, suggesting that artificial autologous skin could also induce the formation of mature lymphatic vessels. These results demonstrate that BHK has in vivo angiogenic and lymphangiogenic potential. In turn, neovessels might be responsible for the excellent biointegration showed by BHK.

INTRODUCTION: Bioprinting requires the use of hydrogels together with cells to produce 3D tissue constructs. Promising biomaterials that can be used as hydrogels for 3D bioprinting are extracellular matrix (ECM) proteins. Some bioinks are made of collagen type I, some contain RGD motifs, and some are added of laminin, fibrinogen/thrombin, among other ECM proteins. However, the extracellular microenvironment of the cells is exceptionally more complex, containing hundreds to thousands of unique proteins. The presence and concentration of such proteins are different for each distinct tissue. Thus, the use of a hydrogel containing the whole protein content of the native ECM would be an ideal candidate for constituting truly representative bioinks. METHODS: We developed a method to produce scalable and reproducible tissue-specific hydrogels based on decellularized extracellular matrix. For 3D bioprinting purposes, these hydrogels can be mixed with cells to compose a thermocrosslinkable bioink. Alternatively, a photocrosslinkable version of the hydrogels is also available. RESULTS: ECM hydrogels were produced from 15 different tissues: adipose tissue, bone, brain, cartilage, colon, intestine, kidney, liver, lung, skeletal muscle, myocardium, skin, spleen, stomach, and blood vessels. These hydrogels demonstrated promising biochemical and biomechanical properties for 3D bioprinting applications. The conventional version can be used with the freeform reversible embedding of suspended hydrogels (FRESH) method, while the photocrosslinkable version can be used for direct printing on culture dishes/plates. CONCLUSION: Tissue-specific bioinks based on ECM are a promising alternative for mimicking the native microenvironment in 3D bioprinted tissue constructs.

INTRODUCTION: Development of viable substitutes of oro-maxillo-facial tissues (OMFT) depends on the capability to generate a biomimetic ECM ex vivo. As mesenchymal stem cells (MSC) are able to synthetize numerous trophic and inductive factors, our hypothesis is that the use of secretome generated by MSC could contribute to optimize OMFT primary cell cultures.

METHODS: Human oral mucosa fibroblasts were cultured in a medium enriched with secretome derived from three MSC: dental pulp, Wharton's jelly and bone marrow. Cell viability was assessed by WST-1 and Live/Dead, whereas the synthesis of several proteins playing a role in ECM function was evaluated using a human proteins array.

RESULTS: The use of the enriched medium did not alter cell viability as compared to controls. Then, we found that several proteins were expressed as similar levels in both groups, including several metaloproteases, although an increase of proteins with a role in ECM composition and wound healing, such as TIMP1 (1), was detected.

CONCLUSIONS: MSC secretome may enhance oral mucosa fibroblasts to the synthesis and maturation of extracellular matrix of bioengineered stromas. Optimization of extracellular matrix synthesis play a key role in the development of tissue engineered oral mucosa substitutes.

PROSTATE CANCER ORGANOIDS: 3D TUMOR MINIATURES AS FRONTLINE MODELS FOR PERSONALIZED MEDICINE

Due to the possibility to recreate more accurate in vitro physiological systems, organoid technology has become very popular among researchers over the past decade. Organoids can be defined as small 3D copies of their in vivo tissue of origin, realistically reproducing its architecture and function. Therefore, they have been recognized as valuable pre-clinical models in the field of cancer research. (1,2)

When it comes to prostate cancer, it is particularly challenging to establish a cellular disease model mainly due to the great interpatient therapy response variability. Although prostate cancer organoids (PCOs) have been obtained, at a low success rate, from metastatic tissue or circulating tumor cells, the isolation of organoids from primary prostate cancer is still missing. (3-5)

In this perspective, we have developed a suitable protocol, with an optimized media formulation, for isolating PCOs directly from primary tumor tissue. Comparing with non-tumorigenic organoids, PCOs show an invasive phenotype in 3D culture resembling the in vivo tumor histological features. Moreover, the expression of tumor specific markers and multicellular composition of the PCOs, containing both epithelial and mesenchymal cells, were confirmed, by immunohistochemistry, to be similar to the parental tissue. The validation of this protocol will allow the establishment of patient specific cancer models for testing personalized therapies and prevent cancer propagation before it achieves a more advanced stage (i.e. metastasis).

Impaired diabetic wounds are one of the major pathophysiological complications caused by persistent microbial infections, prolonged inflammation, and insufficient secretion of angiogenic promoting growth factors [1]. Here, we report the development of nitric oxide (NO) releasing S-nitroso-N-acetyl-pencillamine (SNAP) loaded chitosan/polyvinyl alcohol hydrogel and its application to precondition bone marrow stem cells (BMSCs) for accelerating the healing of the diabetic wounds. The study exhibited that NO-releasing hydrogels significantly increase the cell viability and cell proliferation of hydrogen peroxide (H2O2) pretreated BMSCs depicting its cytoprotective activity on BMSCs which was confirmed through manifold increase in the gene expression of B-cell lymphoma 2 (Bcl-2), stromal cell-derived factor 1alpha (SDF-1α), proliferating cell nuclear antigen (PCNA) and vascular endothelial growth factor (VEGF). Furthermore, the SNAP loaded hydrogel showed continuous cell proliferating activity for six days due to the continuous of NO from the hydrogel samples. Wound healing studies on diabetes-induced rabbits showed that the application of SNAP preconditioned BMSCs first and then NO-releasing hydrogels significantly speed up the healing process compared to the control groups. The wound healing potential of BMSCs plus NO-releasing hydrogel was further validated by improved collagen deposition and epithelial layer formation by histopathological examinations as well as upregulation of VEGF and SDF-1α biomarkers through gene expression analysis assays [2]. The results of this study displayed that the application of BMSCs and NO-releasing hydrogel can help in faster regeneration and repair of damaged tissues. Therefore, BMSCs plus NO-releasing hydrogels can be very useful for the treatment of diabetic wounds.

BACKGROUND: Regeneration of oral mucosa depends on a proper vascular supply. In this regard, human dental pulp stem cells (DPSCs) are known to possess strong pro-angiogenic potential (1). In the present work, we generated and evaluated a tissue-engineered oral mucosa constructs containing pre-vascular components to determine its biointegration potential once grafted in vivo.

METHODS: Nanostructured oral mucosa constructs based on fibrin-agarose scaffolds were developed (2), seeded with DPSCs, and cultured in a preinductive medium con-taining VEGF. Angiogenesis potential was evaluated ex vivo and in vivo using flow cy-tometry and immunohistochemistry.

RESULTS: First, we found that cells tended to decrease the expression of stem cell markers upon ex vivo induction (CD105, CD90 and CD73), with an increase of vascu-lar differentiation markers such as VEGF, endothelin-1, angiogenin-1 and endostatin. Then, in vivo grafting in nude mice resulted in an increased number of blood vessels with positive expression of CD31 and vWF, coinciding with a process of extracellular matrix regeneration.

CONCLUSIONS: These results confirm that DPSCs have pro-angiogenic and endothe-lial-like differentiation potential ex vivo an in vivo and support the use of pre-vascularized human oral mucosa constructs to increase tissue regeneration in patients.

In biological and medical research histology seems to be the ultimate tool for registering structural composition of the specimen. Even though it is rendered as a "gold standard", a huge drawback is inevitably connected to the preparation process, namely, destruction of living tissue. Consequently, histology does not allow to assess changes of state of a specific specimen over time and therefore has no role in monitoring of in vivo experiments.

In tissue engineering experiments, extracellular matrix formation ("networking") of the growing cells is crucial information, which represent tissue maturation and biomechanical stability. We present the application of two photon microscopy for registering the network structure of smooth muscle cells grown in fibrin gel, at the same time registering all the information accessible by histology. Our results show that histological slicing might be misleading in terms of quantification of the compounds (nuclei, SMA, Collagen), as the amount of cell structural proteins varies dramatically in between randomly chosen slices. Such errors are easily avoided by using two photon microscopy, capable of registering the whole 3D cellular and fibrous network.

Furthermore, we report application of two photon endoscopic probe in tissue engineering experiments, enabling longitudinal in vitro (and in vivo) structural assessment. This application proves that such endoscopic technology can be successfully used to monitor maturation in in-vitro tissue engineering applications and is compatible with strict sterility, temperature, and gas composition requirements.

Osteoarthritis (OA) is a painful and debilitating condition that affects over 40 million people just in Europe (1). Together with the knee, the hip is one of the joints most frequently involved in OA. One of the two main causes for hip OA is hip dysplasia (HD) (2). HD is characterized by the instability of the hip joint and is caused by incomplete coverage of the femoral hip by the acetabulum. In this study, we have developed a mechanical competent and fully resorbable magnesium phosphate (MgP) - based implant to enlarge the acetabulum. The appropriate design was obtained from CT-scans of eight dog patients and fabricated using a room-temperature extrusion-based process (3). The mechanical compatibility of the implant as well as stability and optimal femoral coverage in the load-bearing quadrant of dog model is being investigated using a custom-built mechanical set-up simulating canine hip joint forces. Our results demonstrate that the 3D-printed implant design adapted well to the acetabulum of canine dysplastic hips, while the the flexibleMgP material composition supported fixation with metallic screws. Implants were able to withstand a maximum shear force of 900Nwithout failure and plastic deformation, which confirmed a proper fixation of the implant to the defect side. . Currently, implant mechanical performance under accelerated in vitro degradation and physiological loading is being performed. Preclinical evaluation in a canine model is planned to demonstrate safety of the proposed implant to treat hip dysplasia.

Early detection of cancers can make preventative measures possible (1). However, the current methods used to diagnose various types of cancers have severe limitations, resulting not only in missed cases but also in the diagnosis of a high rate of false positives. Genetic heterogeneity has been demonstrated to play a crucial role in all cancers, between individual tumors of the same histopathologic subtype (2). Thus, we developed a novel microchip-based spatial gene expression analysis assay for lung cancer detection along with the heterogeneity of their expression levels in these tumors. We achieved this by performing the analysis using a rapid technique that performs on-chip picoliter real-time reverse transcriptase loop-mediated isothermal amplification (RT-LAMP) reactions on a histological tissue section without any analyte purification while maintaining the native spatial location of the nucleic acid molecules. Using our molecular histopathology technique, we will analyze resistin like alpha (Retnela) gene amplification in lung cancer biopsy tissues on a microchip platform. Lung cancer tissue from transgene mice was harvested to visualize the spatial variation of Retnela mRNA using our technique respectively. We also demonstrated this method by amplifying the Retnela messenger RNA (mRNA) with 100µm spatial resolution and by visualizing the variation in threshold times across the tissue. In future studies, the on-chip reaction will be validated through label-free Fourier transform infrared (FT-IR) spectroscopic imaging, which classifies tumor histology and its spatial genetic heterogeneity in the tissue section.

COMPOSITION-STRUCTURE-PROPERTY RELATIONSHIP IN THREE- DIAMETER DECELLULARIZED PORCINE ESOPHAGEAL MATRIX

Paola GarcíaP[1], Adriana Orozco[1], Metzeri Montes[1], Birzabirh Mendoza[1]

Corresponding author's email: ep.garciatejada@ugto.mx

Xenogeneic biomaterials that retain the composition, bioactivity, architecture, and mechanics of the native tissue can be an alternative for the management of defects in esophageal tissue. Here, decellularized porcine esophageal tubular matrix of three different diameters was derived from piglets' tissue at 1 (D1), 21 (D21) and 45 (D45) days after birth. The removed DNA (99.1, 97.9 and 95.5% for D1, D21 and D45, respectively) and the absence of nuclear structures (H&E staining) were indicators of effective cell removal. Furthermore, the esophageal matrix structural network and its tensile behavior were preserved after decellularization, according to its characterization as a multilayer material or as separate muscular and submucosa layers. The content of residual GAGs (48.6, 74 and 70.2%) and the extracted residual fibronectin (69.7, 74.2, 86.3%) for D1, D21 and D45, suggests the conservation of bioactive components in the matrix. We propose that the decellularized esophageal tubular matrix serve as a template capable of coating it with extracellular matrix gel and therapeutics (epoxyeicosatrienoic acids, cells) as a strategy to enhance bioactivity in the search of restoration of injured esophageal tissue.

Introduction. Hemophilic arthropathy is a debilitating disease due to recurrent joint bleeding and cartilage degeneration [1,2]. Ferroptosis, an iron-dependent mode of regulated cell death, may contribute to tissue damage via lipid peroxidation and altered lipid profiles [3]. We assessed the cytotoxic effects of isolated red blood cells (RBC) on human articular chondrocytes as well as changes in lipid profiles as an indicator of ferroptotic mechanisms.

Methods. Cultured human chondrocytes were treated with intact and lysed RBCs (0-50% v/v) as well as soluble hemoglobin (0-10 μM) for 4 days. Cell viability was visualized with calcein-AM (live) and ethidium homodimer-1 (EtH-1, dead). Lipidomics assessment was performed on isolated lipids and lipid species were identified using METLIN. Lipid peroxidation was detected using a BODIPY 581/591 C-11 Sensor. Data were analyzed with ANOVA with Tukey post-hoc tests ($\alpha < 0.05$).

Results and Discussion. Chondrocyte viability was reduced in all treatment groups compared to control in a dose-dependent manner. EtH-1 was most strongly expressed with RBC lysate, followed by hemoglobin and intact RBCs, suggesting RBC intracellular constituents (e.g., iron) may drive chondrocyte death. Lipidomics assessment revealed upregulated levels of fatty acid and ceramides, which have been implicated in lipotoxicity, apoptosis, matrix homeostasis disruption, and down-regulation of type II collagen in articular cartilage [4]. Lipid peroxidation, a hallmark feature of ferroptosis, was also significantly elevated in RBC-treated groups. Understanding mechanisms of blood-induced cell death can lead to development of chondroprotective therapeutics for patients with chronic conditions (e.g., hemophilia) and acute conditions (e.g., articular fractures).

CHARACTERIZATION OF USPIO-PLGA SCAFFOLD DEGRADATION AND TISSUE REMODELING IN BIOHYBRID VASCULAR PROSTHESIS USING 7T MRI

Elena Rama-P[1]

[1] *Department of Experimental Molecular Imaging*

Corresponding author's email: erama@ukaachen.de

The longitudinal in-vivo monitoring of remodeling processes and pathological dysfunctions of implanted vascular prosthesis remains challenging [1]. This obstacle might be overcome by the integration of contrast agents into the main components of the vascular prosthesis structure [2]. In our study, we developed biohybrid vascular grafts with polyvinylidene fluoride (PVDF) and poly(lactic-co-glycolic acid) (PLGA). PLGA is the biodegradable component of the textile scaffold, which allows cell attachment and colonialization. Unfortunately, PLGA can hardly be visualized in-vivo. Therefore, in this study, we aimed at labeling PLGA fibers with ultra-small superparamagnetic iron oxide nanoparticles (USPIOs) to visualize their presence and degradation by MRI. PLGA fibers were embedded in fibrin gel and incubated at 37°C for 8 weeks and at 70°C for 3 weeks. USPIO-PLGA fibers combined with PVDF were incubated at 37°C in PBS for 3 weeks. With the degradation of the PLGA fibers, which was faster at higher temperatures, there was a strong increase in T2 and T2* relaxation times, which can be explained by the release of the USPIO. Then, the final textile structure (PVDF-PLGA-USPIOs) was molded in fibrin gel containing smooth-muscle and endothelial cells. Here, the degradation of the PLGA fibers was much faster due to the presence of cells. Furthermore, it was shown by immunofluorescence microscopy, that the degraded PLGA fibers were replaced by elastin, which was produced by the smooth-muscle cells. In conclusion, we could establish an MR imaging approach to non-invasively assess the degradation of PLGA scaffolds and could confirm its replacement by endogenous cellular matrix.

Introduction: Decellularization may offer the possibility of obtaining acelular nerve allografts for use in tissue engineering. The aim of this study was to develop a novel chemical-enzymatic decellularization method (CE) for nerve decellularization.
Methods: Rat sciatic nerves were decellularized with the CE method (distilled water, triton X-100, SDS, SDC and nucleases) and compared with the previously-described Sondell (SD) technique (1). Afterwards, the ECM was evaluated by histological and ultrastructural analyses and biocompatibility was determined ex vivo by culturing adipose-derived mesenchymal cells on the surface of the decellularized nerves.
Results: Histological analysis demonstrated a complete removal of cell nuclei in CE and SD. Cells cultured on both models showed high viability, especially in CE. Picrosirius red staining demonstrated a good preservation of the nerve collagen network in CE and SD, whereas alcian blue revealed a substantial loss of glycosaminoglycans in SD, but not in CE. At the ultrastructural level, the ECM was properly preserved and well-organized.
Discussion & conclusion: The CE method resulted in a better preservation of the structure and composition of the ECM components, with good biocompatibility, supporting its potential usefulness in nerve repair.

Introduction: Myocardial infarction (MI) remains the most common type of cardiovascular disease and the main cause of death worldwide. MI leads to myocardial ischemia, subsequent molecular changes, inflammatory pathway activation, and remodeling. In this project we aim to find specific peptide signatures, linked to cardiac remodeling in the mouse heart after MI.Methods: Mice susceptible for cardiac ischemic injury (miR-216a knock-out in a BL6CBAF1 background) were subjected to MI by permanent ligation of the left coronary artery or sham surgery. 4 weeks after surgery, the animals were sacrificed and the hearts were excised and formalin fixed paraffin embedded. 4µm thick transverse sections underwent on-tissue digestion before peptide analysis using MALDI-MSI at 50µm raster size on a RapifleX tissueTyper (Bruker, Bremen, Germany). Afterwards, sections were stained using H&E or Sirius Red.Results: Probabilistic latent semantic analysis revealed peptides belonging to haemoglobin in blood (m/z 1529.73) and actin in ventricles (m/z 976.45 and 1198.70) as the biggest contributors in components 1 and 2, respectively. Other discriminating m/z-values are still unidentified. Component 5 highlighted peptide masses co-localizing with the affected area in the heart as assigned by Sirius Red. Further spectral clustering analysis suggested a decrease of m/z 1906.84 and 2093.11 as compared to the unaffected area.Conclusion: The peptide profiles found for different regions in the heart might help to understand the mechanism underlying remodeling after MI. Validation of the results will be done using another MI mouse model and a MALDI-MSI guided laser capture microdissection proteomics workflow for additional peptide identification.

Various factors, including cells, biomaterials, cell and tissue culture conditions, play a crucial role in tissue engineering. The in vivo environment of the cells exerts complex stimuli on the cells and thus has a direct influence on cell behavior, including proliferation and differentiation. In order to create suitable replacement or regeneration procedures for human tissue, the conditions of the cells' natural environment should therefore be well imitated. Therefore, current research is trying to develop 3-dimensional scaffolds that can elicit appropriate cellular responses and thus help the body to regenerate or replace tissue.

Material and methods: The 3D biolplotter was used to produce the scaffolds. The printed polycaprolactone scaffolds were coated with type I collagen for improved cell-scaffold interaction. Subsequently, three different cell types (human MSC, MG63 and MLO-Y4) were cultivated on the scaffolds and the biocompatibility of the scaffolds was investigated using various tests (WST, LDH, live/dead assay). The test duration was 3, 7 and 10 days.

Results: Reproducible scaffolds made of polycaprolactone could be printed. In addition, a coating process with collagen was developed, which significantly improved the cell-caffold interaction. The cell experiments proved that the cells adhere and proliferate very well to the scaffolds. In the MSC and MG-63, it was also observed that the cells colonize the entire available scaffold surface by spanning the pores. Cell growth within the scaffolds was also examined. MLO-Y4 cells can interact with the collagen coating and migrate through it. All cells showed an increasing proliferation rate. The cytotoxicity was negligible.

Corresponding author's email: jhickman@ucf.edu

We have been constructing human-on-a-chip systems for toxicology and efficacy with up to 6 organs and have demonstrated long-term (>28 days) evaluation of drugs and compounds, that have shown similar response to results seen from clinical data or reports in the literature. Application of these systems for ALS, Alzheimer's, rare diseases, diabetes, and cardiac, immune and skeletal muscle mechanistic toxicity will be described. These models utilize a pumpless platform with serum free recirculating medium that is a low volume system that can evaluate parent compounds as well as metabolites if the liver is included. We have constructed stem cell-based, human-on-a-chip systems demonstrating long-term physiology (>28 days) in configurations of up to five organs [1]. Acute and chronic compound testing in systems has generated drug efficacy and safety responses similar to those seen in clinical data or reports from literature [2]. Concurrent measurement of both efficacy and toxicity can also be done in the same system for therapeutic index estimation for chemotherapeutics [3]. We will describe HoaC systems composed of liver, cardiomyocytes, skeletal muscle myotubes, motoneurons and a functional, rudimentary kidney module in configurations relevant for parent compound and metabolite efficacy and safety testing. We have recently published a paper that described a multi-organ innate immune system that was able to reproduce the the pro-inflamatory and restorative phenotypes from macrophages [4]. This talk will also give results of six workshops held at NIH to explore what is needed for validation and qualification of these new systems.

Methacryloyl gelatin (GelMA) has gained great attention in the tissue engineering field because of its inherent bioactivity and its tunable physicochemical properties. The fabrication of GelMA constructs by extrusion-based 3D printing is challenging due to the higher elastic behaviour of GelMA inks and clog formation inside the nozzle[1,2]. Herein, we reported the development of a novel cell recognizing, printable and mechanically stable interpenetrating polymer network hydrogel (IPN) based on GelMA and a gelatin-hyaluronan dialdehyde Schiff's polymer as a potential bioink for direct extrusion-based 3D bioprinting[3],[4]. The IPN network was stabilized initially by physical interactions and later by chemical crosslinking of methacryloyl groups in the presence of the radical photoinitiator, lithium phenyl-2,4,6-trimethyl benzoyl phosphinate. IPNs with different concentrations of primary and secondary networks were prepared and analysed for 3D printability and mechanical stability. Temperature sweep rheology measurements show a higher sol-gel transition temperature for IPN hydrogels than GelMA. Moreover, analysing the viability of cells encapsulated in this bioprinted IPN hydrogel construct after day 1, day 3 and day 7 by live/dead imaging followed by semi-quantitative image analysis of live and dead cells by using image J software has shown that the novel material supports cell survival, which makes it an interesting ink for the fabrication of 3D constructs for tissue engineering applications.

Three-dimensional bioprinting (3D bioprinting) has been at the forefront of tissue engineering research in the past years, with ever more efficient systems reaching the market(1). While existing 3D bioprinting techniques are numerous and varied, they are limited by long printing times when used at high resolution(2). The technique described in this work aims at enabling fast and accurate production of monolayered skin constructs.

To achieve shorter production times, a digital scanned light sheet is used to produce patterns of polymerized hydrogel, which enables the printing of a full three-dimensional plane in a matter of a few hundred milliseconds. The high resolution resides in the properties of the light sheet itself – the width of the light sheet represents the z-axial resolution of the system (as low as 10 µm) and the x-axial resolution is determined by the intensity profile of the gaussian beam (around 50 µm). In order to fully exploit this system, the hydrogel used to encapsulate the cells must therefore be tailor-made for photoactivated cross-linking.

As a proof of concept, a light sheet microscope is used as a polymerization source for novel photosensitive hydrogels. The upcoming hardware, software, chemical and biological improvements needed to reach the full potential of this system are expected to eventually be sufficient to print a complete skin construct, which could be used in the drug development industry, or as a graft for regenerative medicine therapy. Additionally, the constructs can be used to reduce and even replace animal testing for drug or cosmetic testing.

Uniform distribution of cells in dish or flask at cell seeding is important for stable cell culture. Especially for expanding culture of pluripotent stem cells (PSCs), the uniform cell distribution is required to maintain pluripotency. During cell-seeding process, cell suspension is placed on dish or flask following mechanical shaking to distribute cells uniformly. However, the effect of mechanical shaking during the cell seeding on the function of PSCs is still unclear. Therefore, the mechanical validation of cell-seeding process is quite important to develop the automated cell culture system for PSCs. In this study, we developed a cell-seeding device to control the rate of cell-suspension injection and mechanical shaking. The cell suspension was loaded on a dish using a syringe pump, and the dish was shaken immediately after cell-suspension loading using motorized stages controlled by computer. Using this cell-seeding device, the effect of shaking speed and amplitude on pluripotency and proliferation of mouse iPSCs was assessed to validate the mechanical process of cell-seeding.

INTRODUCTION:An emerging paradigm in the field of bone tissue engineering is to engineer constructs via the endochondral ossification route. We aimed to fabricate a mechanically stable Silk fibroin (SF) carrier incorporating decellularized cartilage derived extracellular matrix (CD-ECM) and hypertrophic chondrocytes as a model of endochondral ossification and characterize superior bone-like tissue formation nondestructively in the case of in vitro studies.

METHODS: Human bone marrow stem cells (hBMSC's) were seeded onto CD-ECM/SF or SF constructs and primed 2 weeks for chondrogenesis followed by further 6 weeks of hypertrophy priming in differentiation medium. Biochemical assays, SEM/EDX, RT-qPCR, Biomechanical tests followed by µCT scanning were used as methods at 4 and 8 weeks to determine hypertrophy mediated ossification.

RESULTS:Calcium deposition biochemically determined increased significantly from 4-8 weeks in both SF and CD-ECM/SF constructs and retention of sGAG's were observed only in CD-ECM/SF constructs. SEM/EDX revealed calcium and phosphate crystal localization by hBMSC's under all conditions. µCT scanning at 8 weeks indicated a cloud of denser minerals in groups after hypertrophic induction but the BV/TV was higher in CD-ECM/SF constructs than SF constructs. Gene expression by RT-qPCR revealed that hBMSC's expressed hypertrophic markers VEGF, COL10, RUNX2 but the absence of early hypertrophic marker ChM1 and presence of later hypertrophic marker TSBS1 as well as the presence of osteogenic markers ALPL, IBSP, OSX under all conditions.

DISCUSSION & CONCLUSIONS: Incorporation of decellularized cartilage derived ECM onto a mechanical stable silk fibroin scaffold promotes the endochondral ossification route
bone tissue regeneration.

In the field of regenerative medicine, the lack of vascularization remains a major limitation, while it is essential for the long-term stability of functional tissues. Due to diffusion limitations of oxygen and nutrients up to 300µm from the closest vessel, thick tissues are unable to receive nutrients or eliminate their wastes. This phenomenon leads to tissue necrosis and induces graft rejection. Therefore, to facilitate the connection between the main circulation and the relevant tissue, we aim at developing an artificial vascular network adjusting the vessel's diameter from 1mm to 200µm via a templating technique using extrusion-based additive manufacturing.

The vascular network is produced incorporating a water-soluble carbohydrate glass (Isomalt) inside a fibrin hydrogel. To prevent the template to dissolve prematurely, it was coated with poly(DL-lactide-co-glycolide) (PDLG5002, 50:50; Corbion), to increase its dissolution time. Adapting the coating concentration, we could tune the Isomalt dissolution time and fit with the fibrin hydrogel's crosslinking time. Adjusting the extruding parameters all along the vascular design, we could control the diameter of the produced fibers (from 851µm to 268µm) using a single needle size.

Besides the achievement of fabricating a reproducible hierarchical vascular network, we aim to move from a planar to a free-form design taking advantage of Isomalt fast crystallization rate. This study is a proof-of-concept of the elaboration of a physiologically relevant in vitro tumor tissue model. Moreover, by including cancer cells in the surrounding hydrogel, we aim to investigate the intravasation of metastatic cells into the main circulation toward target tissues.

Myocardial infarction occurs after damage and death of cardiomyocytes with replacement be a connective tissue scar, which leads to heart failure. Among the various methods of modeling myocardial infarction in experimental animals, pharmacological model of heart tissue damage using isoproterenol, β1-adrenergic receptor agonist is often used. Mesenchymal stem cells (MSC) are actively used in cell therapy of cardiovascular diseases. In 3D culture in spheroids the proangiogenic and regenerative potential of MSCs is increased. Our aim was to compare the therapeutic potential of MSCs from umbilical cord after their transepicardial injections in the form of cell suspension or spheroids to rats with isoproterenol induced focal myocardial infarction. Injection of MSCs suspension and spheroids reduced number and area of fibrous scars, and inflammatory process in comparison with untreated infarction. Treatment with spheroids was more efficient, by 28 day significantly decreased the number and area of connective tissue scars in left ventricle subendocardium, and ultrastructure of the main cellular organelles was more preserved. Isoproterenol impaired the electrical conductivity of the myocardium manifesting in widening of the QRS complex, lengthening of the QT and QTc intervals, and a decrease in the R wave amplitude. However, in the groups receiving MSCs suspension or spheroids, less severe and prolonged disturbances were recorded in comparison with the group of untreated infarction. Thus, cell therapy with MSCs contributed to normalization of the morphofunctional parameters of the heart. Spheroids exhibited higher efficiency in comparison with cell suspension. This work was financed by the Ministry of Science and Higher Education of the Russian Federation within the framework of state support for the creation and development of World-Class Research Centers "Digital biodesign and personalized healthcare" №075-15-2020-926.

Post-traumatic osteoarthritis (PTOA) is characterized by chronic joint inflammation and cartilage degeneration and remains a significant clinical and socioeconomic challenge. Exercise is currently the only clinically proven treatment to provide symptomatic relief and modify disease progression (1). While the exact therapeutic mechanism remains unclear, exercise may resolve chronic inflammation through activation of anti-inflammatory cellular pathways, and by increasing lymph-mediated joint clearance (2). Recent evidence however has revealed that inflammation can lead to dysfunctional mechanotransduction and increased susceptibility to mechanical trauma (3). Thus, concurrent treatment of exercise and injections of mesenchymal stromal cells (MSCs), which are thought to be anti-inflammatory (4), may provide an optimal treatment for PTOA. In these studies, we questioned if, and how, exercise and hMSCs may alter disease progression in a rat model of PTOA. We found that exercise significantly increased the joint clearance rate via the lymphatics, which notably clear both the collagenase sub-group of MMPs and fragmented aggrecan. Exercise also corrected abnormal gait, reduced cartilage attenuation (inversely proportional to sGAG content) and arrested osteophyte growth associated with PTOA. Separately, we found that injection of MSCs significantly reduced pain (secondary allodynia, as measured by von Frey), osteophyte volume, and cartilage surface roughness. We are currently exploring optimal strategies to combine physical and cellular therapies and expect that combined therapy will be more efficacious than either treatment alone. These studies suggest that exercise and MSC injections can restore joint homeostasis, alleviate pain, improve joint function, and attenuate tissue degradation.

The use of 3D microtissues following the developmental engineering concept is a promising skeletal tissue engineering strategy 1-3. Considering the important role of metabolism in defining cellular properties4-6 this study aims to identify metabolic quality attributes indicative of a functional cartilage intermediate construct.

We conducted LC-MS (liquid chromatography-mass spectrometry) tracer analysis experiments to gain mechanistic insight during chondrogenic differentiation of osteochondroprogenitors spheroids. 13C labeled glucose and glutamine have been used, as the major energy source for the cells. Our tracer analysis results showed 13C glutamine enrichment in proline from 15% at day 0 to 20 % at day 14 and 42,5 % at day 21 and a similar trend of 13C glutamine contribution to hydroxyproline. Furthermore, we observed progressive 13C glucose enrichment in palmitate from 0% at day 0 to 8% at day 14 and 22% at day 21, suggesting activation of fatty acid synthesis. Subsequently we carried out loss of function experiments by chemically inhibiting fatty synthesis by using the small molecule c75. Results from this study highlighted changes in transcriptome level related to endochondral ossification with significant downregulation of important genes revealing chondrogenic hypertrophy such as IHH, MEF2C, ALP. Additionally, the chemical inhibition of fatty acid synthesis led to poor survival of the in vivo constructs as opposed to the untreated controls where bone organs were formed upon implantation .

This study highlights the possible role of fatty acid synthesis as a metabolic quality attribute of the bioprocess leading to of chondrogenically differentiated engineered microtissues.

Muscle tissue serves many critical functions including protecting and supporting the skeleton, enabling locomotion, and maintaining homeostasis. Although skeletal muscle has a regenerative capacity, significant impairment or loss of muscle function can result from myopathy and neuromuscular diseases, traumatic injuries, and surgical complications. Unfortunately, current therapies such as functional free muscle transfer and transplantation of exogenous myoblasts are only moderately successful. Engineered skeletal muscle tissue is a potential solution to restore muscle function, but current tissue engineering approaches are not able to recapitulate the various native muscle architectures. Here we report the engineering of skeletal muscle tissues with complex native-like architectures using Freeform Reversible Embedding of Suspended Hydrogels (FRESH) 3D bioprinting [1]. Specifically, we engineered highly aligned muscle constructs with parallel, unipennate, and bipennate myofiber architectures using FRESH printed fibrillar collagen scaffolds around which C2C12 myoblasts were cast and compacted in a fibrin gel. Immunofluorescent images demonstrate that the scaffolds provide directional cues to the cells to organize and align along the collagen filaments and fuse into multinucleated myotubes. Various skeletal muscle architectures were created with high fidelity, and the direction and spacing of collagen filaments were shown to be critical to guiding this process. Further, under field stimulation these constructs displayed active muscle contraction and at higher frequencies (20 Hz) approached tetanus with a positive force-frequency relationship. These engineered muscle tissues are the first to demonstrate control of microstructure and myofiber architecture in 3D space and show the potential to recapitulate different muscle types within the body.

Tissue engineering is a rapidly growing field during the last decade. Cells within an artificial tissue need structural support and guidance for growth. For this purpose, we fabricate polymeric bio-compatible scaffolds by multi-photon lithography (MPL).

In MPL, a femtosecond-pulsed laser focused into a photosensitive resin solution initializes polymerization solely within the focal volume of the laser beam. Hence, sub-micrometer resolution can be achieved in three dimensions. Recently lateral and axial resolution of MPL of below 200nm and around 500 nm have been demonstrated respectively. Hence, its flexible additive manufacturing performance makes MPL a well suited technique for 3D-structuring of biocompatible materials for tissue scaffolds.

The challenge herein is the development of a photoresist that is biocompatible, mechanically stable and can be structured high writing speed. Herein we demonstrate a 2D and 3D biocompatible scaffolds structured onto cell culture membranes, which can be combined with microfluidics. For biocompatibility testing the scaffolds are seeded with cells. In order to promote cell adhesion, we developed strategies to functionalize the scaffolds with biomolecules like antibodies, DNA-linkers or RGD-peptides. This 3D structured cell scaffold within a microfluidic device are seeded with human endothelial cells models of a blood vessel wall. In the future molecular processes like transportation of bio-microparticles or macromolecules will be addressed with our platform.

INTRODUCTION: Successful 3D engineered tissues require viable vasculature, however this poses certain challenges [1-3]. As a result artificial channels were formed in a cast photocrosslinked gelatin methacrylate (GelMA) construct by printing sacrificial networks of Pluronic F127. Human umbilical vein endothelial cells (HUVECS) were co-cultured with adipocytes using the above design to produce a 3D viable vascular tissue construct.

METHODS: The one pot synthesis method was used to synthesize Gelatin Methacrylate [2]. Whilst hexagonal shaped pluronic filaments were printed onto glass slides using the robotic I&J 7300-LF printer (Fishnar, UK). Adipose derived stem cells (Thermofisher) were differentiated into adipocytes whilst being embedded within the GelMa structure. The differentiation was assessed using the oil red O stain. Further experimentation looked at the cell-cell interaction and endothelialisation of HUVECS (PromoCell, UK) with the adipocyte model using VE-Cadhering and E Cadhering. Finally the stability of the 3D model was investigated using immediate diffusion at a constant flow rate.

RESULTS: The oil red stain proved the differentiation of the ADSCs into adipocytes. Whilst data on the cell-cell interaction and the endothelialisation will be presented.

DISCUSSION &CONCLUSIONS: Collectively, our data illustrates that ADSCs can be successfully differentiated and they can remain viable after 7 days within the hydrogel matrix.

ACKNOWLEDGEMENTS: CC and FZ were supported by studentships from EPSRC and CSC.

The tissue-engineered human cornea (hTEC) is a powerful model to study the mechanisms of corneal wound healing and is sparking interest as a suitable substitute for grafting purposes. To ensure hTECs histological and physiological integrity, the primary cultured human corneal epithelial cells (hCECs) must be of the highest possible quality. This study was intended to evaluate the impact of the post-mortem interval (PMI) on the properties of hCECs in vitro. hCECs were isolated from the limbal area of donor corneas either directly upon reception of the tissue (PMI=0) or at different PMI, ranging from 1 to 19 days and grown as monolayers or on hTECs. No noticeable difference in cell morphology was observed. However, short PMI hCECs displayed increased daily doublings and generated more colonies per seeded cell compared with long PMI hCECs. Microarray analyses indicated that short PMI hCECs had a gene expression pattern distinctive from that of long PMI hCECs grown on monolayer. Immunofluorescence analyses revealed that components of the basement membrane and extracellular matrix were deposited similarly in all hTECs, irrespective of the hCECs PMI. Interestingly, wound closure was accelerated in hTECs prepared using short PMI hCECs. Gene profiling analyses on hTECs revealed that most differentially regulated genes encode proteins involved in cell proliferation. Collectively, these results suggest that hTECs reconstructed using short PMI hCECs have a higher number of limbal stem cells and exhibit more efficient wound healing response in vitro, making them the best candidates to produce substitutes for clinical studies.

Aged individuals and astronauts experience bone loss despite rigorous physical activity. Bone mechanoresponse is regulated in part by mesenchymal stem cells (MSCs). We reported daily low intensity vibration (LIV) restores MSC proliferation in senescence1 and simulated microgravity2 models, suggesting reduced mechanical signal delivery to MSCs contributes to declining bone mechanoresponse. We developed a 3D bone marrow analog that controls trabecular geometry, marrow mechanics and external stimuli. Finite element (FE) models of hydrogels, representing bone marrow, were generated using instantaneous compression (1000% strain/s, 20% strain) and relaxation experiments (100s) of both gelatin and hyaluronan-based hydrogels. Experimental and in silico vibration experiments using molded-gelatin wells (widths=3, 4, 5, 6 and 8 mm) were performed under 1g acceleration, 100 Hz for FE model calibration. For MSC experiments, 0.25cm3 gyroid-based trabeculae of bone volume fractions (BV/TV)3 corresponding to adult (25%) and aged (13%) mice were printed using polylactic acid. MSCs encapsulated (1x106 cells/mL) in migration-permissive hydrogels4 within printed trabeculae were exposed to LIV (1g, 100 Hz, 1 hour/day). After 14 days, type-I collagen, Ki-67 and f-actin levels (n=3/grp) were quantified for extracellular matrix composition, proliferation, and morphology and grouped with respect to the maximum von Mises strain for 13% and 25% BV/TV scaffolds using the calibrated FE models. As a result of this work, bone analogs will now be flown to the International Space Station in 2023 to determine if consistent mechanical stimulus from LIV counteracts microgravity-induced aging and preserves MSC function, including osteogenesis.

SUSTAINED VEGF RELEASE FROM LIVER-SPECIFIC LIGAND-CONJUGATED MICROPARTICLES FOR TARGETED ISLET TRANSPLANTATION

I-Ning Lee$_P$[1], Lisa White[1]

Islet transplantation is a therapeutical treatment for type 1 diabetes. A major limitation for successful islet transplantation is the failure of graft survival due to difficulty in achieving timely vascularisation. Vascular endothelial growth factor (VEGF) plays a major role in endothelial differentiation and regeneration. Whilst VEGF can be used to promote neo-vasculature, achieving targeted and controlled delivery kinetics remains crucial. One approach is the use of microparticles (MPs) as drug delivery vehicles. However, the major challenge for clinical delivery to liver is that MPs are typically fabricated from commercially available polymers that are non-specific to the organ resulting in inefficient delivery and extravasation.

The asialoglycoprotein receptor (ASGPR) exhibits high affinity as a galactose receptor and is the only liver-specific receptor to be identified thus far. We demonstrated targeted delivery to the liver by synthesising a novel PLGA polymer by covalent conjugation with galactose moieties to provide specific binding sites to hepatocytes in order to enhance MPs retention in liver.

MPs fabricated from this polymer demonstrated a 90% VEGF encapsulation efficiency and exhibited a mean controlled daily release of 0.3 µg of VEGF per 1 mg of MPs between 2 and 7 days of in vitro release suitable to promote vascular development.

We successfully demonstrated a novel synthesis route for galactosylation of commercial PLGA and the fabrication of MPs as a novel protein carrier for targeted liver delivery with high encapsulation and controlled release kinetics of VEGF with enhanced MP retention demonstrated in vivo in mice.

CREATING ENVIRONMENTS FOR BONE CO-CULTURES

Sandra Hofmann$_P$[1]

[1] *Eindhoven University of Technology*

Corresponding author's email: s.hofmann@tue.nl

Bioengineering bone aims at growing mimics of bone in the laboratory that could be used either for bone regeneration or as model systems to study bone physiology and pathology. There are commonly three cell types described that are the essential contributors to the bone's native function: osteoblasts, osteocytes and osteoclasts. While all three cell types can be investigated separately, co-cultures of them including their precursors and inactive forms still provide a huge challenge, both in terms of culturing conditions and (quantitative) evaluation of functionality. Cell culture media have been optimized for the requirement of single cell types, supporting tissue development. To simulate bone homeostasis, a physiological microenvironment needs to be created that is supportive of all involved cell types. It should enable the cells to interact with each other in particular through soluble factors. This presentation will elaborate on the current practices of co-culturing bone cells for in vitro bone models. Selected examples will show the high susceptibility of cells towards their biochemical and biophysical microenvironment: for example, that components within fetal bovine serum have the power to mask cell-mediated effects and that they can influence the cellular reaction to mechanical load. Overall, this talk will provide a prospective view on the development of in vitro (co-)culture models as functional representatives of processes occurring in bone.

As cardiovascular diseases remain the leading cause of death worldwide, there is an increasing focus on developing of physiologically relevant cardiovascular tissue models. The heart, as a chemo-mechano-electrical -biological system, presents special challenges for the establishment of in vitro models suitable for personalized disease modelling and pre-clinical testing of drugs. Although several methodologies to mimic the key features of cardiac complexity exist; current miniaturized in vitro models do not sufficiently address the self-organization and cellular diversity issues at organotypic level. We aim to establish organotypic cardiac microtissues in vitro that contain the different cell types of the heart derived from human induced pluripotent stem cells (hiPSCs), and use this model in an organ-on-a-chip platform to improve microtissue physiology in a precisely controlled dynamic environment.

We have optimized a scaffold-free protocol to generate multicellular, beating and self-organized cardiac spheroids in vitro from hiPSCs, and monitored the self-organization of cardiomyocytes with a fluorescently tagged Cardiac Troponin I reporter. The spheroids result in clusters between 500 microns - 1 mm that gradually self-organize and generate chamber-like structures in long-term culture. They contain multiple cell types of the heart, beat without external stimuli, are viable for more than 50 days, and respond to cardioactive drugs. Furthermore, we have developed a preliminary microfluidic setup that allows long-term term and dynamic cultivation of hiPSC-derived organoids under an interstitial flow regime[1][2][3]. Ongoing prospects include functional characterization of these microtissues in static and dynamic on-chip environments, as well as implementing sensors for continuous non-invasive monitoring of culture parameters.

In this work, the effect of different concentrations of halloysite nanotubes (HNTs) on the physical, chemical, and biological properties of electrospun polycaprolactone (PCL) nanofibrous scaffold was investigated. HNTs were added to PCL solution at the concentration of 5, 10, 15, 20, and 25 (wt%) regarding PCL matrix, and nanomats were prepared using the electrospinning method. Scaffold samples were studied using FT-IR, XRD, and TGA techniques. The effect of HNTs on the morphology of prepared scaffolds was investigated using SEM imaging. It was found the HNTs with a concentration more than 5% would result in mats with non-homogeneous structure. Also, water contact angel studies showed that higher concentrations of HNTs than 5% had no effect on the hydrophilicity of the scaffold sample. So, scaffold with 5% concentration of HNTs was chosen as the proper scaffold for further investigations. Higher ability of the scaffold with HNTs in comparison to pure PCL sample to induce biomineralization was proved by SEM imaging after 14 days of immersing samples in SBF. MTT assay showed that HNTs would increase the cell viability of fibroblast cells after 24, 48, and 72 h of cell culture.

Despite numerous advances in the field of tissue engineering and regenerative medicine, monitoring the formation of tissue regeneration and its metabolic variations during culture is still a challenge and mostly limited to bulk volumetric assays. Here, a simple method of adding capsules-based optical sensors in cell-seeded 3D scaffolds is presented and the potential of these sensors to monitor the pH changes in space and time during cell growth is demonstrated. It is shown that the pH decreased over time in the 3D scaffolds, with a more prominent decrease at the edges of the scaffolds. Moreover, the pH change is higher in 3D scaffolds compared to monolayered 2D cell cultures. The results suggest that this system, composed by capsulesbased optical sensors and 3D scaffolds with predefined geometry and pore architecture network, can be a suitable platform for monitoring pH variations during 3D cell growth and tissue formation. This is particularly relevant for the investigation of 3D cellular microenvironment alterations occurring both during physiological processes, such as tissue regeneration, and pathological processes, such as cancer evolution.

Melt electrowriting (MEW) is an additive manufacturing technology, capable of producing high resolution fibre scaffolds. Recently, MEW scaffolds were suggested as a promising delivery substrate for cardiomyocytes in bioengineered myocardial constructs (BMC)[1]. The scaffold's microarchitecture and mechanical properties have to be precisely adjusted to recapitulate myocardial organization and allow for the scaffold deformation under myocardium contraction.

Several micro architectures, including hexagonal and auxetic[2] shaped, are considered as promising candidates for BMCs. However, an open challenge for MEW is the production of constructs which allow the required local compliant behaviour and anatomical thickness of the infarcted region, without compromising the cardiomyocyte arrangement.

MEW scaffolds with hexagonal pores (0.25-1 mm thick) were printed and analysed. The accuracy of the scaffolds is achieved by minimizing the fibre wall slant, typically observed in MEW scaffolds. This effect was counterbalanced by a layer-by-layer adjustment of parameters (voltage, collector distance and speed) and the printing path. Collector speed and voltage variation significantly weakened the slant effect, however, did not eliminate it. Printing path adjustment showed higher efficiency in fidelity improvement. The adjustment of the stress-strain curve shape of the scaffolds, intended to comply with the different infarction locations, was done by changing the movement path around a pore, while keeping the pore shape and size constant.

The findings of this study push the current thickness and resolution limitations of complex geometry MEW and provide tools for the adjustment of mechanical properties of MEW scaffolds. In combination, these results allow for increased cardiomyocyte delivery in a BMC.

Silk fibroin (SF) hydrogels were used for regeneration of skin wounds due to exudates absorption and their ability to cover the irregular wounds [1]. Recently, various blend hydrogels have been developed to improve the mechanical, structural and biological properties of SF-based hydrogels. Furthermore, many synthetic and natural hydrophilic polymers were used to be blended with SF to accelerate wound healing [2,3]. They were used to improve the SF bio-functionalities, however, their capability to deliver a full depth regeneration is not optimal yet [1,4]. On the other hand, Pluronic is a known FDA approved polymer which significantly reduces the pathogen adhesion and biofilm formation [5]. In this work, we used the amphiphilic structure of pluronic F127 to induce globular nanostructures combined with Curcumin as a conventional antibacterial agent [6] to increase cell penetration.

Extracted SF solution from B. mori cocoons was poured on the NaCl crystals in 1:1 weight ratio. After drying, the salt crystals were washed for several times by MQ-water and the hydrogels were lyophilized. Four experimental groups namely SF, SF-pluronic (SFP), SF-pluronic-acetone (SFP-A), SF-pluronic-acetone-curcumin (SFP-A-Cur) were prepared. The particulate nanostructure of the pore walls showed a diameter of 10 times larger than pure F127 micelles which was due to SF molecules encapsulations [7]. The morphology of attached fibroblast cells was studied through cytoskeleton staining. The confocal micrographs showed that globular microstructure increases cell penetration in the scaffold. The developed platforms could be potentially applied for the full depth regeneration of the skin.

A conductive hydrogel comprised of hyaluronic acid (HA), gelatin, and gold nanorods (GNRs) was developed and injected/cross-linked in situ in a thoracic level hemi-section spinal cord injury (SCI) in an 8-week study with 38 rats. The long-term goal is to develop a conductive biomaterial to augment electrical stimulation (ES) for patients with severe spinal cord injury (SCI). In the current work, citrate-GNRs were synthesized with high aspect ratios of 7.7 ± 1.2, as measured from transmission electron microscopy, and were incorporated into HA/gelatin hydrogels at 0.4-1.2 mg/mL concentrations, which were determined by inductively coupled plasma-mass spectrometry. The GNR hydrogel precursors had a bioprintable and paste-like precursor with a yield stress of 511 ± 20 Pa and had a quick crosslinking time (~5 min). The crosslinked hydrogels had conductivities up to 1.15x10^-5 ± 0.19x10^-5 S/cm, and compressive moduli of 83 ± 30 kPa. Seeded rat neural stem cells on GNR hydrogels in vitro had similar adhesion and greater metabolic activity compared to control plated cells. While no significant differences in functional recovery/regeneration were found in vivo from Basso, Beattie, and Bresnahan scoring and immunohistochemistry, we demonstrated the feasibility of applying a paste-like hydrogel precursor in situ for SCI and the safety of the GNR hydrogel. To our knowledge, this was the first study that used a GNR-based conductive hydrogel to treat SCI in vivo, and further provided a translational platform that can be refined to promote axon regeneration and be combined with ES for facilitating functional recovery after SCI.

Delay in wound healing is a severe problem in a diabatic patient resulting in significant morbidity and mortality, and increased health care costs, caused by prolonged microbial infections, compromised patient's life, limb amputations, and even death. The decrease in blood supply along with oxygen, nutrients, and growth factors leads to severely reduced blood vessel formation (angiogenesis) inadequate cell proliferation and cell migration as well as collagen deposition in wound area [1]. Therefore, there is a dire need for advanced therapeutic modalities that could promote the healing of diabetic wounds by providing a sustained release of oxygen (O2) and growth factors to the wound area and enhance the rapid formation of the blood vessels. Multiple pieces of evidence have shown that CTGF and reduced graphene oxide possesses angiogenic property and enhance wound healing by increasing the oxygen supply to the wound area, and by proliferation and migration of fibroblasts and keratinocytes cells [2]. In this study, we have developed a novel method for the conjugation of CTGF with reduced graphene oxide nanoparticles using EDC-NHS chemistry to accelerate the wound healing process. The rGO/CTGF was then incorporated in GelMA hydrogel to provide a sustained release. The developed hydrogels were then characterized by different physical characterization methods to confirm the morphology of the material. The biocompatibility of the material was confirmed by the cytotoxicity (Live/Dead, MTT) assay using keratinocyte cells. Finally, the wound healing scratch assay shows the ability of the material to promote faster healing of the wound.

Layer-by-layer technology (LbL) has emerged as a powerful strategy for engineering flat and patterned freestanding multilayered membranes to be applied in wound healing, drug delivery and tissue regeneration.[1] However, freestanding membranes still rely on macroscale multilayered systems without spatial control over cell distribution and organization. In this work, miniaturized multi-shaped freestanding membranes were build-up in a multilayer fashion through the alternate deposition of oppositely charged biopolymers onto spatially confined sacrificial hydrogel microarrays. After the LbL assembly process, sacrificial templates were subsequently liquefied releasing dozens to hundreds of individual multilayered micro-membranes with homogeneous size distribution across the different geometries of the underlying templates. The geometrically shaped micro-membranes were cultured with either human adipose-derived stem cells (hASCs) or human umbilical vein endothelial cells (HUVECs) and ultimately assembled into a sandwich-like co-culture aiming to develop a single and complex bone-like 3D microenvironment. The miniaturized cell-seeding multi-shaped membranes hold great promise to be used as microscale modular units for engineering hierarchical heterogeneous biological tissues.

Leveraging additive manufacturing for advancing the fabrication of next-generation in vitro 3D tumor models with personalized hierarchical features, anatomic size and defined morphology is highly advantageous for recapitulating the cellular and extracellular building blocks of the tumor microenvironment from the bottom-up [1]. The development of such biomimetic testing platforms with anatomic length scales unlocks new avenues to program cancer-stromal cells spatial distribution and introduce tumor-ECM components in a user-defined mode that will contribute for accelerating preclinical drug screening and validation. To engineer such organotypic human-sized tumor models, herein we take advantage of freeform suspension 3D bioprinting using continuous viscoelastic supporting baths comprising cost-effective food thickening polysaccharides [2] and tumor-ECM mimetic photo-crosslinkable bioinks laden with key components found in human tumors. This approach enabled the manufacture of shape-defined, cell-rich, 3D multi-layered tumor constructs with high resolution. Malignant and cancer cells remained viable, proliferated within 3D bioprinted ECM-mimetic constructs and secreted key growth factors (e.g. TGF-β, FGF-2). The biofabricated 3D tumor models were highly reproducible and suitable for screening anti-tumoral therapeutics. Overall, the developed approach is highly programable from the bottom-up and transversal, allowing the manufacture of a myriad of anatomically defined 3D tumor testing platforms for screening candidate anti-cancer therapeutics bioperformance in a preclinical in vitro setting.

The AparTex project focusses on the development of a novel absorbable barrier material to prevent tissue adhesion after surgical interventions.

Adhesion of organs and adjacent tissue after a surgery effects up to 95% of patients during the healing process. This minimizes life quality, can lead to loss of organ function, and displays a huge financial burden on the health care system. Established anti-adhesion materials used as temporary barriers exhibit several drawbacks concerning flexibility, stability, functionality, or handling.

Customized electrospun materials made from functional hydrogel fibers aim to improve the post-operative wound healing and patient recovery.

While one layer of the AparTex textile would stick to the injured tissue, the other layer of the textile will keep the healthy tissue at a distance and act as a physical, absorbable barrier.

Here, we present first prototypes and their properties in terms of mechanical properties, degradation properties and biocompatibility.

Traditional hydrogel lacks fibrous structure, dynamicity and viscoelasticity found in native extracellular matrix (ECM). ECM is the non-cellular component present within all tissues and consists of fibrous structures like collagen, laminin and fibrin. Nature exploits self-assembly and constituents interact via non-covalent interactions to form superstructures found in ECM. Despite recent advances, creating synthetic analogues of ECM with fibrous structure and controlled viscoelasticity remain a challenge. We have explored the use of 1,3,5-benzenetricarboxamide (BTA) based hydrogelators as synthetic mimics of the fibrous ECM for tissue engineering. First, via modular mixing of BTA, we created supramolecular hydrogels with controlled superstructures and viscoelasticity. BTA hydrogels are highly cytocompatible and can direct cell-cell interactions based on their dynamics and mechanical properties. We then developed a desymmetrization method to upscale and shorten BTA synthesis route. With desymmetrization, molecular control has made possible the development of new fibrous architectures, which are injectable, extrudable and show good shape fidelity after 3D printing. Another challenge is the erosion of highly dynamic BTA hydrogels over time in cell culture. We address this by making BTA monomer with norbornene on it. This newly developed hydrogelator form micron-long fibers. These fibers are polymerized using thiolene chemistry, resulting in tougher and stable hydrogel. This hydrogelator showed high cell viability, very good extrusion and amenable to fabrication via digital light processing. These newly developed hydrogelators opens up numerous applications in tissue engineering, and remain one of the few examples of synthetic and tunable supramolecular hydrogels platforms that show applications in 3D printing.

Chronic Obstructive Pulmonary Disease (COPD) presents a significant, incurable, worldwide health burden, identifying it as a prospective regenerative medicine target. Sourcing cells for lung therapies is challenging; progress has been made in culturing upper airway basal cells but information on the culture of distal cells remains scarce.

Distal lung from human donors was minced and digested. Cells were plated on type I collagen-coated flasks in cFAD medium with rock inhibitor (cFAD+)[1]. Cells were characterised by immunocytochemistry for vimentin, smooth muscle actin, pan-cytokeratin, TP63, cytokeratin-5, E-cadherin, Club cell secretory protein (CCSP), mucin-5AC and β-IV-tubulin. Differentiated using air-liquid interface culture, with measurement of trans-epithelial electrical resistance (TEER), in a matrigel culture system, and seeded to porous collagen scaffolds.

Culture in cFAD+ resulted in predominantly epithelial cells expressing pan-cytokeratin and E-cadherin, TP63 and cytokeratin-5 suggesting a distal airway stem cell (DASC) identity. At air-liquid interface cells developed tight junctions with increased TEER (≥350 Ω.cm2), increased levels of CCSP, stained positively for β-IV-tubulin and mucin-5AC and had visible, motile cilia. Matrigel culture resulted in self-organising, mucus producing organoids, with visible motile cilia on the surface in addition to thin-walled, cavitated, alveolar-like organoids. The DASCs attached readily to collagen scaffolds, had excellent viability and exhibited proliferation on the scaffolds over a 14 day period.

We have successfully isolated and expanded epithelial progenitors from the distal lung tissue of COPD and healthy donors. Preliminary work demonstrates the DASC multipotential differentiation capacity in a variety of formats making them a valuable source for regenerative medicine therapeutic approaches.

The biofunctionalization of ECM-mimetic polysaccharide hydrogels with human biomolecule cocktails holds great promise for engineering cell-rich living platforms with improved bioactivity and widespread applicability in numerous biomedical applications. To generate such platforms, herein norbornene-functionalized hyaluronan (HA-Nor) and human-based platelet lysates (hPLs) we combined for engineering click chemistry, orthogonally crosslinkable hydrogel platforms that support mesenchymal stromal/stem cells adhesion and bioactivity. Hyaluronan-norbornene functionalization was performed via a straightforward two-pot grafting-to approach and enabled a rapid combination with hPLs and stem cells under mild conditions, giving rise photo-induced thiol-norbornene crosslinkable networks. Hydrogels fabrication with different concentrations of hPLs impacted constructs viscoelastic properties, swelling kinetics and stem cells metabolic activity. Interestingly, cell viability analysis, via live/dead and metabolic assays, demonstrated that 10% w/v PLs in hydrogels promoted higher cell than their non-functionalized counterparts. Moreover, such platforms were also amenable for MSCs 3D spheroids encapsulation. Overall, the synthesized hybrid platform holds great potential for biomedical applications that can benefit from in situ cells and hPLs delivery, particularly in the context of regenerative medicine.

Introduction

Articular cartilage (AC) is a specialized connective tissue which provides a low-friction gliding surface, supporting shock-absorption and wear-resistance. Nowadays, conventional strategies show several limitations in restoring chondral defects. This work reports the fabrication of a bilayered structure made of gellan gum (GG) and poly(ethylene-glycol) diacrylate (PEGDA), mimicking mechanical and lubrication of AC in deep and superficial zones. Graphene oxide (GO) was analyzed as lubricant agent.

Methods

Blends of GG and PEGDA were crosslinked by UV-light and magnesium chloride. GO was synthesized following modified Hummer's method1, and embedded into the superficial layer. Wear tests, performed following ISO14243, were performed on a knee simulator. Cytotoxic effects on chondrocytes were assessed by Live/Dead and MTT assays.

Results

Mechanical tests allowed to determine the optimal crosslinking parameters, by combining photo (5 min) and ionic crosslinking with MgCl2, to target the Young's modulus of superficial and deep zone2. The presence of GO into the superficial layer provided a lower coefficient of friction in the kinetic regime (~0.03) than the non-doped hydrogels. The wear test confirmed the resistance of the bilayered hydrogel up to 100,000 cycles. The hydrogel formulations did not show any sign of cytotoxicity.

Conclusions

These results are promising in view of the fabrication of a multi-layered synthetic implant for the restoration of AC.

TOWARDS BIOHYBRID LUNG DEVELOPMENT: DE NOVO SYNTHESIS OF ENDOTHELIAL EXTRACELLULAR MATRIX SUPPORTS MONOLAYER STABILITY UNDER FLOW CONDITIONS

Michael Pflaum[P][1], Katherina Katsirntaki[1], Sophie Jurmann[1], Claudia Hartl[1], Zlata Vukadinovic-Nikolic[1], Axel Haverich[1,2], Bettina Wiegmann[1,2]

Background

As alternative to lung transplantation, biohybrid lung development, based on the ECMO-strategy, is promoted. Therefore, blood-contacting surfaces, in particular hollow fiber membranes (HFM) will be endothelialized to generate anti-thrombogenic surfaces for long-term application. In order to improve endothelial monolayer stability on HFMs under flow conditions, the impact of extracellular matrix (EM) synthesis, which is crucial to resist dynamic conditions, was assessed during prolonged static cultivation. Furthermore, changes in gene expression of selected EM-proteins due to flow exposure were analyzed.

Methods

EC-monolayers were established on HFMs, incubated for 2 or 6 days under static conditions, and subsequently exposed to flow conditions for 24 hours. For assessing EC-monolayer integrity and EM-synthesis under static and dynamic conditions, immunofluorescence stainings (IF) of VE-Cadherin (CDH5) and collagen-IV (COLIV) were performed. Expression levels of matrix associated genes collagen-alpha-1(IV)chain (COL4A1), syndecan-2 (SDC2), Laminin-alpha4 (LAMA4), hyaluronan-synthase-2 (HAS2), exostosin-1 (EXT1) were analyzed by qRT-PCR. Additionally, cell counting of adherent ECs on HFMs was performed.

Results

Prolonged static cultivation resulted in higher EC numbers on HFM after flow exposure. IF images indicated time-dependend accumulation of COLIV-containing EM. qRT-PCR detected a flow-induced upregulation of the EM-associated genes SDC2, LAMA4, HAS2 and EXT1, while COLIV-associated COL4A1-gene expression was consistent throughout cultivation remaining on the static level.

Conclusion

EM formation is important for long-term stability of the EC monolayer on HFM, especially to resist clinically relevant flow conditions. Therefore, to optimize EM production within HFM endothelialization, further flow adaption protocols need to provide both, time and flow stimuli for EM maturation.

Intervertebral Disc (IVD) degeneration is associated with a chronic inflammatory response and extracellular matrix (ECM) degradation. Yet, the cell targets involved in IVD degeneration are still scarcely understood. CD44 is an adhesion receptor highly expressed in Nucleus Pulposus (NP) cells [1], with specificity for several ECM components [2] and reported to be involved in inflammation. Here, we explore the role of CD44 as a possible therapeutic target on IVD degeneration.

Fresh bovine (b)NP were sorted based on CD44 expression and studied for gene expression of inflammatory and ECM remodelling markers. To determine its role in the degenerative cascade, bNP cells CD44 expression was evaluated in IVD organ cultures in healthy vs pro-inflammatory/degenerative conditions and correlated with degenerative IVD mrkers [3]. CD44 distribution on bNP and co-localization with CD14 (monocyte/macrophage marker), was assessed by immunofluorescence (IF).

CD44 is highly expressed on bNP cells (20-40%). CD44+ bNP cells revealed up-regulation of IL-8, but not IL-6 or CD14 gene expression, and significantly down-regulation of aggregan (ACAN), compared with CD44- cells. CD44+ cells also tend to express lower levels of collagen type II (COL2), MMP-2/3, ADAMTS-5 and TIMP2. The pro-inflammatory stimuli significantly increased CD44, alongside CD14, IL-6 and IL-8, while down-regulating COL2 or ACAN gene expression. CD44+ cells co-localized with CD14 in 56±23% cells. These results suggest that CD44+ cells are more associated with the inflammatory cascade, while CD44- cells seem to be more associated with ECM.

Overall, the results show the relevance of CD44 as an important therapeutic target on the degenerative IVD.

Cardiovascular disease (CVD) remains one of the leading causes of ill-health and mortality. The ability to derive human induced pluripotent stem cells (hiPSCs) from patients and healthy individuals, and then differentiate into cardiomyocytes (hiPSC-CMs) provides new opportunities to model and understand human diseases. Current approaches produce hiPSC-CMs that lack maturity relative to the adult human heart. The use of biomaterials could improve hiPSC-CM functionality by altering biophysical and biomechanical properties including surface chemistry and topography to better represent the in vivo environment.(1)

In this study, high-throughput micro-array screening approaches were used to assess 24,924 cell-polymer interactions(2) and >2000 unique topographies(3). A third platform, ChemoTopoChip: combining polymer and micro-topographies(4) were subsequently used to identify topographically enhanced cell culture systems for improved maturity of hiPSC-CMs. Experiments at scale, focused on assessing hPSC-CM attachment using high-content imaging and functionality by measuring contractility to polymer substrates.

Multi-generation screening of cell-polymer interactions identified high attachment and improved functionality of hiPSC-CMs with amine-containing polymers(5) which also supported attachment of hiPSCs at scale-up. Screening of hiPSCs and hiPSC-CMs with micro-topographies identified how feature size and frequency influences hiPSC pluripotency and expansion as well as structural maturation respectively. Mathematical algorithms identified surfaces that support both hiPSC expansion and differentiations. Topo-chemical combinations are now being tested to investigate the interplay between surface chemistry and topography. The aim being that this will identify xeno-free topographically enhanced culture systems that mediate both hiPSC expansion and in-situ differentiation of hiPSC-CMs with improved maturity and functionality for better CVD modelling.

Liver transplantation represents the only option for patients with end stage liver disease. Regrettably, this solution is limited by growing demand and inadequate supply of organs available for transplantation. Decellularization is a promising approach in regenerative medicine used to remove the cellular content of organs, preserving a scaffold composed of an intact extracellular matrix and vascular tree. Once decellularized, these scaffolds could be recellularized to create bioengineered organs able to be transplanted.

The main goal of this work is to re-establish a functional vasculature in bioengineered livers of clinical size. Therefore, we are developing a robust reproducible and cost-effective platform for the large-scale expansion of mesenchymal stromal cells (MSCs), smooth muscle cells (SMCs), and endothelial cells (ECs) under dynamic conditions. Firstly, cells were cultured on microcarriers in spinner flasks. Overall, cells reached maximum numbers of 15X106 of MSCs, 20X106 of SMCs, and 7.6X106 of ECs, which corresponds to fold increase values in total cell number of 6, 11 and 3, respectively. Importantly, cells expanded under stirred conditions retained their phenotypical identity. Finally, we were able to expand successfully MSCs and SMCs under fully controlled conditions in stirred tank bioreactors (STBR). Cells reached maximum numbers of 170X106 of MSCs, and 200X106 of SMCs, which corresponds to fold increase values in total cell number of 17 and 33, respectively. As for spinner flask cultures, cells expanded in STBR retained their phenotypical identity. These results could represent an important step toward the production of the necessary amounts of cells required for recellularization purposes.

The rising number of pathologies, including non-union bone defects, skin lesions, neurological disorders and inflammatory processes are greatly debilitating for patients and are becoming an increasing economic burden on the society [1,2]. Most of the clinical remedies result to be palliative and have limited success in alleviating pain and suffering in patients. Regenerative medicine has emerged as a promising field to address these issues. The controlled and targeted delivery of bioactive molecules, such as growth factors (GFs), has shown the potential to induce tissue repair and regeneration [3]. However, despite their efficacy, high doses of GFs are required to obtain significant improvement in clinical settings, leading to severe systemic side effects [4]. Here we present a novel hydrogels system based on acemannan, a bioactive polysaccharide extracted from the inner leaf of the Aloe Vera [5]. The intrinsic anti-inflammatory and immunomodulatory properties make acemannan a promising candidate for tissue regeneration applications. The polysaccharide is engineered to develop 3D hydrogels with tunable physicochemical properties that enable the controlled delivery of GFs, promoting the recruitment and differentiation of stem cells and enabling tissue regeneration. Moreover, the inherent bioactive properties of this carrier, together with the controlled presentation of GFs, will lead to a synergistic effect for efficient tissue repair allowing the use of ultra-low doses of GF, orders of magnitudes lower than the current clinical settings. We believe that this novel hydrogel system will provide a versatile GF delivery platform with potential to be used in different tissue engineering applications.

BMP-9 VARIANT WITH INCREASED ECM-BINDING CAPABILITY DISPLAYS SUPERIOR BONE-FORMING CAPACITY TO THOSE OF NATIVE BMP-2 AND BMP-9

Shorouk Fahmy-Garcia[1], Claudia Siverino[2], Nicole Kops[1], Claudio Di Luca[3], Yanto Ridwan[1], Eric Farrell$_P$[1], Gerjo van Osch[1], Joachim Nickel[2]

Introduction. BMP-9 has shown stronger osteopromotive capabilities in vitro[1] and higher bone-inducing potential on ridge augmentation[2] than BMP-2. However, intramuscular injection of BMP-9 did not induce bone formation, which might be due to fast diffusion. To avoid this issue, we created a BMP-9 variant (BMP-9v) with ECM-binding sites and then compared its bioactivity in vitro and in vivo to BMP-2 and BMP-9. Methods. ALP expression in C2C12 cells was studied after BMP-9,-2,-9v stimulation. The release profile of BMP-9 and BMP-9v from a collagen scaffold was assessed with ELISA. For in vivo studies 1 and 10 µg of BMP-9,-2,-9v loaded on collagen scaffolds, were implanted subcutaneously in rats (n=8, 6 replicates per condition), scanned biweekly for 8 weeks and retrieved for histology. Results & Discussion. BMP-9 and BMP-9v induced a higher expression of ALP with lower EC50 values compared to BMP-2. BMP-9v was released 10-fold slower than BMP-9 ($p=0.0002$). In vivo, the three proteins induced mineralization at 10 µg with no significant differences. However, 1 µg BMP-9v induced mineralization at similar levels than 10 µg conditions, while 1 µg BMP-2 and BMP-9 barely did ($p\leq0.01$). Furthermore, histological analysis revealed a trabecular-like structure in most of the BMP-9v samples. Indeed, blood vessels and marrow adipose tissue were observed within the bone structure, similarly to the beam-like structures observed in a healthy bone marrow. The promising results of BMP-9v position this new BMP variant as a clinically relevant alternative to current growth-factor based therapies, reducing the supraphysiological doses used to induce bone formation.

Two dimensional (2D) monolayer cell culture models fail to accurately model the breast cancer (BC) tumour microenvironment and animal models possess numerous limitations. Three-dimensional (3D) collagen-based scaffolds can be utilised to bridge the gap between these models [1,2]. We hypothesise that collagen-based scaffolds, developed in our lab [3], present a more accurate representation of the tumour microenvironment and may be used to assess the potential of nucleic acid delivery to abrogate primary and metastatic BC cell growth. Breast cancer and epithelial cells were grown on collagen-glycosaminoglycan scaffolds to model BC primary tumours and on collagen-nanohydroxyapatite scaffolds to model bone metastasis. Cell behaviour and gene expression comparison was performed comparing cells cultured on 3D scaffolds and in 2D to validate the model. microRNA (miR-146a-5p) delivery was performed to inhibit breast cancer cell growth. Uptake was confirmed by confocal imaging and PCR. DNA and metabolic assays were performed to evaluate effects of miR-146a-5p delivery on proliferation and metabolic activity. Significant changes were identified in gene expression comparing BC cells cultured on the different scaffolds and to 2D. miR-146a-5p was successfully delivered and inhibited BC cell growth in 3D. Differences in the effects of miR-146a manipulation in 2D compared to 3D were demonstrated. This study characterises collagen-based scaffolds as adequate models of BC primary tumours and bone metastasis. The therapeutic effect of nucleic acid delivery correlates with in-vivo effects as evident in the literature [4,5] showing the suitability of these scaffolds to model different BC tumour microenvironments and enable evaluation of gene therapy.

INTRODUCTION: One of the elementary issues with 3D bioprinting is the proper set-up of the printing parameters to achieve well-defined geometries. Among them, the nozzle size and printing speed are particularly critical. Herein, we investigated the effect of these two parameters on the printability of a hybrid decellularized extracellular matrix (dECM)/polysaccharide bioink. METHODS: Alginate-xanthan solution (1:3) was mixed with a lung dECM hydrogel at a 90:10 weight ratio. Four nozzle sizes (18G, 20G, 22G, and 25G) and printing speeds (0.5mm/s, 1mm/s, 2mm/s, and 4mm/s) were tested at a standardized flow rate. Printability was assessed by filament fusion test using a piston-based 3D bioprinting system. RESULTS: Although all the combinations of nozzles and printing speeds allowed the bioprinting of our bioink, printability differed among the distinct setups. The percentage of defective lines was 1.7%, 10.0%, 30.0%, and 51.7% for increasing nozzle sizes. Defective lines were 31.7% at 4mm/s and around 20% for the other speeds. The spreading of the bioink (diffusion rate, DR) was higher than 60% for all printing speeds and pore sizes for 18G. For 25G, the DR remained between 20% and 60% for all speeds and pore sizes above 2mm. DR for 20G was higher than 22G for all speeds for pores above 2mm. CONCLUSION: The use of a 22G nozzle with a printing speed of 1mm/s or less resulted in the best printability for our hybrid dECM/polysaccharide bioink.

Tissue-tissue interactions, such as those between cartilage and bone in the osteochondral junction, cartilage and ligament in the enthesis, bone and vasculature, etc. play a critical role in joint diseases and repair. However, it is challenging to study tissue interfaces in vitro since each tissue requires a defined and often very different microenvironment. We developed a multiscale approach that combines microfluidic and mesofluidic bioreactor systems that maintain media separation for in vitro culture and engineering of OC tissues and constructs of progressively greater complexity. With this approach, it is possible to perform progressive steps of screening from organoids in a microfluidic system, to constructs that match the dimensions and are closer to the complexity of native tissues, to actual composite human tissue such as the osteochondral unit. Furthermore, this platform preserves the possibility of interrogate tissue-tissue crosstalk thus assessing drug interactions. Importantly, the platform enables mechanistic studies pathological processes and to test the effectiveness of regenerative and tissue engineering approaches, including novel scaffold technologies, prior to application in vivo.

Coupling angiogenesis and osteogenesis within bioactive tissue engineered scaffolds represents a promising approach to recapitulate the natural bone repair process. Several miRNAs have shown potential to influence the angiogenic and osteogenic capacity of mesenchymal stem cells (MSCs) (1). Interestingly, miR-210 and miR-16 possess counter-active targets involved in both angiogenesis and osteogenesis: miR-210 acts as an activator by silencing EFNA3 & AcvR1b, while miR-16 inhibits both pathways by silencing VEGF & Smad5. We hypothesized that dual delivery of miR-210 mimic and miR-16 inhibitor (antagomiR) from a collagen-nanohydroxyapatite scaffold system developed in the lab (2, 3), may hold potential for bone repair, and assessed its potential to accelerate bone repair by directing enhanced angiogenic-osteogenic coupling in host cells in a rat calvarial defect. The nanomiR-210 mimic group significantly increased miR-210 levels and silenced AcvR1b and EFNA3, while nanoantagomiR-16 treatment resulted in >90% silencing of miR-16 levels, followed by enhanced Smad5 and VEGF expression. Silencing of direct targets was remarkably improved with the nanomiR-210/16 dual treatment. Both nanomiR-210 mimic and nanoantagomiR-16 enhanced VEGF secretion and calcium deposition by hMSCs, with levels further increased in the nanomiR-210/16 dual group. These dual-miRNA loaded scaffolds showed more than double bone volume and vessel recruitment increased 2.3-fold in the defect site over the miRNA-free scaffolds only 4 weeks after cell-free implantation in vivo. This work represents a highly promising approach to recapitulate the natural bone repair process in a 3D scaffold miRNA delivery system and underlines the potential of these scaffolds as 'off-the-shelf' miRNA-therapeutic platforms.

To understand the development of disease or the impact of the environment, we need to use in vitro models that can endure a more realistic exposure of not only a few days, but several weeks or months. Our scaffold free and self-assembled dermal compartment made of normal human fibroblasts (fdmDE) achieves an in vivo-like dermis that can sustain epidermal regeneration for several months, reaching tissue epidermal homeostasis, building a stable and reproducible skin equivalent (fdmSE) (1). The versatility of the model not only mimics normal human skin, but also different degrees of malignancy by using different transformed cells (like HaCaT and HasKpw cells) as well as photoaging phenotypes (using fibroblasts from sun exposed skin of old donors). With this tool we have studied the effect of experimental sunlight (simultaneous combination of UV, visual and infra-red radiation) comparing it to UV exposure in young and old normal human skin equivalents as well as HaCaT-based models. In addition, and due to the fdmSE's lack of immune cells, we studied the immune suppression-independent modalities of the immunosuppressant, cyclosporin A (CsA), which increases the risk for cutaneous squamous cell carcinomas (cSCC). The facility of extended exposure of these models has been key to understand their sustained impact on tissues-organ interplay, such as the loss or gain of certain extra cellular matrix proteins, the increase of ECM degradation or the changes in epidermal tissue behaviour. Therefore, we suggest the use of these models to include the important dimension of time into skin in vitro modelling.

Temporomandibular joint (TMJ) degeneration affects over 10 million Americans. Tissue-engineered TMJ reconstruction will require scaffolds that provide mechanical support and provide controlled delivery of biological factors to induce tissue regeneration(1). To address both needs, the goal of this study was to control the release of a model small heparin-binding molecule, crystal violet(CV), through a tunable PEGDA/heparin hydrogel layered within a porous 3D-printed load-bearing scaffold. Laser-sintered porous PCL scaffolds were placed in custom molds and injected with hydrogel solution prior to 20-minute thermal crosslinking at 25°C. Phase-contrast microscopy demonstrated hydrogel penetration throughout void spaces of the 3D-printed porous scaffold in two distinct layers representing cartilage and bone compartments. MicroCT 3D reconstruction revealed ~100% gel uptake in porous scaffolds compared to the theoretical volume from scaffold design software. Stress-relaxation compression tests demonstrated viscoelastic properties for composites(~23% decrease in force after 5-minute constant strain). Scaffolds were modeled as a homogenized cylinder with effective hyperelastic properties and optimized to experimental data to determine material coefficient(c1) in the Neo-Hookean hyperelastic material model: $W = C1(I1-3)$. C1 was 1.24 MPa with an R2 of 0.99, verifying that the composites can be modeled as a nonlinear elastic Neo-Hookean material during the ramp-up phase of viscoelastic testing. Zero-order release of CV was observed over 7 days. Cumulative release decreased by ~24% when heparin wt.% was increased from 10 to 15 due to greater electrostatic interactions with the positively-charged CV. Further development of our composite system may lead to an alternative to current treatments for anatomically complex osteochondral defects.

MODIFICATION OF NATURAL ECM GELS WITH TRIFUNCTIONAL OLIGOURETHANES/SILICA PARTICLES AND ITS IMPLICATION IN THE PROMOTION OF AN ANTI-INFLAMMATORY MICROENVIRONMENT

Paola García[P][1], Pedro Ulises Munoz-Gonzalez[1], Laura Castellano[1], Birzabith Mendoza[1]

The modification of extracellular-matrix (ECM) gels with trifunctional-oligourethane(TO) and silica is proposed to generate templates for the treatment of pathologies with a highly inflammatory environment such as the degenerative intervertebral discs (DID). The role of the crosslinkers derived from lysine diisocyanate and ethoxylated glycerol, and modifiers of silica particles is evaluated to generate an anti-inflammatory response in the context of DID. Gels were manufactured by crosslinking of ECM materials (pericardial tissue or Achilles tendon) with trifunctionalized-oligourethanes (CX) and optionally doped with silica (CXSi). The gelation kinetics(turbidimetry/rheometry) of the crosslinked hydrogel indicated a gelation in 40min at 37°C. The crosslinking degree, estimated by quantification of residual primary amine groups, was of 27% for CX and 31% for CXSi. The diameter of the formed fibers in the gels was estimated by turbidimetry in 72.8nm, with a mass-length ratio of 2.39x10^12(Da/cm). The G' of the gels was around 50–80Pa transitioning to a stable-gel capable of in-situ after injection. The strain required to make the ECM gel flow correlates with the increase in the type I collagen concentration; however, the required strain increases for the crosslinked gels. The injection of the CXSi gels induced a significant reduction in the expression of genes that code the pro-inflammatory markers IL-6 and iNOS in an IL-1β-induced inflammation ex vivo model in bovine intervertebral discs. In contrast, the CXSi gel application upregulated the gene expression of aggrecan. Further studies are underway to evaluate the performance of the CXSi gels in promoting an anti-inflammatory microenvironment in the DID context.

PCI is a very successful method of placing stents in occluded coronary arteries. This restores blood flow in patients suffering from acute or sub-acute coronary occlusion. Research continues to be conducted worldwide on new biocompatible materials for use in stent devices, which on the one hand offer sufficient strength for vascular support during constructive remodeling and on the other hand allow good cyto- and hemocompatibility. Complications continue to occur with stent implantation; the main problems are in-stent restenosis and thrombosis due to inadequate mechanical properties or poor biocompatibility. A major drawback of BMS and DES is the durability of the stent scaffold, which is associated with several adverse events. Fully resorbable stents are the latest development. It is believed that scaffold resorption following vascular repair offers several benefits, including reduced risk of late stent thrombosis, avoidance of repeat treatments and prevention of lateral branch obstruction. To guarantee highly valid and reliable preclinical data, countless animal experiments have to be carried out. This is unethical, costs a lot of money and the results are often not completely transferable. To address this, we have developed a biomechanoreactor using ex vivo porcine heart coronary arteries obtained from regular pig slaughter to study novel and conventional stents under blood flow conditions in direct comparison regarding their biocompatibility over time. The data on biomechanics, degradability, drug release and reendothelialization of different stent types collected over 12 weeks will be used for in silico simulations. In this way, animal experiments can currently be reduced by 50%.

The combination of rehabilitation protocols and regenerative therapies offers the outstanding opportunity to promote and enhance the endogenous regenerative and repair processes occurring in tissues damaged or lost due to injury, disease, or age. Still, one of the main hurdles in the clinical approach to regenerative rehabilitation is the lack of easily accessible and sensitive biomarkers for the evaluation of rehabilitation and therapy efficacy. Extracellular vesicles (EVs) are nanoscaled vesicles that mediate intercellular communication among organs. EVs were shown to be involved in the onset, progression and resolution of many disorders, being also used as valuable tool in the regenerative medicine field. However, the initial enthusiastic approach to EVs has been hindered in its transfer to clinics because of technological obstacles related to their dimensions and to their limited amount. We show herein the application of a Surface Plasmon Resonance imaging (SPRi)-based biosensor(1) for the detection and characterization of blood EVs from stroke patients, before and after rehabilitation. After the successful SPRi detection of EVs of different cellular origin (brain and non-brain cells), the quantification of specific surface molecules related to pathological or regeneration processes was accomplished. Our results demonstrated the ability of the SPRi biosensor to reveal differences in the relative amount of specific cell-derived EV subpopulations and in their cargo during disease progression and rehabilitation induced recovery. Our results provide support for using the proposed SPRi-based biosensor for the detection and characterization of circulating EVs in order to evaluate the efficacy of rehabilitation protocols and regenerative therapies.

The most effective treatment for type 1 diabetic patients is transplanting a whole pancreas or islet cells. However, major limitations of allogeneic transplantation are organ shortage and the need of life-long immune suppression medication. In the last decade, the field of regenerative medicine has combined engineering and biological techniques in the attempt to regenerate organs. The European VANGUARD project, funded by the European Commission, aims to engineer immune-protected bioartificial pancreases for transplantation into non-immunosuppressed type 1 diabetic patients. This project is creating a 'combination product' using cells from a variety of sources, including animals, donors and patients, resulting in a chimeric bioartificial organ for transplantation. Developing such a product faces several research-ethical issues. One pertains to the risks and burdens of first-in-human clinical trials, and subject selection. Under what conditions can the product safely be tested in humans for the first time? Which research participant group should be invited first for participating in clinical trials to receive a transplantable bioartificial pancreas? The aim of our study, which is part of and runs in parallel with the VANGUARD project, is to investigate the ethical conditions for responsible research when bio-engineered pancreatic organs are developed and tested in clinical trials, e.g. subject selection, study design, informed consent and risk-benefit assessment, and contribute to research-ethical guidance in the field of regenerative medicine. In this presentation, we present the results of a review of the literature on the ethics of regenerative medicine, and discuss one or two issues more in depth.

Coronary artery disease affects 335M people worldwide. There are no small-diameter vascular grafts to compete in the replacement of coronary arteries with autologous grafts, often unavailable. Decellularized arteries (dArteries) emerge as preeminent alternative, but have unsatisfactory mechanical and biological performance, due to thrombosis and infection. This study proposes the coating of dArteries with graphene oxide (GO) to surpass these limitations.

Human placenta/umbilical cord arteries were isolated and decellularized [1], exhibiting low amounts of DNA. Two different GO were purchased or produced by modified Hummers' method [2] and perfused through the dArteries lumen to coat it. XPS analysis showed that both GO present similar atomic composition, ~34%O/66%C, while DLS and TEM imagens showed that they have different sizes, 1.3µm(sGO) and 1.9µm(lGO). GO-coatings are homogeneous, stable and completely cover the inner lumen of the dArteries, as shown in SEM images. Uniaxial tensile tests of dArteries rings showed that only the lGO-coating of umbilical cord dArteries increases 29% burst pressure and 25% strain, reaching values similar to human saphenous vein. In vitro biological assays showed that GO coatings reduce human platelets and bacteria (S. aureus) adhesion to dArteries without compromising endothelial cells (HUVECs) adhesion. Preliminary in vivo acute thrombogenicity studies (porcine AV-shunt) show that heparin covalent binding to both uncoated and GO coated dArteries seems to prevent their occlusion when exposed to non-heparinized blood.

Overall, lGO-coatings have a significant role in improving dArteries performance, representing a step forward in the transition from lab bench to market of these grafts.

Non-healing wounds are among serious complications of diabetes resulting in significant morbidity and mortality, and increased health care costs, caused by prolonged microbial infections, limb amputations, and even death. Therefore, there is a dire need for advanced therapeutic modalities that could promote diabetic wound healing. One of the major reasons for the delayed healing of diabetic wounds is poor supply of oxygen (O2) that causes decreases in cell viability, cell migration and cell proliferation. Lack of vascularization is another challenge in diabetic wound healing. A number of potential solutions have been investigated to solve the problem of delayed healing of diabetic wounds including the use of growth factors, stem cells, and combinations of both . However, the high cost, fast degradation, rejection of cells by the immune system restrict their effective use. The short shelf life and low stability of growth factors during the transportation and storage conditions as well as their high costs pose a huge barrier towards the commercial application of these growth factors-based formulations for widespread clinical use. Studies indicated that exogeneous delivery of nitric oxide (NO) can promote angiogenesis. Herein, we developed a microneedle array-based patch for diabetic wound healing that can effectively deliver a sustained amount of O2 and NO through the micro sized needles to achieve an angiogenic effect and abundant supply of O2. We noticed that the delivery of NO and O2 using microneedle array-based patch promoted new blood vessel formation around wound sites and hence increased the healing of refractory diabetic wounds.

Osteoarthritis affects a large proportion of the aged population worldwide. Cartilage tissue engineering approaches have emerged to replace invasive surgical techniques aiming to restore articular cartilage [1]. Human bone marrow stromal cells (HBMSCs) offer the potential as a cell source for differentiation into cartilage. However, their application is hindered by a crucial limitation: subpopulation heterogeneity [2].

The aim of this study was to achieve high-throughput cell aggregation to test the hypothesis that SOX9 was an early marker upregulated upon condensation and could be used to enrich HBMSC chondroprogenitor subpopulations.

HBMSCs were injected into a PDMS chip with continuous gentle stirring. QX200™ generation oil (Bio-Rad) was used for droplet stabilisation. Droplets were incubated at 37°C, 20% O2 and 5% CO2 in chondrogenic differentiation medium. Aggregates were later recovered from microdroplets on days 1, 2 and 3 for biological characterisation (i.e. colony formation assay, RT-qPCR and immunofluorescence).

The droplet microenvironment enabled the formation of minimal HBMSC aggregates (comprising only a few cells) within one hour of culture. HBMSCs aggregates displayed maintained colony formation functionality when re-plated for 14 days. In addition, HBMSC aggregates expressed higher SOX9 mRNA levels than monolayer cultures as early as one day of chondrogenic induction. At that time point, aggregates expressed SOX9 at the protein level with marked heterogeneity among them.

The work presented in this study confirms the potential of application of droplet microfluidics for cell aggregation, short-term culture and sorting on the basis of early markers opens new prospects for harnessing HBMSCs for cartilage tissue engineering.

Wound management, nutrition and drug delivery do constantly attract significant attention leading to recent evolution of nano-based dosage forms and wound dressings for active wound management of contaminated and slow-to-heal wounds. Among all types of nanomaterials, nanofibres have shone due to their unique properties leading to barrier effect and increased drug bioavailability. In addition to these properties held by nanofibres in general, the chemical nature is a crucial parameter, possibly able to modulate wound healing process through molecules released into the wound site. From this point of view, chitosan-based nanofibres represent a very promising material based on natural and sustainable material, which can be manufacture using green solvents and doped with multiple active compounds enhancing their natural antibacterial activity. In this study, we evaluated impact of Zn+, Ag+ and Cu2+ ions as potential bioactive dopants. Ion incorporation into electrospun chitosan nanofibres was studied in terms of effects on bacterial film elimination (E. coli and S. gallinarum), cytocompatibility to normal human dermal fibroblasts (NHDF) and Hacat keratinocytes, cellular stress and proliferation and pro-inflammatory cytokines (IL-1α and IL-6) expression. The bioactive ions doped chitosan nanofibres exhibited altered antibacterial activity against both bacterial strains in comparison to pristine chitosan nanofibres. The strongest antibacterial effect was observed in the case Ag+, yet incorporation of Zn+ and Cu2+ led to higher cell viability and modulated cellular stress in comparison to Ag+. This work was supported by projects HyHi (Reg. No. CZ.02.1.01/0.0/0.0/16_019/0000843) and TAČR FW17134.

Introduction

Engineered neural tissue (EngNT), an artificial tissue made using purified type I collagen hydrogel, has been shown to promote axonal regeneration in vivo [1]. Decellularised extracellular matrices can create a pro-regenerative environment [2]. We hypothesised that EngNT fabricated from decellularised matrix hydrogels will be beneficial for peripheral nerve repair. Three specific ECM hydrogels were screened in vitro for ability to promote neurite extension, with one material then tested in vivo.

Methods

ECM hydrogels were biochemically and mechanically characterised. Cellular alignment was assessed using confocal microscopy 3D image analysis. Rat dorsal root ganglia were harvested and seeded onto stabilised EngNT sheets. Neurite extension was visualised using fluorescence microscopy. A 10 mm rat sciatic nerve transection model was used to compare ECM EngNT with collagen I derived EngNT alongside an empty tube and nerve autograft.

Results

ECM hydrogels differed in stiffness, gelation, and strain responses, as well as sGAG and dsDNA content. Cellular alignment was observed in EngNT made using bone ECM (B-ECM) and small intestinal submucosa ECM (SIS-ECM), but not in liver ECM (LIV-ECM). In vitro neurite extension was observed on all EngNT sheets. Directional outgrowth was exclusive to B-ECM, SIS-ECM, and collagen I EngNT. B-ECM EngNT and collagen I EngNT had comparable in vivo axonal regeneration.

Discussion and conclusions

Hydrogels varied in mechanical properties and biochemical composition, likely affecting cell behaviour. DRG neurite outgrowth on B-ECM was comparable to that of collagen based EngNT and supported regeneration in an in vivo nerve injury model.

Tissue engineering strategies, particularly the use of decellularized extracellular matrix (ECM)-based biomaterials, have emerged with undeniable promise for IVD regeneration. Independently of human or animal origin, donor age can influence the therapeutic success of tissue decellularized scaffolds [1]. We have shown that fetal nucleus pulposus (NP) ECM is enriched in pro-regenerative proteins (Collagen XII and XIV), when compared with adult and aged animals [2]. Thus, we propose to evaluate the ability of fetal NP-based scaffolds to promote IVD regeneration by ECM remodeling.

Fetus, young and old bovine NPs were decellularized using an SDS-based protocol and characterized for DNA presence and biochemical, structural and mechanical properties. Adult bovine NP cells were cultured ex vivo on decellularized matrices from fetus, young and old NPs. After 7 days, cell survival, metabolic activity and ECM production (Collagen type II and Aggrecan) were analyzed at molecular and protein level.

As results, an SDS-based protocol enabled successful cell removal, while preserving ECM architecture and composition. Fetal and young NPs matrices were more effective in promoting NP cell viability and adhesion than old matrices. Finally, NP cells cultured in fetal matrices promoted higher Aggrecan expression both at mRNA and protein level.

In conclusion, all NP decellularized matrices supported adult NP cell culture. However, fetal NP scaffolds were shown to have an increased capacity to promote ECM synthesis. This is the first report demonstrating a higher pro-regenerative potential of fetal NP matrices, thus opening new avenues for the development of IVD therapeutic strategies.

Intro: End stage renal disease affects millions of patients worldwide. Allotransplantation is the only curative treatment, yet is only accessible to a fraction of patients. Hemodialysis does not adequately replace lost renal function. Engineered kidney-replacing devices could be an alternative, however, excepting native extracellular matrix, no biologic scaffolding system to support cell-based filtration and absorption has yet been developed.

Methods: Biomimetic thin film scaffolds were fabricated by 3D printing, embedding, and leaching opposing networks of sacrificial material across 5µm thick microporous biologic membranes. The separated channel systems were co-seeded with primary glomerular microvascular endothelial cells and immortalized podocytes (glomerular grafts, N=3), or human umbilical vein endothelial cells and immortalized proximal tubule epithelial cells (tubular grafts, N=4) to recapitulate glomerular and proximal tubule anatomy and physiology.

Results: Scaffolds supported cell engraftment, polarization, and barrier formation in vascular and epithelial channels, enabling filtration and reabsorption. Acellular scaffold vascular perfusion at 30mmHg resulted in a flow rate of 5.82mL/min/cm2 (N=9), producing filtrate at 8.01µl/min/cm2 of membrane. Confluent glomerular grafts produced filtrate at a rate of 3.76µL/min/cm2 (48h, N=3). At 1 week, mature tubular grafts retained 96.8% of Inulin-FITC in the tubular epithelium (N=3). At maturity, glucose was transported into the vascular channel at a 24 hour rate of 0.11mg/mL/cm 2 (N=4).

Discussion: Biomimetic thin film scaffolds support formation of perfusable 3D tissues and higher level renal cell based functions such as filtration and reabsorption in vitro. At scale, cellular constructs could enable fabrication of a fully biologic implantable renal replacement device.

Multiple sclerosis (MS) represents the most frequent demyelinating disease affecting young people. Although there are oligodendrocyte precursor cells (OPCs) capable of differentiating in oligodendrocytes and producing myelin sheaths in denuded axons, the process of remyelination fails with disease progression leading to irreversible functional failure. Growing evidences suggest that matrix rigidity plays a crucial rule throughout OPC differentiation and oligodendrocyte myelination by unbalancing the intra/extracellular forces.

Here we propose the use of a “tool-box” by constructing a 3D tissue engineered model of an CNS scar exploring nanomaterials(1). The platform consists on a modified alginate (ALG) matrix able to recreate the 3D environment of the glial scar. ALG hydrogels were produced by combination of ALG formulations with cell adhesive moieties and metalloproteinase-cleavable sequences (PVGLIG). OPC metabolic activity increased for matrices containing high concentration of PVGLIG and, consequently, low stiffness values. This was accompanied by the increase of MBP+ cells and the complexity of cellular morphology at D5, D9 and D14 of differentiation. Astrocytes were found to rapidly extend long processes and create an astrocytic network with increased cellular complexity for high PVGLIG content matrices, acquiring an astrogliotic-like phenotype in response to a cocktail of cytokines. The crosstalk between these cells and the effects of the astrogliosis processes on oligodendrocyte differentiation is being investigated. The final aim is to setup a high-throughput platform to study possible targets and drug candidates involved in the modulation of oligodendrocyte differentiation that can ultimately be explored in the treatment of MS.

Work funded by the UTAustin-Portugal Program.

Constructs derived from pericardial ECM mesh material covered with porcine small intestine submucosa ECM gel and allogeneic vesical cells and platelet gel were assessed in the reconstruction of rabbit urinary bladder defects. Bovine and porcine pericardial tissue was decellularized by a method described previously. Porcine small intestine submucosa tissue was decellularized and hydrolyzed to render a pre-gel that was combined with water-soluble oligourethanes and silica. Some mechanical, physicochemical, and biological characteristics of the constructs were tested envisaging applications in bladder tissue engineering. The functionality of neobladder was assessed by histological, cystometric and mechanical tests. The urine capacity after 16 weeks of implantation was of 64-75% and 18-46%, relative to the control, when rabbit bladder was repaired with constructs derived from bovine and porcine pericardial ECM, respectively. After 17-week implantation, the integration and formation of neobladder was observed, as well as a complete regeneration of urothelium with presence of smooth muscle like the native bladder. We also found the formation of bladder stones, which can be related to the high levels of urate in the urine; that dissolving with the pH promotes the CaOx precipitation by “salting-out” and induces CaOx crystal formation, causing the urolitiasis. Constructs composed of bovine pericardial ECM mesh material covered with ECM gel and allogeneic vesical cells deserve further study in search of suitable alternatives for the reconstruction of defects in the urinary bladder.

The majority of the existing in vitro cardiac models do not incorporate the temporal load-length patterns observed in the pressure-volume (PV) loop of the human ventricles. Improved models would elucidate the effect of changing hemodynamic loads in the distinct PV phases on cardiac structural and function during development, adaptive remodeling and maladaptive remodeling. Here, we fabricate 3D concave tissues that can simulate the ventricular ejection within a microfluidic system. We demonstrate that two photon direct laser writing (TPDLW) is an enabling 3D-printing technique for 3D microscopic scaffolds that are designed to mechanically support embedded contracting induced pluripotent stem cell (iPSC)-derived tissues. Our tissue constructs display notable scaffold deformation and ejection fractions, and recapitulate the response of cardiac tissue to well-characterized chemical compounds. We additionally use TPDLW to fabricate miniaturized passive microfluidic check valves that are sensitive enough to be actuated by the tissue-generated flow. We demonstrate that the valves can regulate and rectify the flow, replicating the unidirectional pumping function of the human ventricles and producing a multiphasic pressure-volume diagram resembling a preliminary PV loop. Our microfluidic system highlights a new path towards advanced in vitro cardiac models that represent more accurately the in vivo heart.

EMULATING EFFECTS OF RADIATION ON HEMATOPOIESIS IN AN ENGINEERED MODEL OF HUMAN BONE MARROW

Cosmic radiation is the most serious risk encountered during long missions to the Moon and Mars, and an important concern for patients undergoing radiation therapy. There is a compelling need to understand the exact effects of cosmic radiation, safety thresholds, and mechanisms of tissue damage, in order to develop measures for radiation protection during extended space travel. As the bone marrow (BM) is highly susceptible to radiation damage, serious injury can cause inability to form blood/immune progenitors and eventual BM failure. We describe here (i) a human, patient-specific model of BM that has capacity for hematopoiesis, (ii) the assessment of the effects of cosmic radiation on the hematopoietic niche, and (iii) applications of radioprotective agents (like G-CSF) for mitigating cellular damage. To this end, we engineered our in vitro model by populating decellularized bone scaffolds with osteoblasts, mesenchymal stem/stromal cells, endothelial cells, and cord-blood-derived hematopoietic stem/progenitor cells. Marrow tissues were subjected to doses representative of therapeutic cancer therapy (photon rays, 0-6 Gy) or deep space radiation (neutron rays, 0-2 Gy). Three weeks post-radiation, flow cytometry, histological staining, and cytokine assays were performed, and the early markers of double-stranded DNA damage and molecular changes in lineage fate were identified. At an approximately 4-fold higher rate than in photon ray exposure, neutron rays resulted in decreased proliferation capacity of CD45+ cells, aberrant matrix formation, and tissue necrosis. Using engineered human systems, we hope to provide a test bed for radioprotective therapeutics to circumvent downstream damage during space exploration. (Funding: NASA TRISH FIP0014)

RAPIDLY PROTOTYPED HUMAN LUNG-ON-A-CHIP FOR DISEASE AND TOXICITY MODELLING AND COUNTERMEASURE DEVELOPMENT

Shiny Rajan[P][1]

[1] *Wake Forest Institute for Regenerative Medicine*

Corresponding author's email: shrajan@wakehealth.edu

Recent studies have been involved with developing biomimetic microsystems that can reconstitute major organ functions like the air-liquid interface of lung. These bioinspired in vitro models are more physiologically relevant than 2D models and weakly-transferrable animal models for drug and toxicity studies. Here, we propose a rapid prototyping approach by combination of adhesive-film based microfluidics and 3D printing to scale up chip fabrication and improve reproducibility and consistency. This was accomplished by constructing a microfluidic architecture that features a chamber separated by a porous membrane, each side of which can be accessed by the 3D printer independently. First, we bioprinted the apical bi-layer epithelia consisting of an ECM hydrogel layer with human lung fibroblast (HLF) and then a monolayer of human bronchial epithelial cells on upper surface of the membrane. Then, the endothelial monolayer was bioprinted on the opposing lower surface, thus mimicking the multicellular 3D organization and air-liquid interface of lung. The system is capable for rapid biofabrication and scale up and is compatible with fluorescent/colorimetric plate readers and microscope imaging stages and other equipment designed for tissue culture plates/chambers. High-throughput and non-invasive analysis of parameters like surface liquid pH, transepithelial resistance, metabolic activity, cell viability as well as immunohistochemistry and imaging have been demonstrated with this system. The physiologically relevant lung model is capable of disease and toxicity modeling and development of appropriate drug and medical countermeasures by analyzing post-treatments effects on the organ.

The gene encoding dystrophin is one of the largest genes, and results in a rod-shaped dystrophin protein that is responsible for connecting the cytoskeleton to the extracellular matrix. Therefore, the restoration of this protein is hoped to compensate for these effects. In this study, stable minidystrophin-eGFP tagged transfected myoblasts were used. Both C2C12 (non-dystrophic) and dfd13 (dystrophin-deficient) myoblasts were transfected with ~5.8 kb pCR3.1 eGFP-mini dystrophin (pMDysE) using Lipofectamine® LTX and PLUS™ Reagents. All transfected myoblast were culture in low mitogen condition for 10 days to induce differentiation. The cells were subjected to immunofluorescence analysis and total protein extraction prior to western blotting assay technique. The introduction of minidystrophin into dfd13 myoblasts showed no expression of MyHC and MF-20 throughout the differentiation day Whilst, MyHC and MF-20 were found expressed late in C2C12-minidystrophin when compared to C2C12-eGFP myoblasts. In dfd13-minidystrophin myoblasts, PTEN expression was found to be reduced upon differentiation. Akt activation was found to be significantly increased in undifferentiated dfd13-minidystrophin myoblasts compared to dfd13-eGFP myoblasts. However, its expression was found reduced upon differentiation to levels comparable with dfd13-eGFP myoblasts. Surprisingly, p70S6K showed significant massive activation in dfd13-minidystrophin myoblasts compared to dfd13-eGFP myoblasts. In this study, the introduction of minidystrophin into dfd13 indicates that non-full length dystrophin is insufficient to improved dfd13 differentiation. However, there is some improvement of dfdf13-minidystrophin where Akt is activated at the undifferentiated stage and increases of P70S6 kinase activation during differentiation. MinidystrophinΔH2-R19 partly improves PTEN/PI3kAkt signalling in dystrophin-deficient myoblast.

SINGLE-CELL RNA SEQUENCING FOR PULMONARY TISSUE ENGINEERING

Allison Greaney$_P$[1], Micha Sam Brickman Raredon[1], Taylor Adams[1], Jonas Schupp[1], Naftali Kaminski[1], Laura Niklason[1]

[1] *Yale University*

Corresponding author's email: allison.greaney@yale.edu

Single-cell RNA sequencing (scRNAseq) has revolutionized our understanding of native, developing, and diseased organs, and can be further leveraged to characterize engineered tissues. This is particularly useful in lung engineering, as pulmonary tissue is comprised of four cell classes and upwards of two dozen distinct cell types. In this work, we developed scRNAseq analysis pipelines to identify cell type and behavior within our engineered constructs, as well as benchmarking engineered to native lung tissue(1). Our engineered lungs are grown using decellularized rat lung scaffolds that are recellularized in bioreactors with epithelial and mesenchymal cells in the airway compartment, and endothelial cells in the vascular compartment. Lungs are cultured for a week in cell-type specific media under arterial perfusion, with continuous pressure monitoring at the inlets and outlets of the organ to measure changes in flow patterns within the organ in real time. By analyzing our engineered lungs with scRNAseq, we identified distinct and heterogeneous changes in cell phenotype associated with perturbations in culture parameters, such as media composition, perfusion rate, and added cell types (i.e. epithelium, endothelium, and mesenchyme, vs. epithelium alone). We further compared transcriptomic patterns between engineered and native lungs to gauge our progress towards a functional tissue that may perform well on implantation. We have leveraged Seurat, SCANPY, Monocle, and Connectome software packages in our scRNAseq analyses(2). Overall, this work introduces paradigms for applying scRNAseq analysis techniques to engineered tissues, which in turn can provide high-resolution translational roadmaps.

Rotating wall vessel (RWV) bioreactors have been used as microgravity analogs to produce cell spheroids and organoids at a faster rate than in other bioreactor devices and with higher structural and functional fidelity. One of the limitations of traditional RWV systems is their well-documented tendency for air bubble formation during operation. The presence of these bubbles negates key features of the RWV environment, such as zero headspace, low shear, and simulated microgravity We recently described the design, construction, and testing of a novel RWV bioreactor capable of continually removing air bubbles from the system without interfering with the fluid dynamics that produce optimized cell culture conditions (1). We modeled this capacity using computational fluid dynamics (CFD) and validated the model with alginate beads and spheroid cultures of A549 human lung adenocarcinoma cells. The areas of spheroids assembled from A549 cells in the novel bioreactor in the presence of air bubbles were an order of magnitude larger than in conventional bioreactors when bubbles were present. We also designed a perfusion RWV bioreactor with improved performance characteristics and differentiated retinal organoids from induced pluripotent stem cells in and outside of the bioreactors (2). The ensuing organoids were evaluated by Imaging and IHC. Organoids generated in both static conditions and the perfused bioreactor exhibit retinal phenotypes as demonstrated with IHC, However, bioreactor cultured organoids developed faster and grew significantly larger. We anticipate that the novel designs will increase experimental reproducibility and consistency when using RWV bioreactors as microgravity analogs.

Laryngotracheal reconstruction (LTR) is often required following trauma, tumor resection, or as treatment for subglottic stenosis. Engineered cartilage has been proposed as an alternative to autologous cartilage. This would avoid donor site morbidity and the frequent risk of insufficient autologous cartilage for a successful LTR. For successful translation, a cartilage engineering approach should enable sufficient initial mechanical strength in the engineered constructs with a relative short in vitro maturation time (<1 months) so as to match the clinical timeframe. Decellularized allogeneic or xenogeneic extracellular matrix (ECM) has been a promising approach to engineer almost any organ. In this work we combine decellularized ECM with ear cartilage progenitor cells (eCPCs) that can be harvested in a minimally invasive manner. Our preliminary data show that ECM can indeed be easily recellularized eCPCs to achieve density (~400 cell/mm2) and distribution that match that of native cartilage within 2 weeks. Furthermore, the dynamic (~600 kPa) and bulk (~100kPa) mechanical properties of the eCPCs-ECM match those of native cartilage. Additionally, as the eCPCs differentiate, the GAG and collagen content increases and is comparable to native cartilage. Furthermore, we have shown that eCPCs produce better cartilage than bone marrow derived mesenchymal stem cells, with a lower incidence of calcification and a gene expression profile superior to that of expanded chondrocytes. We have tested the eCPCs-ECM cartilage constructs in a rabbit model of laryngotracheal reconstruction with successful functional outcomes and animal survival. Our findings provide strong pre-clinical evidence of functional cartilage repair using a eCPCs-ECM.

Hydrogel of Decellularized extracellular matrixs (dECMs) represent a promising alternative to develop bioinks that closely mimic the native environment of cells. In the present study, a hydrogel as bioink was developed and characterized from the decellularized dentin extracellular matrix (dECM) to be used in dental tissue engineering. The hydrogel as bioink was characterized in terms of biochemical composition and biological properties. Also, determination of decellularization efficiency was investigated upon quantification of DNA content. The accumulation of collagen was quantified to analysis the bioink. Furthermore, we recellularized the bioink with stem cells of apical papilla (SCAPs cells) and its adhesion was analyzed by fluorescence-based assays. The cytotoxicity of bioink was analized by MTT. Our results showed that acellular dECM contained higher detectable collagen contents and the lower content of DNA. We further demonstrate that high retention of collagen gradients were detected and retained in decellularized samples after decalcification and decellularization process. The results pointed that dentin from extracted teeth can be decellularized and highly efficient hydrogel was produced, and the resulting bioink supports the adhesion of SCAPs for 48 hours and were not found to be cytotoxic in 24hrs. The dentin decellularized matrix bioink may be a promising for 3D printing in regenerative dentistry.

SIMULATED MICROGRAVITY ENHANCES THE DIFFERENTIATION OF CULTURED MOUSE EMBRYONIC STEM CELLS TOWARDS DEFINITIVE ENDODERM

Peter I Lelkes[P][1], Liat Oss-Ronen[1], Robert A Redden[1]

[1] *Dept. Bioengineering, Temple University, Philadelphia PA, USA*

Corresponding author's email: pilelkes@temple.edu

Directed in vitro differentiation of pluripotent stem cells towards definitive endoderm (DE) is of great translational interest since DE cells can further differentiate into cells of numerous internal organs, such as lung, liver, and pancreas. We hypothesized that culturing mouse embryonic stem cells (mESCs) under simulated microgravity (SMG) conditions in Rotating Wall Vessel Bioreactors (RWV-BRs) will enhance directed DE differentiation. To test our hypothesis, we cultured the cells for 6 days in two dimensional (2D) monolayer colony cultures, or as embryoid bodies (EBs) in either static conditions or, dynamically, in RWV-BRs. We used flow cytometry and qPCR to analyze the expression of marker proteins and genes, respectively, for pluripotency (Oct3/4) and the induction of mesendodermal (Brachyury T), endodermal (FoxA2, Sox17, CxCr4), and mesodermal (Vimentin, Meox1) lineages. Culture as EBs in maintenance media (MM) in the presence of LIF, in static or SMG conditions, induced the expression of some of the differentiation markers, suggesting heterogeneity of the cells. This is in line with previous studies showing that EB culture will initiate mESC differentiation even without supplementing differentiation factors to the media. Culturing mESCs under SMG conditions in RWV-BRs in differentiation medium (DM) upregulated Brachyury T and all of the DE markers, and reduced Oct3/4 expression, indicating the advantage of dynamic cultures in RWV-BRs to specifically enhance directed DE differentiation. Given the reported discrepancies between the SMG conditions on earth and actual microgravity conditions, future experiments in space flight are required to validate the effects of reduced gravity on mESCs differentiation.

Abstract **#1655**

FRESH 3D BIOPRINTING OF SURGICAL TISSUE TRAINING MODELS USING NATIVE BIOMATERIALS

Andrew Lee[P][1], Riley Patten[1], Thomas Hinton[1]

[1] *FluidForm*

Corresponding author's email: andrew@fluidform3d.com

Surgical simulation has emerged in recent years as a critical path to surgical success. The ability to accurately simulate surgical environments has been shown to reduce costs and risks of operations in an ever-evolving landscape of medical devices, surgical techniques, and cross-functional surgical teams. Recent efforts to simulate surgery has largely involved hands-on training modules that are designed for specific tissue types in individual operations. 3D printing has been an important tool for recreating the highly specific surgical tissue environments. Models of organ systems has been successfully 3D printed using a variety of synthetic resins. However, these models are limited by the materials they choose in that they lack comprehensive surgical feedback that involves simultaneous visual and tactile response. Here, we show the ability to print large-scale tissue simulation constructs with macroscale and microscale control of geometry, using native biomaterials tailored for tissue mechanical properties. Using the Freeform Reversible Embedding of Suspended Hydrogels (FRESH) 3D bioprinting technology, we demonstrate the ability to accurately pattern native biomaterials such as collagen to create patient-specific constructs that offer life-like simulation of tactile and visual response. The ability to create multi-material constructs with patterned regions of mechanical properties is shown to better mimic the surgical environment for a variety of tissue types, ranging from heart valves, adult and pediatric tracheas, intervertebral discs, and ligaments and tendon. The use of these printed constructs from native biomaterials will provide a more accurate, on-demand simulation that should drastically reduce surgical training cost and increase core surgical competencies.

Osteoarthritis (OA) is one of the most common joint disorders related to cartilage. Taking NSAIDs, hyaluronic acid (HA) or platelet-rich plasma (PRP) injection are common non-operative treatment for OA. Recently, researchers found pro-inflammatory cytokines, such as interleukin 1 beta (IL-1β), tumor necrosis factor alpha (TNF-α) and interleukin 6 (IL-6), plays critical roles in the pathophysiology of OA, and they affect both quantity and quality of the cartilage matrix. Among various cell-based therapies for OA treatment, mesenchymal stem cell (MSC) injection is the most high-profile therapy method. It can exist in various human tissue including bone marrow, adipose tissue, synovium and infrapatellar fat pad (IPFP). In the study, we evaluated the anti-inflammation effect of IPFP-MSC by chondrocyte or peripheral blood mononuclear cell (PBMC) co-cultivation. Results showed that IPFP-MSC have highly proliferative and differentiate capability, they can express CD73, CD90, CD105, lack expression of CD11b, CD19, CD34, CD45, and express aggrecan, type II collagen and SOX-9 mRNA. When we co-cultured IPFP-MSC and PBMC together, we found IPFP-MSC can inhibited the proliferation of PBMC and decrease TNF-α synthesis in IPFP-MSC/macrophage co-culture system. Moreover, we also found that IPFP-MSC could down regulated inflammation related mRNA of chondrocyte including IL-1β, TNF-α, IL-6 and COX2 under the stimulation of 10 ng/mL IL-1β in IPFP-MSC/chondorcyte co-culture system. Through this study, we proved that IPFP-MSC possess well anti-inflammation effect, and it may further improve cartilage repair environment in OA knee. The findings of this work can provide the direction of cell therapy or drug development for OA treatment.

Our study investigates the feasibility of the Raman technique for the monitoring of mineralization formed by 3D-cultured cells.

Jaw periosteal cells (JPCs) were grown within β-tricalcium phosphate (β-TCP) as well as polylactic acid coated (β-TCP/PDL) constructs for 17 days under undifferentiated and osteogenic conditions. Before cell colonialization compressive strength (N/mm2) of uncoated/coated β-TCP scaffolds was determined. Raman spectra of 3D-cultivated JPCs from 3 donors were recorded. Cell-seeded constructs were histologically analyzed.

PDL-coated β-TCP constructs showed a significantly higher compressive strength in comparison to that of uncoated scaffolds. Histological analyses showed a relatively homogenous cell colonialization of both materials. On the surface of the composite material, a thin but very dense cell layer was detected, whereas the uncoated β-TCP core material seemed to be covered by a thicker layer of loosely distributed cells.

Recorded Raman spectra from cell-free scaffolds showed that the composite material could be clearly identified. On the surface of uncoated scaffolds, the amount of free phosphate groups was shown to be much higher than on the surface of PDL-coated scaffolds. Due to strong scattering of the material, the cell-specific hydroxyapatite peak was covered by material-specific peaks. However, cell material could be clearly identified by two specific peaks.

The obtained data show clear material and cell specific peaks. However, the cell-specific hydroxyapatite peak is difficult to be identified due to strong scattering of material. Further analysis should optimize the process of data analysis in order to be able to detect cell mineralization within ceramic scaffolds using Raman spectroscopy.

Islet cell death and loss of function after isolation and during the culture period is considered a main obstacle to successful islet transplantation outcomes (1). Mesenchymal stem cells (MSC) have been shown protective effect on islet viability and function through paracrine interactions and/or direct contact both in the culture period and after transplantation (2). The paracrine function of MSCs are mediated by the secretion of soluble factors and release of extracellular vesicles including exosomes(3). Studies on the effect of extracellular vesicles on islets are very limited. In the present study, we examined the effect of exosomes derived from MSCs on the survival and function of isolated mouse islets. Isolated islets were cultured for 72 hours with MSC-derived exosomes (MSC-Exo), MSCs, or MSC- conditioned media without exosomes (MSC-CM-without-Exo). Islet viability evaluated by fluorescent staining. Apoptosis investigated by TUNEL assay and expression of anti-apoptotic BCL-2 and PI3K and pro-apoptotic BAD and BAX genes in the cultured islets. Beta cell function evaluated by insulin gene expression and protein secretion. The MSCs and MSC-Exo, but not the MSC-CM- without-Exo, significantly decreased the percentage of apoptotic cells and increased islet viability following the downregulation of pro-apoptotic genes and upregulation of pro-survival factors, as well as the promotion of insulin gene expression and secretion. Therefore, exosomes derived from MSCs are as efficient as MSCs for attenuating cell death and improving islet survival and function, suggesting a potential strategy for ameliorating islet transplantation outcomes.

Interactions between the pancreatic extracellular matrix (ECM) and islet cells are known to regulate multiple aspects of islet physiology, including survival, proliferation, and glucose-stimulated insulin secretion. Recognizing the essential role of ECM in islet survival and function, various engineering approaches have been developed that aim to utilize ECM-based materials to recreate a native-like microenvironment. However, a major impediment to the success of these approaches has been the lack of a robust and comprehensive characterization of the human pancreatic proteome. Herein, by combining mass spectrometry (MS) and multiplex ELISA, we have provided an improved workflow for the in-depth profiling of the proteome, including minor constituents that are generally underrepresented. Moreover, we have further validated the effectiveness of our detergent-free decellularization protocol in the removal of cellular proteins and retention of the matrisome. It has also been established that the decellularized ECM and its derivatives can provide more tissue-specific cues than traditionally used biological scaffolds and are therefore more physiologically relevant for the development of hydrogels, bioinks and medium additives, in order to create a pancreatic niche. The data generated in this study would contribute significantly to the efforts of comprehensively defining the ECM atlas and also serve as a standard for the human pancreatic proteome to provide further guidance for design and engineering strategies for improved tissue engineering scaffolds.

In cartilage tissue engineering, it is important to determine the distribution and degradation profiles of implanted engineered cartilage tissues. Observing collagen dynamics is helpful to understand the metabolism of cartilage tissues. However, studies of in vivo follow-up of collagen have not been conducted enough due to limitations of existing labeling methods. Thus, in this study, we used azide-proline metabolic labeling method because this method is bioorthogonal and suitable for dense and complex tissues as well as cells cultured in vitro.

Firstly, to observe the collagen secretion according to releasing time and density of extracellular matrix in a single cell, the cells were encapsulated in agarose and then cultured in chondrogenic medium. Labeled molecules were widely distributed over time and narrowly distributed as the density of the agarose gel increases. Next, we incorporated azide-proline into the engineered cartilages. Then fluorescence imaging and collagen contents assays were performed. Dependently on time, the amount of collagen and the fluorescence intensity increased correspondingly. To evaluate real-time monitoring the azide-proline-labeled collagen in engineered cartilage in vivo, we applied it to a nude mouse subcutaneous window chamber model. The amount of collagen also corresponded to the fluorescence intensity.

In conclusion, using bioorthogonal and specific labeling methods, collagen synthesis, distribution, and degradation profiles were observed in real-time at both the single cell and tissue level. The applications presented in this study is expected to be useful for understanding collagen metabolism in various other tissues containing collagen as well as engineered cartilage tissues in vitro and in vivo.

The conventional skin tissue engineering approaches have developed several skin substitute products such as Integra and Matriderm. Moreover, these commercial skin products must be changed multiple times during healing process. Nowadays, 3D bioprinting, a high-throughput technology for precise fabrication of 3D construction,is used to raise applicability and function of cell-laden scaffolds.Currently,natural hydrogels used to support epidermal regeneration are mainly gelatin-based, which mimic the natural dermal extracellular.GelMA,which forms covalently cross-linked hydrogels under UV light exposure with the presence of a photoinitiator, has recently gained increasing attention, especially in the field of biomedical applications. GelMA is synthesized by the direct reaction of gelatin with MA in phosphate buffer at 50 °C. This reaction introduces methacryloyl substitution groups on the reactive amine and hydroxyl groups of the amino acid residues. We present a method to create multi-layered engineered tissue composites consisting of human skin fibroblasts and keratinocytes which mimic skin layers. In this study multiple layers of fibroblast containing GelMA hydrogel precursor will be print and crosslink using LAP,constituting the dermal layer. Keratinocytes will be sequentially printed and then, by collagen, these two layers of print will be attached to form two layers of skin.GelMA is developed from a natural polymer gelatin via one-step chemical modification. GelMA has a lot of advantage such as high adhesive, high biocompatibility, and high gelation but in return has a limitation such as low mechanical properties, non-elasticity and fast degradation rate in vivo. To eliminate these constraints, various concentrations of gelatin were added to GelMA before printing.

Introduction: Human Adipose Derived-Mesenchymal Stromal Cells (hAD-MSCs) are multipotent stromal cells with a high potential application in tissue engineering and regenerative medicine. Laser irradiation of the place where the cells were implanted can stimulate their proliferation, increase the secretion of growth factors and thus increase the therapeutic effect.

Aim: The aim of this study was to evaluate the influence of two lasers: Er:YAG and diode on the growth of hAD-MSCs in vitro.

Material and methods: AD-MSCs were isolated from human subcutaneous adipose tissue. Immunophenotype of AD-MSCs was confirmed by flow cytometry. Multipotency of AD-MSCs was confirmed by differentiation into adipogenic, osteogenic and chondrogenic lineages.

AD-MSCs were irradiated with Er:YAG laser (wavelength 2940nm, frequency 5, 10Hz, doses: 0.1-1.2J/cm2) for 2s and 4s and diode laser (wavelength 635nm and doses: 1- 8J/cm2) for 5, 10, 20, 30 and 40s. Cell viability was analyzed 24 hours after the exposure using MTT assay.

Results: Growth stimulation of AD-MSCs after 5Hz Er:YAG laser exposure, 0.1J/cm2 dose for 4s and 0.3J/cm2 dose for 4s was shown in comparison with the control group. Significant growth stimulation of AD-MSCs after diode laser irradiation in doses 1-4J/cm2 was demonstrated compared to the control group.

Conclusions: The presented results indicate that both lasers, Er:YAG and diode can be used to stimulate stem/stromal cell growth in vitro. The biostimulative effect of laser therapy on stromal cells may be used in the future in esthetic dermatology in combined laser and cell therapy.

The application of tissue engineering approach for reproductive organs has been introduced recently (1), raising the interest of the scientific community. Even if the impact on patients' quality of life is very promising, in particular for adult and pediatric oncological patients, only few scaffold fabrication technologies have been investigated for this purpose. Electrospinning technique has been selected for its ability to allow the fabrication of nano and microfibers, which resemble the native morphology of medulla and ovarian cortex. Starting from this biomimetic approach, the use of electrospun scaffolds have been investigated for the support of in vitro ovarian follicles growth. Several requirements need to be fulfilled to maintain the vitality and support the follicles development, in fact previous studies reported that the ovarian follicles need to keep their spherical shape, which can be strongly affected by the substrate used for the in vitro culture. In previous works, we demonstrated that the patterned electrospun fibers are able to provide a suitable support for the growth and development of ovarian follicles, being able to investigate also the infiltration of the follicles inside the scaffolds (2,3). In this work, we further investigate the effect of the fiber diameter, pattern and orientation as well as different polymeric blends on ovarian follicles viability and growth.

Lipids are highly diverse biomolecules crucial for the formation and function of cellular membranes, for metabolism, and for cellular signaling. In the mammalian skin, lipids additionally serve for the formation of the epidermal barrier and as surface lipids, together regulating permeability, physical properties, acidification and antimicrobial defense. Recent advances in accuracy and specificity of mass spectrometry have allowed studying enzymatic and non-enzymatic additions and modifications of lipids – the epilipidome –, multiplying the known diversity of molecules in this class. Exposure to frequent oxidative, chemical or thermal stress, injury and inflammation makes it an ideal organ to study epilipidomic dynamics.

We investigated lipid changes in skin equivalents, ex vivo human and animal samples in the context of aging. High resolution mass spectrometry using a 7T MALDI FTICR instrument allowed for accurate mass measurement and therefore immediate lipid identification. In the course of our study we evaluated sample preparation techniques in respect to matrix application but also in the context of multimodal imaging approaches combining MALDI MSI, Raman Imaging and immunohistochemistry. Results were complemented by quantitative lipid profiles from LC-MS/MS.

We found that the relative content of LysoPC and other investigated oxidized phospholipids was upregulated in aging skin and these modified lipid species could specifically be localized in dermal tissue by MALDI MSI. Multimodal image analysis has been performed that correlates these findings with enzymatic activity, Raman fingerprints and immunohistological parameters of senescent cells.

[2] *Qazvin University of Medical Sciences*

Corresponding author's email: seyedjafari@ut.ac.ir

Induction of mineralization in the dental pulp tissue is essential for the success of a pulp capping material for the treatment of pulp exposure. The purpose of the present study was to investigate the attachment, proliferation and odontogenic differentiation of dental pulp stem cells (DPSC) on poly (L-lactide) (PLLA) nanofibers coated with mineral trioxide aggregate (MTA). Electrospinning was used to fabricate polymeric nanofibers and then their surface was coated with MTA. DPSC were isolated from dental pulp and their viability was evaluated on scaffolds and the control group using MTT assay. During odontogenic differentiation, biomineralization, alkaline phpsphatase (ALP) activity, and the expression of odontogenic genes were analyzed. Isolated DPSC showed fibroblast-like morphology with multi-lineage differentiation potential. MTA-coated PLLA (PLLA/MTA) exhibited nanofibrous structure and interconnected pores and also suitable mechanical properties. Similar to MTA, these scaffolds were shown to be biocompatible and support the attachment and proliferation of DPSC. During odontogenic differentiation, biomineralization, ALP activity and odontogenic-related genes were significantly higher on PLLA/MTA scaffolds compared with control groups. Taking together, MTA/PLLA electrospun nanofibers enhanced the odontogenic differentiation of DPSC and showed appropriate characteristics of a pulp capping material.

The repair of peripheral nerve injuries with nerve gaps requires autologous nerve grafts to bridge the injured nerve stumps. Autologous nerve grafting is the gold-standard method with good nerve regeneration potential due to the Schwann cells that the graft supplies along with its scaffold function. However, sacrificing healthy nerves leads to donor site morbidities such as loss of sensation and pain. To overcome these disadvantages, artificial nerve conduits have been developed. The three main components required for regeneration are a scaffold, cells and growth factors. Because artificial nerve conduits provide a scaffold only, their use results in nerve regeneration that is not as good as that permitted by autologous nerve grafts. Researchers have attempted to apply various cells to artificial nerve conduits to improve the results, but previous application methods have had low administration efficiency and the cells have had low survival rates. As an alternative application method, we used a Bio 3D printer (Cyfuse Biomedical K.K.) to effectively apply the kinds of cells that are essential to regenerative medicine in peripheral nerve regeneration. In this presentation, we introduce our method by which peripheral nerve injuries can be repaired using nerve conduits created from various cells using a Bio 3D printer.

POLYMERIC SCAFFOLDS FOR DIRECT CARDIAC GENETIC REPROGRAMMING

Priyadharshni Muniyandi[1], Vivekanadan Palaninathan[1], Toru Maekawa[1], Tatsuro Hanajiri[1]

[1] *Toyo University*

Corresponding author's email: priyadharshni8612@gmail.com

Regeneration of injured myocardium is critical and challenging. Around the world, more than one million patients suffer myocardial infraction annually, most of whom are affected lack shortage of tissue and organs. Thus, there is a great need for the development of new and innovative method mirroring the naive ECM features to improve the quality of patient's life. To overcome these challenges, the development of in-situ direct reprogramming using genetic and epigenetic factors to develop a functional patch to mimic defined microenvironment for reprogramming hold promise for future. The role of delivery of "in-situ" scaffold mediated miRNA/drug delivery for cardiac regeneration is crucial as it can help to mobilize on the site of injury and trigger the reprogramming capacity.The electrospun PLLA scaffolds, combined with both biochemical and physical cues when implanted to the injured site can unlock the regenerative ability. In turn, this induces and drives the differentiation of targeted cardiac fibroblast cells into functional cardiomyocyte like cells. Based on our previous finding to overcome the limitation of current therapies, PLLA scaffolds were fabricated with engineered factors to negate the off-target effect and safety concern of existing delivery systems as a clinical translation of regenerative medicine demands an effective localized delivery system for direct drug/miRNA delivery. Thus, multi-modal drug delivery systems using polymer-based scaffolds can help to negate this issue by not only co-existing with the tissue by providing intramyocardial cellular environment but also can give precision control of the release of miRNA that may be crucial for direct cardiac reprogramming.

Transplantation of pancreatic islets is one of the treatment strategies of type 1 diabetes. Despite many advantages, the therapeutic outcome of this procedure is limited due to high islets loss associated with lack of dense vascular network, among others [1]. In this context, 3D multi-material bioprinting (BP) offers the possibility to fabricate heterogeneous structures composed of pancreatic and vascular compartments.

The aim of this work was to develop tissue-specific bioinks for simultaneous microfluidic-assisted BP of pancreatic islets and blood vessels.

To this end, alginate was blended with decellularized pancreatic extracellular matrix, ECM, or fibrinogen to prepare pancreatic and vascular bioinks, respectively. The BP was performed using commercial bioprinter (Bioplotter) equipped in multi-inlet and single coaxial nozzle outlet microfluidic platform. The 3D-BP scaffolds were characterized with respect to shape fidelity, swelling, mechanical properties and diffusion of glucose and insulin. Porcine pancreatic islets and mixture of human mesenchymal stem cells (MSC) and human umbilical vein endothelial cells (HUVEC) were successfully bioprinted. Islet functionality was assessed using GSIS assay and angiogenic potential by staining against CD31 endothelial marker and implantation onto chick chorioallantoic membrane (CAM).

The bioprinting did not affect islets viability but reduced MSC and HUVEC viability to approximately 80%. The islets sustained their functionality as demonstrated by secretion of insulin under glucose stimulation. During culture, HUVEC spread on the surface of the fibers and formed dense layer, as well as vessel-like structures, of CD31-positive cells. Moreover, denser network of capillaries was formed at the CAM interface, suggesting increased angiogenesis.

Additive manufacturing (AM) has become one of the techniques most intensively utilized for fabrication of 3D porous scaffolds for tissue engineering (TE) applications. In the case of bone TE, the scaffolds are usually made of thermoplastic polymers and polymer-based composites. However, these biomaterials induce fibrous encapsulation at ectopic sites and result in limited bone regeneration. On the other hand, calcium phosphate (CaP) biomaterials are commonly used in orthopaedics both as implants or coatings thereof. One of the advantages of CaPs is that they allow to omit fibrous encapsulation at osseous site due to their ability to directly bond with bone. Here, we present a straightforward method allowing for homogeneous coating of 3D porous scaffolds.

Poly(ε-caprolactone)-based (PCL) samples were fabricated by means of AM using BioScaffolder (SYSENG, Germany) and coated by incubation in medium containing sodium glycerophosphate as alkaline phosphatase (ALP) substrate and bovine ALP. The formulation was further modified by introduction of NaHCO3. The coatings were characterized using SEM, XRD, FTIR and micro-computed tomography and evaluated with respect to adhesion, proliferation and osteogenic differentiation of human mesenchymal stem cells (hMSCs).

The obtained results indicate that the proposed method yielded homogeneous coatings of external and internal regions of 3D porous scaffolds with chemical composition typical for hydroxyapatite. Presence of the coatings significantly enhanced cell adhesion and accelerated osteogenic differentiation, when compared to unmodified samples. The results showed also the positive effect of introduction of bicarbonate on cell adhesion, ALP activity and migration of hMSCs out of the multicellular spheroids.

BIOHYBRID HYDROGEL WITH ENHANCED ELECTROCONDUCTIVITY ADVANCES MATURATION OF HIPSC-DERIVED CARDIOMYOCYTES

Kaveh Roshanbinfar[P][1], Felix Engel[1]

[1] *Friedrich-Alexander Universität Erlangen-Nürnberg*

Corresponding author's email: k.roshanbinfar@gmail.com

Cardiac tissues derived from human induced pluripotent stem cells (hiPSC) can be utilized for patient-specific therapies and drug screening.[1] However, the immature state of these cells limits their application. To date, external electrical stimulation resulted in the most eminent maturation.[2,3] Here, we developed an electroconductive 3D biohybrid hydrogel involving collagen I, sodium alginate, and PEDOT:PSS. It enhances beating properties and maturation of hiPSC-derived cardiomyocytes to near-adult characteristics without applying external stimulations.

hiPSCs differentiated in cardiomyocytes in 12 days using CHIR-9902 and IWR-1-endo and mixed with the pre-gel solution of collagen I, sodium alginate, and PEDOT:PSS. Constructs were fixed after 11 days and immunostained for sarcomeric α-actinin, cardiac troponin I, connexin 43, and DNA. Beating movies were recorded and analyzed by the Musclemotion plugin by NIH ImageJ software.

Compared to constructs without PEDOT:PSS, the electroconductive biohybrid hydrogels improved the maturation and beating properties of hiPSC-derived cardiomyocytes. These cells formed more condensed structures, exhibited 1.9 µm near-adult[4] sarcomeric length, enhanced beating frequency, higher contraction speed, and greater contraction amplitude.

Our data indicate that these electroconductive biohybrid hydrogels enhance the maturation of hiPSC-derived cardiomyocytes. In conclusion, we provide a new and versatile approach to fabricate engineered cardiac tissues that beat and maturate on their own without external mechanical or electrical stimulations. These constructs can find their potential application in drug testing to reduce the burden on laboratory animals or cardiac disease treatment tissues.

In the last 5 years, bioprinting became a highly active scientific area for regenerative medicine applications. Nevertheless, in-vitro production and maturation of large living tissues (in the range of dm3) is still strongly limited by nutrient supply and cell environment control. Each tissue has his own specific geometry / culture rules to maturate. To sustain cell viability and maturation, a tissue-specific design of their culturing processes have to be developed to reach customized large tissues' production. Such bioprocesses and scale-up will have to go through specific and controlled bioreactors modelling to better rationalize parameter impacting the tissues maturation. Our approach was to design and print single-use bioreactors with optimized internal geometry allowing for tissue nutrient perfusion. Such bioreactors were regulated by an external feeding vessel regulated in pH, temperature and oxygen. Bioreactor's design was optimized with Computational Fluid Dynamics (CFD) allowing to describe and chose the medium perfusion flow path within the bioprinted tissue. Several tissues geometry were targeted, either flat dale for dermis models, porous cubes for conjunctive neo-vascularized tissues or tubes for vascular tissues. A comparative study between static and dynamic culture in bioreactor was performed with bioprinted conjunctive tissues. We observed nutrient flow impact on cell growth and maturation through production of extracellular matrix. Perfusion flow rate of 600mL/h was chosen for its compromise between flow heterogeneity (presence of stagnant zone) and a well-established laminar regime. Clear differences between static and dynamic cultures were observed with an enhanced extracellular matrix production while conserving bioprinted tissue internal geometry.

REGENERATIVE MEDICINE & TISSUE ENGINEERING: CLINICAL TRANSLATION

Frank Luyten[P][1]

[1] *KU Leuven & RegmedXB*

Corresponding author's email: frank.luyten@kuleuven.be

Cell based therapies, classified in Europe as Advanced Therapy Medicinal Products, have been explored for more than 2 decades now as potential therapeutics in a large variety of clinical indications, including the repair of cartilage and bone. Their clinical impact has so far been limited and this is due to many factors such as our lack of understanding of the mechanisms of action, the poor correlation between in vitro assays and in vivo outcome, the lack of robust manufacturing processes and underpowered, poorly designed clinical studies. Moreover, it is widely accepted that the process design and scaling of engineered cell based products at reasonable cost has been challenging. Recent scientific insights in regenerative medicine strategies indicate that the mechanisms by which cell based implants exert their potency in vivo are multiple, not only contributing to the cellular compartment of the repair tissue but also affecting tissue repair by paracrine mechanisms thereby boosting the endogenous repair potential. However in large tissue defects and in compromised conditions, the data indicate that the extrinsic cellular component is required for successful clinical outcomes. Clinical translation involves many challenges including the appropriate animal models for well-defined patients. Examples will be discussed including combination products using adult periosteal cells and Bone Morphogenetic Proteins (BMP) on optimized scaffolds. Furthermore, we have been focusing on the manufacturing of living implants for cartilage and bone repair and generated cartilage tissue intermediates, following a developmental engineering paradigm, to repair large long bone defects and deep osteochondral joint defects in vivo.

Stomach drug development is largely relies on animal models, which often do not provide results that are translatable to human patients. Organ-on-a-chip represents a new avenue in a range of area in preclinical precision drug validation and new drug discovery using microfluidic technology. Additionally, the use of stomach organoid generated from patient's adult stem cells as a cell source for organ-on-a-chip can emulate individual organ-level function. It enables better understanding of the individual pharmacokinetics and pharmacodynamics properties of various medications providing personalized drug discovery opportunities. Here, we report a personalized stomach-on-a-chip lined by stomach epithelium prepared from organoid interfaced with primary gastric fibroblast that recapitulates the secretion of mucus, gastric enzyme, and stomach barrier function. The enhanced function of stomach-on-a-chip was acquired by peristaltic flow, co-culture, and small molecules enhancing the interaction between the cells. Our stomach-on-a-chip showed potential for Helicobacter pylori research showing the advantages for infection studies over gastric organoids and human gastric cell line.

Conventional tissue engineering (TE) of bone involves fabrication of 3D porous scaffolds, followed by their inoculation with cells. Recently, 3D bioprinting (BP) emerged as a powerful technology for biofabrication of complex heterogeneous tissue substitutes. In contrast to conventional additive manufacturing, 3D-BP operates in cell-friendly conditions and employs deposition of cell-laden aqueous solutions of biopolymers, so called bioinks. Bioinks used currently for TE applications, although resemble the tissues with respect to high water content, lack of tissue-specific biopolymers and growth factors, which leads to suboptimal tissue formation in vitro. Therefore, decellularized exstracellular matrix (dECM)-based bioinks were proposed for bioprinting of tissues and organs.

The goal of this study was to develop a bioink containing solubilized dECM isolated from porcine bone (dbECM). Following demineralization by hydrochloric acid and decellularization with Triton X-100, the obtained dbECM was dissolved by pepsin digestion. The biochemical analysis revealed that the bioink retained the major component of bony ECM, namely collagen, and was cleared of cellular components (DNA content < 30 ng/ mg of dbECM). The rheological measurements demonstrated shear-thinning behavior. Gelation kinetics increased significantly at higher concentrations of dbECM. The printability of dbECM hydrogels was investigated using 3D printer (Bioplotter, Envisiontec) and the printing parameters were optimized to ensure possibly high shape fidelity. DbECM bioink was also tested for cytocompatibility using human mesenchymal stem cells (hMSC). The ability of hydrogels to support hMSC proliferation and to induce osteogenic differentiation was confirmed by means of MTS assay, measurements of ALP activity, histological stainings and microcomputed tomography.

Comprehensive examination of electrospun networks (ESNs) made of aliphatic polyesters in terms of mass transport, mechanical behavior and morphology was performed to explore the possibility for using them as the engineered Bruch's membrane (a multilayered cell-free barrier that separates the retinal pigment epithelium (RPE) from the choriocapillaris) being the component of the developed in vitro model of posterior ocular barrier. The analysis was carried out by means of novel micro-mechanical computational models of ESNs using of morphological data extracted from X-ray microtomography (μCT).

Data obtained from μCT scanning was used to create volumetric finite element meshes representing the investigated ESNs. It was proven that the rendered ESNs micro-structural FEM models well resembled the actual structures of the investigated ESNs.

The model of diffusion-convection transport of different species through the investigated ESNs as well as the mechanical model of ESNs stretching were developed. The developed transport model uses convective fluxes calculated in CFD simulation and it was used to simulate transport of selected drugs and oxygen through the investigated ESNs. The obtained computational results were verified against the experimental data.

It was confirmed that the developed modeling tools enabled for verification of fabricated ESNs for using them as the engineered Bruch's membrane. The presented computational approach enables for time as well as the experimental effort saving.

The developed model enables for accurate identification of properties of ESNs made of aliphatic polyesters, however the authors expect that it should be able to identify properties of ESNs fabricated from the other materials.

Background: Platelet-rich plasma (PRP) contains high concentrations of growth factors that stimulate proliferation and migration of various cell types. Earlier experiments demonstrated that local PRP administration activates Schwann cells (SCs) to improve axonal regeneration at a transected peripheral nerve lesion[1,2]. However, the optimal concentration of human PRP for activation of human SCs (hSCs) has not been determined, while mechanisms by which PRP activates SCs remain to be clarified.

Methods: hSCs were cultured with various concentrations of PRP in 5% FBS/DMEM. Cell viability, microchemotaxis, flowcytometry, and quantitative RT-PCR assays were performed to assess proliferation, migration, cell cycle, and neurotrophic factor expression of the hSCs, respectively. hSCs were co-cultured with neuronal cells to assess their capacity to induce neurite extension. Neutralizing antibodies for platelet-derived growth factor-BB (PDGF-BB) and insulin-like growth factor-1 (IGF-1) were added to the culture to estimate contribution of these cytokines to the hSC stimulation by PRP.

Results: An addition of PRP at 5% strongly elevated proliferation, migration, and neurotrophic factor production of hSCs. Both PDGF-BB and IGF-1 may be involved in mitogenic effect of PRP on hSCs, while PDGF-BB may also play an important role in the migration-inducing effect of PRP. Neutralization of both PDGF-BB and IGF-1 cancelled promoting effect of PRP on neurite-inducing activity of hSCs.

Conclusions: The present findings may suggest the optimal concentration of PRP for hSC stimulation as well as potential mechanisms underlying the activation of hSCs by PRP, which may be quite useful for the PRP therapy for peripheral nerve regeneration.

We present a novel, based on alkaline phosphatase activity, approach to the production of calcium phosphate coatings on polycaprolactone scaffolds. Enzymatic hydrolysis of sodium glycerophosphate in the presence of calcium chloride led to the rapid formation of coating. Both external surfaces and in porous 3D scaffolds also its internal walls were covered. Since PCL scaffolds are hydrophobic for effective attachment of calcium coating, their surface required modification either by heating or by mild lipase digestion. Effective deposition of calcium coating occurred during first hour of incubation, longer exposition was, however, needed for appearance of crystalline forms, including hydroxyapatite. The new coatings allowed for protein adsorption to the scaffolds and supported cell adhesion, proliferation and osteoblastic differentiation. It appears that phosphatase based strategy may be also applied to scaffold produced from other materials, providing adequate surface activation. Phosphatase method may represent an interesting alternative to the simulated body fluid (SBF) approach for coating formation.

Skin is a very complex and heterogeneous tissue and mimicking its complexity remains a difficult challenge for Tissue Engineering 1,2. Skin tissue models have been used for decades for the treatment of burns but also for knowledge and cosmetic and pharmaceutic evaluation studies. In that sense, there is an inherent need for more physiological and predictive skin models 3,4. This study aims to use bioprinting technology to deposit in a controlled manner two populations of human keratinocytes to introduce heterogeneity in in vitro epidermal models 1,5. As a first proof of concept, we have validated the concept through a patterned epidermal model in which a same keratinocyte population was divided into two subpopulations, one of which was transduced with GFP. As a second step we proved that pattern models can have a real physiological relevance by generating a heterogeneous model consisting of a filaggrin down-regulated part, considered as one of the epidermal models for Atopic Dermatitis and Ichthyosis Vulgaris pathologies, and its associated control part. This first report of human patterned epidermal models, following predefined designs using bioprinting-based strategy, provides concrete proof of the power of bioprinting to reproduce human skin microanatomy.

Medical imaging and 3D bioprinting strategy converged to allow the fabrication of a complex structure with inner architecture based on patient anatomy and biomimicry. In this study, we tested a biomimetic design based on the architectural arrangement of bone, which provides a porous core for bone ingrowth and a dense external layer resisting fibrous tissue ingrowth. Biomimetic bone constructs were made of a composition of poly(ε-caprolactone) and β-tricalcium phosphate (PCL/TCP) and fabricated on the Integrated Tissue-Organ Printing (ITOP) system. The osteoconductivity of this PCL/TCP bone constructs was confirmed by in vitro osteogenic differentiation using human placental stem cells (hPSCs). We also examined this biomimetic bone construct in a critically sized mandibular bony defect of rabbits. The results showed the increased bone density and volume and new bone formation and maturation with time. Our finding suggests that bone regeneration could be enhanced by the biomimetic bone construct designed to minimize competing for fibrotic tissue forming in the bony defect. We demonstrated the concept that patient-specific anatomy could be translated to 3D bioprinting strategy through medical imaging and image processing software with strong clinical relevance.

One of the challenges in 3D bioprinting is finding an appropriate bioink that provides a tissue-specific microenvironment supporting the cellular growth and maturation. Accordingly, decellularized extracellular matrix (dECM)-derived hydrogels have been proposed as bioinks for the cell-based bioprinting due to their capability to inherit the intrinsic cues from native ECM. In this study, we developed a photo-crosslinkable kidney ECM-derived bioink (KdECMMA) that could provide a kidney-specific microenvironment for renal tissue bioprinting. Porcine whole kidneys were decellularized through a perfusion method, dissolved in an acid solution, and chemically modified by methacrylation. This KdECMMA-based bioink was formulated and evaluated for rheological properties and printability for the printing process. Afterward, the bioprinted cell-laden constructs were implanted in the kidneys of nude rats for subsequent analysis. The results showed that the bioprinted human kidney cells in the KdECMMA bioink were highly viable and matured with time. Moreover, the bioprinted renal constructs exhibited the structural and functional characteristics of the native renal tissue. We demonstrated the potential of the tissue-specific ECM-derived bioink for cell-based bioprinting that could enhance cellular maturation and eventually tissue formation.

Abstract **#1684**

AN EXTRUSION-BASED BIOINK ARTIFACT FOR QUANTIFYING PRINTABILITY AND AN EXPLORATORY ANALYSIS ON ITS RELATIONSHIPS WITH RHEOLOGICAL PROPERTIES

Corresponding author's email: sjlee@wakehealth.edu

The limited availability of bioinks is a key limitation to bioprinting technology. Meanwhile, the bioink development process itself is limited by the methods for assessing printability and a poor understanding of how rheological factors influence printing outcomes. An extrusion bioink-specific artifact has been developed to increase the quantification, comprehensiveness, and standardization of printability assessment. This exploratory study aims to validate the artifact and utilize it to relate various bioink candidates and their rheological properties to their printability. The artifact was designed according to criteria previously established by other 3D printing modalities. Various hydrogels as bioinks were tested on the artifact and rheologically. Measures from the artifact and image analysis aligned well with expected ranges and relative values. Rheologically, the high-performing bioinks demonstrated high storage modulus, low tan(δ), high shear-thinning capabilities, high yield stress, and recovery abilities which were both fast and near-complete. However, no rheological measure alone was correlated with the differences in printability between the various bioinks. In addition to presenting a novel methodology, these results demonstrate the need to take a holistic view of a bioink's rheological properties and the importance of measuring printing outcomes directly.

To achieve rapid skeletal muscle function restoration, many attempts have been made to bioengineer functional muscle constructs by applying physical, biochemical, or biological cues. Here, we develop a self-aligned skeletal muscle construct by printing a photo-crosslinkable skeletal muscle ECM (dECM-MA) bioink containing human muscle progenitor cells (hMPCs). To induce the self-alignment of hMPCs in the printed constructs, in situ uniaxially aligned micro-topographical structure is produced by a fibrillation/leaching of poly(vinyl alcohol) (PVA). The in vitro results demonstrated that the synergistic effect of tissue-specific biochemical and topographical cues improve the myogenic differentiation of the printed hMPCs with cellular alignment. This self-aligned muscle construct shows the accelerated integration with neural network and vascular ingrowth in a rodent model of muscle defect injury, resulting in rapid restoration of muscle function. We demonstrate that combined biochemical and topographic cues on the 3D bioprinted skeletal muscle constructs can effectively reconstruct the extensive muscle defect injuries.

clinical need for the development of functional vascular substitutes. In this study, we aimed to develop a biofunctional electrospun vascular scaffold by chemically conjugating antibody and anti-thrombogenic agent. We hypothesized that multiple bioconjugation of endothelial cell (EC)-specific antibodies and anti-thrombogenic agents onto the vascular scaffold could facilitate in situ endothelialization while preventing blood clotting. To achieve this goal, bioconjugation parameters on a vascular scaffold was optimized to provide proper biological properties and structural configuration that enhanced cellular interactions of ECs on the lumen. This biofunctional vascular scaffold was validated in a sheep carotid arterial interposition model. The implanted scaffolds were followed by an ultrasound to evaluate the vessel diameter, as well as patency quantitatively. In vivo experiment showed that these vascular scaffolds maintained a high degree of patency and structural integrity and produced the matured EC coverage. We demonstrated that the generation of the biofunctional vascular scaffold, along with directed immobilization of bioactive molecules, could provide the necessary components for successful vascular tissue engineering applications.

Skin models are used in the evaluation of efficacy and safety of active compounds and drugs in cosmetic and pharmaceutical research, especially after the ban of the animal testing in cosmetics research in 2013 [1-3]. Many advances have been made in skin engineering but challenges still exist for constructing thick or complex tissues with all in vivo functions [4]. One of the main challenges is vascularization. Given that the diffusion coefficient of oxygen is limited to 200µm in human tissues, skin constructs thicker than 200 µm have a diffusion limitation [5, 6].Therefore, developing perfusable vascular networks is mandatory to improve the functionality and viability of skin grafts as well as the relevance of in vitro applications. To address this issue, our study focused on the development of a perfusable vascularized full thickness skin equivalent with more complex vasculature than existing models. We here combined molding, auto-assembly and microfluidics techniques in order to produce a skin equivalent that recapitulates a mature epidermis, a complex microvascular network and three vascular channels with angiogenic sprouts required for the perfusion of the reconstruct. We then evaluated skin permeability to compounds with different chemical properties and systemic delivery of the Benzo[a]pyrene pollutant. Our results demonstrated that perfusion of the vascular plexus resulted in a more predictive and reliable model in order to assess both topical and systemic applications. This model is therefore aimed at furthering drug discovery and improving clinical translation in dermatology.

Despite special advances in regenerative medicine, wound healing is a challenging medical problem. The skin is the largest organ in the human body that has essential and important functions, so any damage to its normal structure should be treated as soon as possible. Easy access to skin stem cells has received a great deal of attention in its therapeutic applications. Cell therapy is a new method in restorative medicine, especially when old therapies have disappeared. Candidate populations for therapeutic applications include mesenchymal stem cells, hair follicle stem cells, and pluripotent cells. Hair follicle bulge stem cells with scaffold and growth factors can improve wound healing.

Materials and methods: In this study PCL/SSD, PCL/Coll as two -layered nanofibrous mat were designed with electrospinning. Bulge stem cells were isolated from rat vibrissa and cultured on two – layered nanofibrous mat with nanoparticles containing EGF and bFGF as growth factors. Nanoparticles containing EGF and bFGF were made with ionic gelation processes. EGF and bFGF release were analyzed with human EGF and bFGF Quntikine human ELIZA kit. Bulge stem cells were analyzed with Immunocytochemistry and flow cytometry. These cells were tracked with CM-Dill 7000C. Tracked cells were seeded on nanofibrous mat and grafted to rat skin. The healing process was evaluated with macroscopic observation on 7,14,21 and 28 days' post wounding. Hematoxylin - eosin and Trichromasons staining was done to evaluate tissue remodeling and collagen synthesis. Real time PCR analysis performed to assess gene expression after 14 days of treatment.

THE BIOLOGICAL FUNCTIONS OF SMALL WORLD NEURONAL NETWORKS

Francesco Gentile[P][1]

[1] *University Magna Graecia of Catanzaro*

Corresponding author's email: francesco.gentile77@gmail.com

Neuronal cells are the smallest building blocks of the central and peripheral nervous systems. Information in neural networks and cell-substrate interactions have been heretofore studied separately. Understanding whether surface nanotopography can enhance the computational efficiency of neuronal networks may yield to decipher the brain's code, and provide new tools for a better understanding of neuro-degeneration and cell clustering. Here, we recapitulate recent studies of cell behavior at the region of contact between the cell with nanomaterials. Using functional, multi-calcium imaging techniques, and information theory approaches, these studies (1-4) have illustrated that for certain configurations of the nanomaterials and of the topography of the biointerface, neuronal cells form networks with small world characteristics. Small world networks feature high clustering and short paths between the cells of the networks: in small world networks, information is transported more efficiently than in equivalent random or periodic networks of the same size. Moreover, research also displayed that the maximum cluster size in those networks is of approximately 200 neurons. This value - resulting from the competition between the binding energy of cells with other cells and the substrate, and the kinetic energy of the system - is notably similar to the number found in the cortical minicolumns, i.e. the elementary computational units of the cerebral cortex. Results led us to formulate a biological principle of equivalence, i.e. the hypothesis that neurons evolve to form structures with a topology that minimizes energy and maximizes information.

IN VIVO TRACKING OF THE IMMUNE RESPONSE TO ECM BIOSCAFFOLDS

Mike Modo[P][1]

[1] *University of Pittsburgh*

Corresponding author's email: mmm154@pitt.edu

Magnetic resonance imaging (MRI)-based guidance of extracellular matrix (ECM) hydrogel affords its implantation into a tissue cavity caused by a stroke. A major immune response occurs that leads to the biodegradation of the implanted hydrogel and a reconstitution of brain tissue ensues (2). To improve our understanding of the spatio-temporal dynamics of the immune cell infiltration into ECM hydrogel, we used 19F MR imaging to trace immune cells that were systemically labeled using perfluorcarbon (PFC) nanoemulsions. Using this approach the invasion of peripheral immune cells into peri-infarct stroke tissue was evident by 6 hours post-ECM implantation. Cell invasion into the ECM bioscaffold was observed 9 hours and a peak signal at 18 hours post-implantation. The 19F signal in the ECM hydrogel slightly decreased by 24 hours. Histological investigations of tissue revealed a strong infiltration of neutrophils into the ECM hydrogel at 24 hours, as well as macrophages. No lymphocytes were observed at this time point. Almost all neutrophils and macrophages contained PFC indicating that these were the source of the 19F MR signal. 19F MRI combined with PFC nano emulsions therefore provide a unique tool to assay the spatio-temporal response of immune cells to ECM hydrogel implantation.

The application of Amniotic Membrane (AM) in chronic wounds has proven very successful at resetting wound healing, in particular re-epithelialization. TGF-ß plays a very important role at the wound healing process and alteration of its expression may end up in a chronification of the wound, thus impeding its natural healing. When applied on epithelial cells, AM activates several important signaling pathways required for migration and proliferation. Importantly, we have seen that AM exert a fine control on TGFß signaling pathway. To investigate AM molecular mechanisms behind its effect, we used cryopreserved AM on HaCaT´s wound healing scratch assay. In parallel, we measured the expression of important cell migration proteins at the wound healing front of HaCaT´s scratch assays. An important effect of AM in the cytoskeleton and focal adhesions restructuring was detected. The AM control of TGF-ß managed cell proliferation together with its stimulatory effect on cell migration could explain AM positive effect into wounds re-epithelialization. The chronic wound environment has been mimicked by long term TGFß-stimulation in the absence of serum of HaCaT cells. In this TGF ß chronified keratinocytes, the presence of AM produces a clear improvement of several issues related with successful wound healing. Amniotic membrane is a successful agent at healing complicated wounds, thus the precise knowledge of the molecular mechanisms involved on the phenomena will allow us to improve its application and to look for efficacious AM-based cell-based alternatives for future therapeutic application.

Diabetes foot ulcer (DFU) is a severe diabetes complication which affects 15% of patients with advanced stages of the disease. Despite improvements in the treatment, DFU remains the main causes of amputation of the lower limb. Furthermore, one of the most relevant diabetic wounds healing issues is the reduced peripheral blood flow and the diminished neovascularization. Amniotic membrane (AM) has shown promising results in the treatment of DFU. Here, the potential role of AM on endothelial cells isolated from umbilical cords of gestational diabetes affected women (GD-HUVECs) have been investigated. Indeed, GD-HUVECs have shown reduced migration capacity and decreased vessels formation on Matrigel compared to control HUVECs, thus representing a useful model for studying the role of AM in the neovascularization of chronic non-healing wounds. Hence, GD-HUVECs cell migration and tube formation ability were evaluated in the presence of AM. Moreover, the anti-inflammatory properties of AM have been assessed using a monocyte-endothelium interaction assay stimulated with TNF-a. Results showed that AM treatment significantly improved cell migration and vessel formation in GD-HUVECs. Strikingly, AM significantly reduced TNF-a stimulated monocyte-endothelium interaction and the membrane exposure of the endothelial adhesion molecules VCAM-1 and ICAM 1 in C- and GD-HUVECs. These results suggest that AM improves chronic wounds healing by both enhancing angiogenesis and decreasing inflammation, thus reinforcing its clinical applications for diabetic foot ulcers. Additional preliminary data would be presented on the effect of oleanolic acid on the improvement of tubule formation assay on GD-HUVECs.

Natural triterpenoids, particularly oleanolic acid (OA), have shown wound healing benefits. To understand OA effect on wounds, we have studied OA-triggered molecular mechanisms in two epithelial cell lines: Mv1Lu and MDA-MB-231, by using in vitro wound healing scratch assays. Besides these, we have studied pro-migratory proteins expression and its subcellular localization. Epithelial cells migration is essential for wound closure and rely on key regulator proteins. In this sense, we have shown that OA induces the activation, at cells of the wound edge, of c-Jun; a master regulator of migration. On top of that, cell migration is mediated by dynamic changes in cell architecture: cytoskeleton reorganization and focal adhesion (FA) remodeling. Thus, we have shown that OA activates focal adhesion kinase (FAK), a critical factor for FA remodeling, and also the reorganization of paxillin and actin, indicating that OA promotes a remodeling of the cell architecture. In addition, we have performed scratch assays in human fibroblasts, which are involved in tissue remodeling during wound healing. Similarly, OA enhances fibroblast migration. Due to its lipophilic nature, OA delivery to cells is difficult. Cyclodextrins are well-known to improve lipophilic molecule solubility and bioavailability, so we have created OA/cyclodextrin complexes to test them in migration assays. Strikingly, we have shown that these complexes facilitate OA in vitro use and enhance its cell migration properties. All these results encourage us to pursue on OA/cyclodextrins as a way of improving OA application in wounds.

Nowadays, the assessment of the mechanical competence of tissue engineering scaffolds based on computer simulations is a well-accepted technology. Typically, such simulations are performed by means of the Finite Element (FE) method, with the underlying structural model being created based on micro-computed tomography (microCT). Here, this analysis modality is applied to a new, ternary composite, consisting of PHBV, poly(3-hydroxybutyrate-co-3-hydroxyvalerate), PLGA, poly(lactic-co-glycolide), and TCP, tricalcium phosphate hydrate. The studied scaffold structure is made up by fibers of this new composite material, manufactured by means of the rapid prototyping method. The data collected from microCT is utilized for adequately defining the mechanical properties of the FE model. In particular, the three-dimensional field of grey values is interpreted in terms of the underlying field of attenuation coefficients, taking into account the photon energy employed in microCT imaging. For the sake of keeping the FE simulations as efficient as possible, groups of voxels are combined into one finite element; the grey value of the latter is obtained by volume averaging. Employing a two-step micromechanical homogenization scheme, the experimentally accessible stiffness of the three constituents is then, finite element by finite element, upscaled to the composition-dependent stiffness of the composite material. The plausibility and adequacy of the FE model is demonstrated by simulating the effects of uniaxial compression on the scaffold structure, in terms of resulting stress and strain fields, highlighting the importance of the fiber junctions, and that neglecting the material heterogeneity would lead to a potentially significant underestimation of stresses and strains.

COMMERCIAL TRANSLATION FROM LAB TO TRADE SALE

Anthony S Weiss[P][1]

[1] *University of Sydney*

Corresponding author's email: *tony.weiss@sydney.edu.au*

We discovered how to assemble tropoelastin into synthetic elastin biomaterials that accelerate and improve the repair of scars and wounds. This work over two decades has led to a dominant position, and the patented biomaterials inventions recently led to one of the largest commercial transactions in regional healthcare history. The company completed in-depth primary market research which demonstrated the potential for bio-based TE products to address unmet, high-value market demand across multiple applications. The company also scaled production from lab to Good Manufacturing Practice, and successfully completed multiple clinical trials for injectables that enhance skin repair, including local damage and scars (1, 2, 3, 4). This strong position attracted a range of commercial suitors and the company was sold to a large biopharmaceutical company.

BUILDING AND REPAIRING ELASTIC TISSUES

Anthony S Weiss[P][1]

[1] *University of Sydney*

Corresponding author's email: tony.weiss@sydney.edu.au

Elastic fibers are integral components of the resilient extracellular matrix. They provide the structural support and elastic recoil required for the continuous mechanical stretching and recovery of soft force-bearing tissues with durability and persistence. They are made using a protein intermediate that possesses a structure that is organized enough for assembly but flexible enough to confer elasticity. This tightly controlled hierarchical process delivers versatile materials that are used for in vitro building of three dimensional elastic materials, in vivo tissue assembly and repair, and unique hybrid materials. Elastin's properties have made it an attractive candidate for incorporation into biomaterials for a range of applications in regenerative medicine. This presentation will summarize recent advances in understanding how the sequence and structure of elastin influence the processes that govern the functionality of elastin and its derivatives, and describe innovations in harnessing these mechanisms to create tunable elastin-based biomaterials (1, 2, 3, 4, 5).

Introduction: Hepatocellular carcinoma (HCC) is most common liver cancer and presents poor prognosis. Human amniotic membrane (hAM) has interesting anti-tumor properties. We previously showed that hAM extract (hAME) leads to anti-tumor effects on HCC. We aimed to assess effects of hAME fractions (protein/lipidic) and thermal denaturation on HCC cells.

Methods: Fractionation was performed through ammonium sulphate (AS) precipitation by sequentially adding 10%, 25% and 50% AS to hAME, on ice, 15min, centrifuged at 14000 G, 15 min. Precipitated fractions (10P/25P/50P) were resuspended on PBS; soluble fractions (10S/25S/50S) were submitted to salting out with PBS by centrifugation (4000G, 60 min), on VivaSpin® tubes (30 kDa cutoff). Lipid isolation was performed by Folch method (chloroform:methanol (2:1), two extraction steps and solvent evaporation on vacuum). hAME thermal denaturation was performed at 100ºC, 5min. HepG2, Hep3B and HuH7.sil cells were incubated with total hAME, fractions, thermal denaturated hAME and isolated lipids (1µg/µL), for 72h. Metabolic activity was accessed by MTT assay.

Results: Results showed decreased metabolic activity of HCC cells incubated with hAME, compared to control (HepG2: 57.07±9.26; Hep3B: 50.66±9.78; HuH7.sil: 58.16±6.05). Protein fractions induced a lower metabolic activity (2 to 30%, cell line-dependent) compared to total hAME. Incubation with isolated lipids decreased metabolic activity of HCC cells, compared to control and total hAME. Thermal denaturation partially inhibited effects of total hAME.

Conclusions: These findings indicate that both proteins and lipids could have an important role on hAME induced anti-tumor activity.

We have studied initiator free, UV-controlled self-initiated photografting and photopolymerization reaction on glass substrates. By combining surface chemical modifications and 2-hydroxyethyl methacrylate, PEG methacrylate and methacrylic acid monomers we determined the conditions for efficient synthesis that we monitored by employing a set of surface analysis techniques. Furthermore, we studied the swelling behaviour of the resulting hydrogel coatings (HPMAA) [1]. Also, we microfabricated and characterized fibronectin (FN) patterns on such coatings aiming at efficient mimetics of the extracellular matrix. The resulting glass-supported HPMAA layers performed as reliable substrates for microfabrication of covalently bound FN patterns for controlled cell adhesion. The obtained FN patterns consisted of densely packed protein molecules. They maintained the structural integrity upon HPMAA swelling. Finally, we evaluated the applicability of the synthesized HPMAA hydrogel coatings as substrates for fabrication of tissue-on-a-chip modelling systems using human corneal epithelial cells and human skin fibroblasts. Our study paves the way to new solutions toward efficient tissue mimetics and engineering that are compatible with the state-of-the-art microscopy techniques.

Mesenchymal stromal/stem cells (MSCs) have reported therapeutic efficacy for bone repair in animal and clinical studies. Although the therapeutic effects of MSCs were originally predicated on the differentiation potential of these cells, it is now widely accepted that MSCs mediate tissue repair through the secretion of trophic factors, particularly 50-200nm small extracellular vesicles (sEVs) which include exosomes. In this study, we investigated the therapeutic effects of MSC-sEVs loaded in collagen sponge for regeneration of critical-size bone defects in an immunocompetent rat calvaria defect model. We observed that sEV-mediated repair of critical-size bone defects was characterized by increased cellular proliferation and infiltration, enhanced vascularization and mineralization, and a regenerative immune phenotype. Specifically, defects treated with MSC-sEVs displayed a regenerative immune phenotype characterized by a higher infiltration of CD206+ regenerative M2 macrophages over CD86+ pro-inflammatory M1 macrophages, with a concomitant reduction in pro-inflammatory IL-1β+ and TNF-α+ cells. To gain insights to the cellular processes activated by MSC-sEVs during bone repair, cell culture studies utilizing MSCs, endothelial cells and macrophages were performed. We observed that addition of MSC-sEVs accelerated osteogenic mineralization of MSCs and promoted angiogenic tube formation of endothelial cells in a dose-dependent manner. Furthermore, addition of MSC-sEVs to macrophages enhanced M2 macrophage polarization while suppressing M1 macrophage polarization. Together, these findings demonstrated that MSC-sEVs work through a multi-faceted mechanism of action to promote bone regeneration.

Numerous reports in the literature demonstrate reparative benefits of stem cells. Obstacles to widespread clinical stem cell usage include regulatory and sourcing of stem cells. Moreover, harvesting, processing and application of stem cells have inconsistencies. Overcoming many of these challenges could be achieved if a mechanism to stimulate in vivo stem cell release were developed. In the mid 1980's, shock wave therapy(SWT) was invented in Germany to treat gallstones noninvasively. SWT soon found application for kidney stones as well, commonly referred to today as lithotripsy. Over the past 35 years, the clinical indications for SWT have expanded. The purpose of this paper is to present the SWT stem cell basic science data that has been obtained and to demonstrate clinical examples of soft tissue success with SWT in an orthopaedic practice

ANTI-BIOFILM THERAPIES IN DENTISTRY

Hamdan Alghamdi[P][1]

[1] *Department of Periodontics and Community Dentistry, College of Dentistry, King Saud University, Riyadh, Saudi Arabia*

Corresponding author's email: dalghamdi@ksu.edu.sa

In fact, oral diseases are the collective effect of the bacteria community in the dental biofilm. Nutritional synergy between bacteria can be seen in the development of dental biofilm. Dental biofilms are well implicated in dental/oral chronic infections. Biofilms are multicellular communities of microbial organisms embedded in extracellular polymeric matrix that forms the 3D scaffold of biofilm and is responsible for adhesion to surfaces. A cell–cell communication mechanism, called quorum sensing (QS), plays an important role in biofilm formation. The microbial organisms could disperse from the biofilm to find new niches and initiate new biofilm formation (i.e. biofilm life cycle).

Therefore, it is still demanding to discover new therapies that can dysregulate biofilm formation and development. The strategies of anti-biofilm therapies should target on each step of biofilm development, including the inhibition of microbial attachment, disturbing polymeric matrix generation, and interruption of QS signaling.

Recently, several therapeutic strategies have been proposed to combat dental biofilms. One is the inhibition of bacterial adhesion to dental surfaces. Therefore, it is important to consider the physical structural organization of multispecies biofilm from physical point of view.

Second, extensive efforts have been made to develop dental biomaterials with control-releasing antimicrobial property.

This presentation will summarize recent scientific knowledge on the recent ingredients and substances with clear-cut anti-biofilm properties. Besides, anti-biofilm therapeutic strategies undergoing clinical trials are highlighted.

3D PRINTING OF NANOCOMPOSITE HYDROGELS/POLYMERS FOR LOCAL DRUG DELIVERY APPLICATIONS

Nermin Seda Kehr$_P$[1]

[1] *WWU Münster*

Corresponding author's email: seda@uni-muenster.de

Injectable hydrogels/polymers have received considerable interest in the biomedical field due to their potential applications in minimally invasive local drug delivery, more precise implantation, and site-specific drug delivery into poorly reachable tissue sites and into interface tissues, where wound healing takes a long time.[1] Furthermore, injectable hydrogels/polymers are important for improving the efficiency of cancer treatment: They can provide site-specific delivery of chemotherapeutics into cancer tissue and, thus, limit the potential circulation of the chemotherapeutics in the body, thereby reducing the toxic side effects of chemotherapeutics to healthy tissues.[2]
In this context, we described injectable hydrogels/polymers made of stimuli responsive nanomaterials.[2,3] The prepared biomaterials were used to generate multifunctional 3D NC scaffolds via by 3D printing technique and used for cell- or bacteria-biomaterial interaction studies. Our results showed that the 3D printed NC scaffolds provide sustained and pH-responsive release of drug molecules that improved cell adhesion and inhibited bacterial growth on the NC scaffolds surfaces.[3] Furthermore, 3D NC scaffolds inhibit the growth of cancer cells, while improve the viability of healthy cells.[2]

Intra-articular (IA) injection is an attractive route of administration for the treatment of osteoarthritis (OA). However, free drugs injected into the joint space are subjected to clearance mechanisms, which reduce their IA retention time. Additionally, several drug candidates can induce adverse off-target effects on different IA tissues. To overcome these limitations, here we propose the use of tissue-binding, nano-composite microgels as IA small molecule drug delivery vehicles. Micron-scale poly(ethylene glycol) (PEG) hydrogels, presenting cartilage- or synoviocyte-binding peptides and containing small molecule-loaded poly(lactic-co-glycolic) acid (PLGA) nanoparticles (NPs) were synthesized using microfluidics technology. Microgels loaded with a model small molecule (rhodamine B) exhibited a sustained, near-zero order release over 16 days. Additionally, PEG microgels conjugated with synoviocyte- or cartilage-targeting peptides, presented specific binding to rabbit and human synoviocytes, and to bovine articular cartilage in vitro, respectively. Using a rat model of knee OA, microgels were shown to be retained in the IA space for at least 3 weeks and did not induce detectable joint degenerative changes as measured by EPIC-µCT and histology. Finally, histological analysis demonstrated that all microgel formulations get trapped within the synovial membrane and significantly increase the IA retention time of a model small molecule near infra-red dye in vivo. Overall, these results suggest that nano-composite PEG microgels presenting tissue-binding peptides could be a promising strategy to achieve tissue-localized drug delivery and prolonged IA retention of small molecule drugs for OA treatment.

Cardiac tissue engineering (CTE) is the in vitro creation of functional heart tissue that can elucidate tissue development, disease progression, pharmaceutical efficacy, or be implanted to replace lost heart functioning [1, 2]. Three-dimensional (3D) scaffolds are often used as a template for cardiomyocytes (heart muscle cells) to form cardiac tissue. However, more active supports may be required as current methods are unable to engineer tissue that is representative of endogenous myocardium [3, 4].

In this project, flexible, porous, biocompatible micro-bioelectronic meshes were combined within a traditional CTE arrangement of hydrogel and cardiomyocytes. Embedding the mesh allows for the seamless incorporation of electronic components within the engineered cardiac tissue. Such components include flexible electrodes and the provision of electrical stimulation (ES), which is a proven method of influencing cell alignment, contractility, and maturation [5]. While integrated biosensors can achieve extensive monitoring by detecting cell impedance and electrophysiology, allowing for a valuable understanding of the tissue being created [6, 7].

The biomimetic design of the electronic devices allows for the efficient diffusion of oxygen, nutrients, and metabolic waste as well as the movement and penetration of heart cells for more reliable cardiac tissue growth [8]. The introduction of flexible mesh bioelectronics within CTE methods allows for an intimate interaction with cardiac cells, monitoring capabilities, and the regulation of tissue formation. Such additions could overcome current limitations and produce physiologically relevant cardiac tissue that has the potential to be used in both research and implantation.

Preclinical assessment of novel therapies to fight cancer requires models that reflect the human physiology and immune response. While two-dimensional (2D) cultures lack tissue context, animal models poorly predict human immune responses, with the result that potential new drugs fail in the clinical setting. Here, we established an in vitro three-dimensional (3D) reconstructed organotypic human melanoma-in-skin (Mel-RhS) model to investigate tumor formation and progression over a six week period. Tumor nests were observed to develop over time and to spread towards the dermis, disrupting the basement membrane. This coincided with the secretion of matrix metalloprotease 9 (MMP-9) by melanoma cells. These features resemble the initial stages of invasive melanoma. Interestingly, while interleukin-10 (IL-10) could not be detected in monolayers of the employed SK-MEL-28 melanoma cell line, the cellular cross-talk in the 3D model led to IL-10 expression by the melanoma cells, as well as by the surrounding keratinocytes and fibroblasts. Indeed, culture supernatants from Mel-RhS interfered with monocyte-to-dendritic-cell differentiation, leading to the development of M2-like macrophages, which was partly prevented upon antibody-mediated IL-10 blockade. Thus, the 3D configuration of the Mel-RhS model revealed a role for IL-10 in immune escape through misdirected myeloid differentiation, demonstrating the potential of the Mel-RhS in research on melanoma development and invasion in the setting of an immune competent model.

Chemically modified messenger RNA-Lipid nanoparticles (cmRNA-LNP) represents a powerful tool not only for vaccine applications but also in regenerative medicine. Gene Activated Matrices (GAM), consisting in biomaterial formulations containing cmRNA-vector have been proposed to serve as support to transfect the colonizing cells and ensure localization of the cmRNA in the tissue to be regenerated. Despite the RNA chemical modification increases its in vivo stability, vectors or delivery vehicles are still required for efficient transfection and optimal pharmacokinetic in vivo. Thus, nanomaterials that can protect efficiently cmRNA and facilitate its uptake would be of great help in regenerative therapy. The goal of the project is to design, screen, study and select a lipid-based transfection reagent that will represent the best vector for cmRNA delivery in vivo. For this purpose, Ethris has designed and developed stable and efficient cmRNAs while OZB has screened a library of lipid-based transfection reagents for their capacity to complex cmRNA, protect and release it within hydrogels. A screening was performed by mixing cmRNA with the different novel synthesized lipids while LNPs were formed using a microfluidics technology. The five top reagents have been extensively characterized for their physicochemical properties (size, charge), complexation, release capacities and transfection efficiency. We show that high quality cmRNA together with our best candidates offer a highly relevant system for GAM-mediated hMSCs transfection. Their capacity to modulate vascularization, innervation and osteogenesis in vivo will be further studied.

The subacromial bursa is an important friction-reducing structure in the shoulder joint, but knowledge regarding the mechanical competence of bursa tissue is missing. Therefore, the study aimed to investigate how bursa-derived cells respond to physiological and pathological loading regimes.

Bursa-derived cells were stimulated over 3 days for 1h or 4h with 1%, 5%, or 10% strain on collagen-coated silicon dishes. Orientation of actin cytoskeleton, YAP nuclear translocation and activation of non-muscle myosin II (NMM-II) was evaluated for 4h-stimulations to investigate mechano-transduction processes. After 1 and 4h, cell viability, gene expression of Integrin A1/A2, Collagen I/III, Versican, Fibromodulin, MMP1/2/3, TIMP1/2 and protein secretions were analyzed.

With higher loading, the orientation angle of the actin cytoskeleton significantly increased towards a perpendicular direction. The lowest variations in orientation occurred for the 5% loading group. With pathological loading (10%), cells showed a loss in actin density and a slightly reduced cell viability. A significantly increased YAP nuclear translocation was observed for the 1% loading group with a similar trend for the 5% group. NMM-II activation was weak for all conditions. On gene expression level, only the TIMP2 expression was significantly decreased in the 1h group compared to control. Collagen I and MMP2 protein secretion significantly increased with pathological loading, whereas TIMP1 secretion was significantly reduced leading to an MMP/TIMP imbalance.

This study documents for the first time a clear mechano-responsiveness of bursa-derived cells with specific reactions to physiological and pathological loading conditions. This hints to a physiological function of mechanical loading in bursa-derived cells.

Drainage tube or trabeculectomy surgeries in late-stage glaucoma remains troubled by post-operative inflammation and fibrosis. Current approaches to remedy this rely on administration of anti-metabolites (mitomycin C) and an intensive course of patient-administered corticosteroid drops. These present their own issues, particularly adverse side-effects and poor patient compliance. Therefore, we describe a proteoglycan (PG)-modified hyaluronic acid (HyA) drug-device that aims to address post-surgical inflammation and remove patient compliance issues.Hydrogels were assessed for crosslinking, swelling, degradation and insertion into cadaveric rabbit eyes. The innate ability of the modified gels to reduce collagen deposition in the absence of drugs was tested using primary human conjunctival fibroblasts stimulated with Transforming Growth Factor-Beta (TGF-β). The device was further enhanced using prednisolone drug loading with release assessed over 28 days and efficacy evaluated in a chick embryo model.Hydrogels were capable of rapid swelling, stability up to 4 weeks and enzymatic degradation. The device was easily implanted using standard surgical tools. In vitro analysis using drug-free, PG-HyA gels in TGF-β stimulated conjunctival fibroblasts demonstrated a reduction to normal collagen levels at 24 hours. Release of prednisolone from gel composites were found to exhibit a biphasic release with burst release over 72 hours and sustained release up to 28 days. Furthermore, this was found to effectively inhibit angiogenesis at 5 days ex-vivo. This work demonstrates proof of concept validation for a straightforward solution to a long running issue in glaucoma. Work now focuses on pre-clinical studies.Supported by Science Foundation Ireland:17/TIDA/5098. Enterprise Ireland: CF-2019-0764Y and CF-2020-1336

The reconstruction of large bone defects (> 5 cm3) remains a challenge for clinicians. To address this challenge, we developed a new critical-size mandibular bone defect model on mini-pigs (12 cm3), close to human clinical issues. We analyzed the bone reconstruction obtained from a 3D-printed scaffold made of clinical-grade PLA, coated with a polyelectrolyte film delivering an osteogenic bioactive molecule (BMP-2) at different doses (20, 50 and 110 µg/cm3 of scaffold, corresponding to 0.02-0.08 mg/mL). We compared the results of new bone quality and quantity using CT-scans, µCT, and histology to what is obtained with the gold standard solution, bone autograft. We proved that the dose of BMP-2 delivered from the scaffold through the polyelectrolyte film significantly influenced the amount of regenerated bone, its mineralization, and the repair kinetics, with a clear BMP-2 dose-dependence. Furthermore, bone was homogeneously formed inside the scaffold with little ectopic bone formation, independently of the BMP-2 dose used. Bone repair was as good as for the bone autograft. The BMP-2 doses applied in our study were reduced 20 to 75-fold compared to the commercial collagen sponges currently used in the clinical applications (dose of 1.5 mg/mL), without any adverse effects. 3D-printed PLA scaffolds combined with 2D biomimetic polyelectrolyte films and loaded with reduced doses of BMP-2 thus open perspectives in personalized medicine, since 3D-printing allows the customization of the scaffolds shape and the biomimetic film allows the controlled delivery of BMP-2 in space and time.

ENGINEERING A NOVEL IN VITRO MODEL OF THE BLOOD BRAIN BARRIER

Christina Schofield$_P$[1], Aleixandre Rodrigo-Navarro[1], Tom van Agtmael[2], Matt Dalby[1], Manuel Salmeron-Sanchez[1]

The blood-brain barrier (BBB) is a dynamic interface, regulating the movement of solutes, for example metabolites and drugs, between blood and brain. While the barrier is predominantly formed by the endothelial cells (ECs), these characteristics are not intrinsic to the cells and are induced by the relationships between the different cells which exist within the neurovascular unit (NVU). [1] Neither static nor dynamic in vitro BBB models fully capture in vivo-like conditions, and while coculturing EC monolayers with other NVU cell types has induced better barrier properties, the complexity of these culture conditions detracts from their usefulness for high-throughput drug discovery, testing, and disease modelling. Our proposed model utilises material-driven fibrillogenesis by PEA to present an EC monolayer grown on an electrospun PLLA membrane, which promotes the synergy of growth factor and integrin binding sites available on fibronectin (FN). While there are a handful of papers on electrospun-based BBB in vitro models [2] [3], we hypothesise that an effective in vitro model can be created with the use of key growth factors and EC monolayer grown on ECM protein coated PEA/PLLA electrospun membranes, which additionally provide a more flexible, biodegradable, and potentially thinner scaffold on which the ECs can grow.
We have demonstrated that this is a versatile, tuneable design capable of inducing barrier characteristics in both hiPSC and immortalised brain microvascular cells and have been able to show that different growth factor combinations, as well as protein coatings in combination with FN, are all capable of being incorporated.

HYBRID GLYCO-BIOMATERIALS ABLE TO MIMIC THE ECM MICROENVIRONMENT FOR 3D BIOPRINTED IN VITRO MODELS

Federica Barbugian$_P$[1]

[1] *Università degli studi di Milano Bicocca - Dipartimento di Biotecnologie e Bioscienze*

Corresponding author's email: f.barbugian@campus.unimib.it

Glycans are involved on cell fate modulation in physiological and pathological conditions. The intricate glycosignature at cellular and extracellular level is strongly involved in cell-cell and cell-ECM interactions that are at the basis of cell adhesion, spreading, differentiation and proliferation events [1]. The generation of glycoconjugate biopolymers to mimic ECM composition are a fascinating way to obtain tailorable in vitro systems able to replicate the cell microenvironment [2].
In this contest hyaluronic acid (HA) – a polysaccharide ubiquitous in ECM - represent a versatile platform for the development of tissue engineering and 3D advanced in vitro systems applications.
These different application perspectives are based on the possibility to fine-tune the physiochemical properties of the HA-based hydrogel by adjusting the concentration and degree of functionalization, resulting in tailored gelling behavior, viscosity, elasticity, mechanical strength, and also bioresponsiveness within biological systems. Here in this work, HA has been employed by conjugation with different ECM proteins taking advantage of linkers with different length and branching. The final goal of the project is to understand and test the biochemical and physical behavior of these different combinations in order to obtain a bioink as similar as possible to the ECM. Since we want to use these models for the study of brain tumor development, high-performance predictive screening, and the development of more effective drug therapies also their biocompatibility will be evaluated.

NANOSTRUCTURED SCAFFOLDS MIMICKING FUNCTIONAL MENISCUS EXTRACELLULAR MATRIX (ECM)

Federica Barbugian$_P$[1]

[1] *Università degli studi di Milano Bicocca - Dipartimento di Biotecnologie e Bioscienze*

Corresponding author's email: f.barbugian@campus.unimib.it

Meniscus injuries are the most common knee injury among athletes [1]. Despite many advances in orthopedic sports medicine, emerging data suggest that fewer and fewer athletes are able to return to sport at the same level as before their injury. In fact, many of them continue to develop arthrosis at a younger age.

With the present study we want to produce a living construct based on 3D bioprinted fibrous scaffolds, designed ad hoc for the patient, that can be implanted and integrated in damaged site for meniscal replacement.

In order to ensure a better re-vascularization, tissue remodeling and healing, one of the aspects to be taken into account for grafting and faster post-operative recovery is also the cellular component. For this reason, nanostructured will be loaded with patient-derived mesenchymal stromal cells (MSCs) [2].

The produced scaffolds will be obtained by functionalization and adsorption with ECM derived growth factors (GF) and bioadhesive motifs to facilitate pre-vascularization with different degrees of functionalization and release.

The ultimate goal of the project is to provide a construct (cellular and acellular constructs) that are able to recapitulate the full biomechanical properties, biological characteristics to replace the loss of native tissue. The final implantable construct will also have a degradation rate that allows proper regeneration of the structure and induce a chondro-protective effect [3].

We previously utilized 3D-Bioprinting to develop an in vitro model of the Outer Blood Retinal Barrier (OBRB). This model contains a fully-polarized retinal pigment epithelium (RPE) monolayer and an underlying dense capillary-bed resembling the choroidal vasculature. Using this OBRB model we replicated AMD-related pathological processes like choroidal neovascularization (CNV) and RPE-choroidal degeneration. The purpose of this study was to investigate the role of macrophages, a constituent cell type in the choroid, on vascular development and pathology by incorporating polarized human macrophages in this previously established model.

Endothelial cells, choroidal fibroblasts, and ocular pericytes were encapsulated in a collagen-derived gel and 3D-printed on a degradable scaffold to facilitate capillary formation. Induced pluripotent stem cell (iPSC)-RPEs were seeded on the apical side of the scaffold 7 days after bioprinting. Primary activated M1 (pro-inflammatory), M2(pro-angiogenic), and M1+M2 polarized macrophages were added to the tissue at the time of printing (day 0) or 28 days post printing.

Macrophages when added at day 0 as M1 or M2 single populations, or mixed populations of M1+M2, increased the speed of vascular maturation and also increased proangiogenic or inflammatory secretions. The greatest increase in maturation (described as length, width, and # of branch points) was achieved by combining macrophage subtypes, reflecting in-vivo behavior. Finally, macrophages were able to extend their lifespan to 3-4 weeks when embedded in tissues, as opposed to 7-10 days in 2D flasks. This 3D in vitro model may enable investigations into immune mechanisms influencing OBRB development in humans.

Tissue-engineered vascular graft for the reconstruction of small arteries is still an unmet clinical need, albeit a number of promising prototypes have entered the preclinical development. Here we tested poly(3-hydroxybutyrate-co-3-hydroxyvalerate)/poly(ε-caprolactone) 4 mm diameter vascular grafts equipped with vascular endothelial growth factor (VEGF), basic fibroblast growth factor (bFGF) and stromal cell-derived factor 1α (SDF-1α) and surface coated with heparin and iloprost (PHBV/PCL[VEGF-bFGF-SDF]Hep/Ilo, n = 8) in a sheep carotid artery interposition model, using biostable vascular prostheses of expanded poly(tetrafluoroethylene) (ePTFE, n = 5) as a control. Primary patency of PHBV/PCL[VEGF-bFGF-SDF]Hep/Ilo grafts was 62.5% (5/8) 24 hours postimplantation and 50% (4/8) 18 months postimplantation, while all (5/5) ePTFE conduits were occluded within the 24 hours after the surgery. At 18 months postimplantation, PHBV/PCL[VEGF-bFGF-SDF]Hep/Ilo grafts were completely resorbed and replaced by de novo vascular aneurysmatic tissue. Therefore, biodegradable PHBV/PCL[VEGF-bFGF-SDF]Hep/Ilo grafts showed better short- and long-term results than biostable ePTFE analogues, albeit these scaffolds must be reinforced for the efficient prevention of aneurysms.

Classical in vitro testing platforms for implantable biomaterials offer limited predictability of clinical performance, which presents a major challenge in implant development. While classical platforms facilitate the study of biomaterial-tissue interfaces using relevant cell types, the importance of the first interaction a biomaterial encounters in vivo, that with whole human blood, is often neglected. In the context of titanium (Ti) implant soft tissue integration, for dental applications, the aim of this study was to assess how the blood-biomaterial interaction influences the tissue healing response. Clinically available Ti implant surfaces (machined, SLA, and SLActive) were used to study the response of relevant soft tissue cells (human gingival fibroblasts, gingival keratinocytes and macrophages), with and without a pre-incubation step in blood. Findings show that, depending on their surface properties, including rough-ness (Sa), contact angle and micro/nanostructures, distinct fibrin networks formed on the Ti surfaces after incubation with blood. Generally, across all cell types, pre-incubation of the Ti surfaces with blood led to enhanced attachment, metabolic activity, proliferation and matrix production. Ti surface properties were a key determinant of inflammatory marker (TNFα, IL-6 and IL-8) production by macrophages and pre-incubation of the Ti surfaces with blood led to significant changes in their relative amounts. Collectively, these findings indicate that while material surface properties play a large role in determining the tissue healing response, the interaction between a biomaterial and whole human blood can significantly alter this response. In conclusion, this study highlights that blood-biomaterial interaction should be taken into ac-count during implant development.

The decrease of regenerative potential enhances the risk of postoperative liver failure. Standard clinical methods do not allow predicting the function of the remaining liver. Using modern label-free methods of multiphoton microscopy with the FLIM (fluorescence lifetime imaging) and SHG (second harmonic generation) it is possible to evaluate the metabolic state of hepatocytes during regeneration. In addition, time-of-flight secondary ion mass spectrometry (TOF-SIMS) provides information on the lipid and amino acid composition of the liver tissue.

The experiments were performed on Wistar rats weighing 400-500 g. Two models were selected- 70% parietal hepatectomy (PH) and 30% PH. Metabolic imaging was performed on 3th and 7th days after surgery. A separate analysis of NADH and NADPH was presented to evaluate the contribution of different metabolic pathways, as well as synthetic activity in hepatocytes. TOF-SIMS provide data on lipid composition of liver tissue.

As a result, a rise in the contribution of oxidative phosphorylation and biosynthetic processes in hepatocytes was shown, compensating energy consumption of hepatocytes during regeneration. Using TOF-SIMS it was shown an increase in the signal from fatty acids, sphingomyelin and cholesterol, in combination with a decrease in the signal from amino acid fragments.

The obtained parameters will be useful in determining the criteria for the intraoperative express assessment of the liver regenerative potential after surgery.

The work was supported by the Grant from the Russian Science Foundation №19-15-00263, and the Grant of the President of the Russian Federation MK-1649.2021.3. TOF-SIMS measurements were supported by Semenov FRCCP RAS CCE (no.506694).

Intervertebral disc (IVD) degeneration is associated with the loss of healthy matrix(1) and reduced osmolarity(2) within the nucleus pulposus (NP). Adjusting medium osmolarity represents a promising strategy for treating IVD degeneration since recent work demonstrated that increasing osmolarity during expansion exerted regenerative effects on human NP cells (NPCs) in vitro(3). Here, we investigated the effects of culture medium osmolarity on the identity and regenerative capacity of canine NPCs. Beagle NPCs were expanded in medium with standard osmolarity (300 mOsm/L) or adjusted to 400 or 500 mOsm/L. Following expansion, cells were re-differentiated for 14 days in 3D micro-aggregates (standard medium osmolarity). Osmolarity changes during cell expansion lead to changes in NPC morphology and growth rate, with cells expanded in 300 mOsm/L appearing more fibroblast-like, while at higher osmolarity the cells were sphere-shaped and at 500 mOsm/L showed a significantly decreased growth rate. At day 3 of the re-differentiation culture, micro-aggregates were harvested for gene expression analysis and NPCs expanded at 500 mOsm/L showed significantly increased expression of the osmolarity response gene NFAT5 and several NPC and progenitor markers (KRT18, CD73, CA12, FOXF1, ACAN) compared with NPCs expanded at 300 or 400 mOsm/L. Furthermore, expansion in 500 mOsm/L resulted in a significantly increased glycosaminoglycan and DNA content of the micro-aggregates compared to expansion at 400 mOsm/L, but not to 300 mOsm/L. In conclusion, expansion of NPCs in high osmolarity could have beneficial effects by selecting for a subpopulation of NPCs with a specific phenotype at the expense of the growth rate.

Low back pain due to intervertebral disc (IVD) degeneration is a major health and socioeconomic problem throughout the world(1). In the young and healthy IVD, large and vacuolated notochordal cells (NCs) are present(2). These cells are, in some species (e.g. humans(2) and dogs(3)), replaced by chondrocyte-like nucleus pulposus cells (NPCs) during maturation and ageing. In previous studies porcine NC-derived matrix (NCM) induced regenerative and anti-inflammatory effects in human and bovine NPCs in vitro and canine IVDs in vitro and in vivo(4,5). However, since the precise mechanism behind NCM remains elusive, the aim of this study was to determine the mode of action of NCM. For this, canine NPCs were cultured with and without NCM. Afterwards, targeted proteomics was performed using DigiWest technology and results were confirmed in in vivo canine IVDs treated with NCM. DigiWest analysis showed that NCM mainly induced changes in the Mitogen-activated protein kinase (MAPK) pathway. The expression of key proteins downstream the MAPK pathway was mostly inhibited by NCM, such as p-ERK1/2, p-JNK/SAPK, and p-PKC. The expression of proteins that are known to dephosphorylate MAPK key signalling molecules, DUSP5 and DUSP6 was increased in NCM-treated canine NPCs. Confirming the DigiWest results, in vivo canine IVDs treated twice with NCM demonstrated increased DUSP5 protein expression compared with control IVDs. Taken together, these results indicate that NCM exerts its anti-inflammatory effects by increasing nuclear DUSP5 expression, which inactivates and dephosphorylates pERK1/2 and pPKC and by directly inactivating pPKC. This subsequently leads to reduced expression of inflammatory cytokines.

Traditional methods to promote bone healing (e.g. autograft) and advanced therapeutics (e.g. recombinant human bone morphogenetic protein-2 [rhBMP-2]) have been associated with performance limitations and dose-related safety concerns, respectively. Thus, there is an unmet need for osteoinductive bone graft substitutes that can support bone healing using lower doses of rhBMP-2. This study aimed to determine the therapeutic efficacy of low dose (5 µg) rhBMP-2 for inducing bone formation using: a thermoresponsive hyaluronic acid hydrogel doped with gelatin and laminin (HyA-GL), a collagen-only (CO), and a collagen-hydroxyapatite (CHA) scaffold. Efficacy over 14 weeks was evaluated using 2 mm segmental femoral defects in skeletally mature female F344 rats, internally fixated using a 1.25 mm-thick polyetheretherketone plate. Empty defects failed to bridge but administration of rhBMP- 2 using either CO or CHA scaffolds led to successful bridging, while using HyA-GL resulted in non-union. CHA scaffolds induced enhanced and stiffer new bone formation compared to both CO and HyA-GL scaffolds. Limited luminal remodeling occurred in both CO and CHA groups. Taken together, this study has determined that the healing of weight-bearing femoral defects using low dose rhBMP-2 is achievable, while its efficacy is highly dependent on the biomaterial-based platform used for local delivery.

Corresponding author's email: akinola.akinbote@embl.es

Cardiovascular diseases (CVDs) are the single leading cause of deaths worldwide and are projected to be for the next 10 years. Owing to the high failure rates of bringing a drug to market, in part due to inadequate preclinical models, there is a pressing need to develop physiologically relevant platforms to study CVDs. Here, we present a novel vascularized cardiac tissue model to study coronary microvascular disease—responsible for about 42% of all CVDs. Utilizing only human cardiac primary cells, we developed functionally perfusable cardiac-specific vasculature. We evaluated endothelial barrier function, vessel morphology, stromal-endothelial cell interactions, as well as intra- and extra-vascular solute transport under different culture conditions. We found that while stromal cells were needed to develop non-leaky vessels, there is an optimal ratio of endothelial-to-stromal cells for developing functional (i.e perfusable) vessels. Moreover, we report dynamic vessel remodelling—defined by decreased vascular branches, increased vessel diameter, and quantified tight junction protein expression—in response to flow conditions. We present a 3D on-chip platform to study the coronary microvasculature in physiologically relevant in-vitro environments, a tool we are now optimizing for precision medicine using induced pluripotent stem cells.

Integrative cartilage repair requires the ability of chondrocytes to invade an acellular biomaterial implanted into the defect. Chondrocyte migration into the biomaterial is supported by good integration of the biomaterial to surrounding tissue in the defect.

The aim of this study was to compare cell migration of endogenous chondrocytes into semi-synthetic biomaterials with similar mechanical properties (1-5 kPa) using a cartilage explant model.

Full thickness cylindrical cartilage discs were isolated from bovine (6-month-old) patellae groove (diameter 8mm, thickness 1.5-2.5mm). Cartilage defects (diameter 4mm) were filled with cell-free hydrogels: collagen-I (col) or norbornene-functionalized hyaluronan (norHA) with dithiol (DTT, non-degradable) or MMP (degradable) crosslinker, tyramine-functionalized HA (THA), THA-col and gelatine-methacryloyl (GelMA 50% and 80% degree-of-functionalization DOF). Samples were cultured for 21 days in high-glucose DMEM containing 50ug/ml ascorbic acid and 10% FBS. Biomaterial integration, presence and location of chondrocytes were scored on Safranin-O-stained sections. A migration-index (MI) was developed and interobserver reliability, expressed as intraclass-correlation-coefficient (ICC, 1=excellent, 0=low reliability), was calculated.

Addition of col or lower DOF increased MI with highest MI-score for col (MI:6.9), followed by norHA-DTT, GelMA (50&80% DOF) and THA-col (MI: 3.0-5.3, ICC=0.926). THA and norHA-MMP showed least cell invasion (MI<1.7). Beside GelMA, biomaterials remained in the defect with majority of cells located at the biomaterial periphery. Chondrocytes migrated up to the defect center only in col (<0.5kPa) group.

Chondrocyte migration into biomaterials is a first step to improve cell-free approaches to repair cartilage defects with the aim for deposition of collagen II rich matrix and preventing fibrocartilage formation.

Despite several advances in skin tissue engineering and regenerative medicine, severe burns remain a major therapeutic issue. Mesenchymal Stromal Cells (MSC) have become a real therapeutic option in the field of tissue repair for their immunomodulatory and remodeling properties. This last years, these properties seem to be closely related to their secretory products such as proteins or small RNA. Recent discoveries have highlighted their sensitivity to external stimuli and therefore the possibility to orientate their secretory products to enhance their potential. Interleukin 1β (IL-1β) was used in a previous study as priming molecule, and IL-1β-primed gingival MSCs was shown to be superior to naive MSCs to improve wound healing and epidermal engraftment in vitro and in vivo.

The present study investigates whether bone marrow MSC respond similarly to IL-1β to favor wound healing through the secretion of proteins and miRNA. Naive and IL-1β-primed MSCs from gingival or bone marrow sources were evaluated in different in vitro models of migration, inflammation, dermal-epidermal junction formation. Preliminary results indicated that both MSC sources responds similarly to IL-1β priming and promote skin cell migration, favor extracellular matrix deposition and reduce inflammation in vitro. Their secretory profile for proteins and miRNA was evaluated using ELISA and RT-qPCR. We identified different important pro-healing actors induced by IL-1β priming as IL-6 and miR-146a-5p and tested their mechanisms of action in in vitro tests. These results underline the impact of IL-1β priming on MSC and its potential benefit in a burn wound treatment strategy.

Aim and Background: Autologous adipose tissue derived microvascular fragments (ad-MVF) are shown to form functional vascular networks after implantation in animal models suggesting their potential to pre-vascularize tissue engineered constructs. Limited data is available regarding human ad-MVF1. We aimed to assess the behavior of human ad-MVF in vitro.
Methods: Human ad-MVF were isolated from abdominal lipoaspirate – as previously described in mice with minor modifications2. Ad-MVF were imaged with light microscopy, validated for viability (Hoechst and Propidium Iodide staining), and frozen. After 30 days, ad-MVF were thawed, resuspended in fibrinogen component of the fibrin sealant (TISSEEL), and transferred to 96-well plates (50 µl per well, containing 35,000 ad-MVF). Equal volume of thrombin was added to obtain gel consistency (Final concentration: 20 mg/ml fibrinogen and 2 IU/ml thrombin). At baseline and after 12 days of culture in endothelial medium, constructs were embedded in paraffin and stained for CD31 (endothelial), αSMA (pericyte) and ki67 (proliferation) markers.
Results: Ad-MVF were viable before and after cryopreservation. Sections at baseline contained ad-MVF that stained positive with both anti-CD31 and anti-αSMA. After 12 days of culture similar structures that still showed positivity for the both antigens were observed. They were lower in number but larger in size. Additionally, CD31 positive cells co-stained with ki67 suggesting cell proliferation and angiogenic activity.
Conclusion: Human ad-MVF survive cryopreservation and retain vascular characteristics after culture in fibrin gel suggesting they may be suitable to pre-vascularize tissue engineered constructs. Studies are in progress to test their angiogenic properties in vivo.

Extracellular vesicles (EVs) are considered promising nanoscale therapeutics for bone regeneration. To date, EVs are procured from cells cultured on tissue culture plastic (TCP), limiting cell growth and not replicating conditions in situ. Studies have demonstrated the impact of 3D culture on promoting osteogenesis. Additive manufacturing has facilitated the fabrication of biomimetic environments. Therefore, this study investigated the influence of 3D printed scaffold architecture and composition on the therapeutic efficacy of osteoblast-derived EVs for bone repair.

Ti6Al4V titanium scaffolds with different pore sizes (500 and 1000 µm) and shapes (square and triangle) were fabricated by selective laser melting. Scaffolds were treated with/without a nano-needle hydroxyapatite (nnHA) coating. EVs were procured from scaffold-cultured osteoblasts over 2 weeks. EV size and concentration were defined using nanoparticle tracking analysis. Human bone marrow stromal cells (hBMSCs) osteogenic differentiation with scaffold-derived EVs was evaluated by qPCR, biochemistry and histological analysis.

Titanium scaffolds promoted osteoblast mineralisation compared to TCP. Scaffold-cultured osteoblasts secreted significantly enhanced EV quantity when compared to TCP, with scaffolds exhibiting larger pore sizes (1000 µm) and permeabilities (triangle) promoting EV yield. Moreover, osteoblast-derived EVs isolated from triangle pore scaffolds significantly increased hBMSCs mineralisation when compared to EVs from square pore scaffolds and TCP. Interestingly, nnHA coating significantly improved osteoblast mineralisation, EV production and EV-induced hBMSCs mineralisation compared to uncoated scaffolds.

Together, these findings demonstrate the impact of scaffold architecture and composition on EV therapeutic efficacy, indicating the potential of bone-mimetic culture platforms to enhance the production of pro-regenerative EVs for bone repair.

Abstract **#1733**

A NOVEL MODEL TO STUDY OSTEOCHONDRAL TISSUE DAMAGE RESPONSES IN PTOA

Isabel Amado$_P$[1,2]

[1] *Royal College of Surgeons in Ireland*

[2] *Trinity College Dublin*

Corresponding author's email: isabelamado@rcsi.com

Post-traumatic osteoarthritis (OA) is a disease subset, which leads to joint changes [1] after acute mechanical joint injury. While moderate mechanical loads are essential for maintaining tissue health; excessive mechanical damage can result in pathological changes in both cartilage [2] and subchondral bone (such as microdamage) [3]. How the initial damage, and subsequent responses, occur and whether they are inter-dependent or not is an important, but challenging, question. Here we propose a novel patellar explant to study osteochondral tissue dynamics. Existing models (femoral head, osteochondral plugs) require direct tissue damage during harvest – this presents a challenge when initial tissue damage is the object of study. Thus, we exposed patellar explants both to chemical and mechanical damage, and then assessed tissue damage responses using a series of assays. For chemical damage, explants were treated with IL-1B for 0, 1, 3 and 7 days, while mechanical damage was generated by compression to 10 % strain for 10 cycles at 0.5Hz, at the same time points. In both cases, Sulfated glycosaminoglycan (sGAG), and matrix metalloproteases 13 (MMP-13) were measured to assess cartilage responses whilst alkaline phosphatase (ALP) assessed bone responses. Our data show that patellar explants are viable for at least 28 days. Explants treated with IL-1B showed that both proteoglycan content and bone metabolism markers were increased ($p<0.05$) after 7 days. Furthermore, mechanical damage caused a significant increase in MMP-13. In summary, we demonstrate a novel patellar explant model that can be a useful tool to study bone-cartilage crosstalk in PTOA.

The blood-brain barrier (BBB) is a semipermeable part of the central nervous system's microvasculature, separating the blood from brain tissue. It consists of an endothelial cell layer covered with pericytes and astrocytes, which together protect the brain from non-selective substances, including pathogens but also therapeutics, e.g. against cancer. Therefore, recreating this environment in vitro in order to characterize and enhance drug uptake and distribution is imperative.
Here, melt electrowriting (MEW) is used to fabricate a thin scaffold on which endothelial cells are encouraged to form a confluent, monolayer. MEW has been chosen because of its unprecedented accuracy and precision. Scaffold design and properties, such as fibre thickness, pore size, number of layers, can be adjusted and modified up to the micrometric range and tailored to support an adequate cellular response. The aim is to obtain a tight monolayer, favouring cell-cell interactions, which is a feature that conventional inserts, commonly used for BBB models, lack.
Scaffolds were manufactured from medical grade poly(ε-caprolactone). They were seeded with relevant cell types and their designs were tailored to support the cellular response, favouring the desired growth morphology. Cell behaviour along with tissue formation was investigated via live and fluorescent imaging techniques. Membrane permeability was also assessed.
The future steps will include co-cultures and the design of a customised microfluidic device for drug screening studies. Further development of this BBB model will improve the accuracy of the final in vitro microfluidic system which could be used in preclinical studies to improve drug uptake.

Collagen based hydrogels are broadly used in tissue engineering as they are biocompatible, biodegradable and allow adhesion of conjonctive cells. Unfortunately, these biomaterials are poor drug delivery systems, thereby limiting their utilization to prevent infection or modulate inflammation1. Associating collagen with biodegradable hydrophobic polyesters constitutes a promising method for the design of medicated biomaterials. Current collagen-polyester composite hydrogels consisting of pre-formed polymeric particles encapsulated within a low concentrated collagen hydrogel suffer from poor physical properties and low drug loading. Herein, an amphiphilic composite platform associating dense collagen hydrogels (40 mg/mL) and up to 50 wt% polyesters with different hydrophobicity and chain length was developed. An original method of fabrication was disclosed based on in situ nanoprecipitation of polyesters impregnated in a pre-formed 3D dense collagen network. Composites made of PLGA and PLA but not PCL exhibited improved mechanical properties compared to those of pure collagen dense hydrogels while keeping a high degree of hydration. Release kinetics of Spironolactone, a lipophilic steroid used as a drug model, could be tuned over one month. No cytotoxicity of the composites was observed on fibroblasts and keratinocytes and spironolactone remained active after release from composites. Unlike the incorporation of pre-formed particles, the new process allows for both improved physical properties of collagen hydrogels and controlled drug delivery. The ease of fabrication, wide range of accessible compositions and positive preliminary safety evaluations of these collagen-polyesters will favour their translation into clinics in wide areas such as drug delivery and tissue engineering.

Keywords

Dense collagen hydrogels; Composites; In situ nanoprecipitation

THE IPSPINE PROJECT: LEARNING TO INTEGRATE ETHICS IN A MULTIDISCIPLINARY SCIENTIFIC SETTING

Marianna Tryfonidou[P][1]

[1] *Faculty of Veterinary Medicine, Utrecht University, the Netherlands*

Corresponding author's email: M.A.Tryfonidou@uu.nl

In the iPSpine Horizon 2020 project 21 partners joined together to develop an ATMP for the treatment of chronic low back pain caused by disc degeneration. Key opinion leaders joined forces with academic partners, university medical centers, research institutes, and end users represented by a patient representative foundation and companies. Induced pluripotent stem (iPS) cells are differentiated into notochordal cells, specialized cells that only reside in juvenile discs. They are combined with smart biomaterials to provide them with the necessary instructions and support to thrive within the degenerate disc. Hereby iPSpine hopes to achieve biologic disc repair and ultimately offer improved quality of life for millions of patients, through long-lasting reduction of low back pain.

These technological advances will be supplemented with recommendations on ethical and regulatory affairs to enhance further development and implementation of iPSC-based therapies. In that respect, the consortium contributed into mapping of hard and soft impacts to widen the understanding of the ethical implications of stem cell research at different levels (scientists, regulators, patients). Furthermore, the partners receive training and advice by regulatory experts to meet the demands of the regulatory field of ATMPs during development up to proof-of-concept in clinically relevant animal models. During the keynote I will elude on my experiences as coordinator of such a multidisciplinary project and how we managed to integrate ethics and humanities in its scientific context with the ultimate aim to set an example on long term, fast forwarding, preclinical research that is closer to the patient in need.

Bone regeneration is a complex mechanism, and the application of growth factors will accelerate the regeneration process. Ferulic acid (FA) is a small molecule of Chinese herbal medicine that has bone regeneration properties. The sustained release of these growth factors is critical for the long-term new bone formation at the defect site. In the present study, the FA was mixed with polylactide-co-glycolide (PLGA) and extruded using a twin-screw hot-melt extruder. The extruder polymer-drug composition was fed into the thermoplastic canister that fits into the bioprinter's print head (Cellink, Sweden) and printed into 8x2 (diameter x height) mm porous structures. The PLGA-FA scaffolds delivered a sustained release of FA for seven days. The scaffolds were implanted into 8 mm critical calvarial defects of Fisher344 male rats. The rats were euthanized after 30 days, and the bone regeneration was analyzed using microCT and H&E histology for bone volume and new bone quantification. The results showed that the PLGA-FA scaffolds showed significant BV/TV compared to PLGA and empty-defect groups.

Tissue engineering and regenerative medicine (TERM) is an emerging field focusing on the development of alternative therapies for tissue and organ repair by merging tissue and organ bioactive scaffolds, cells, and signal molecules into functional tissues. Tissue and organ scaffolds play a vital role and act as a crucial player in the game of 'TERM'. In the current study, we employed supercritical carbon dioxide (SCCO2) technology to produce tissue and organ scaffolds for experimental and clinical tissue engineering and regenerative medicine. We used proprietary SCCO2 extraction technology to produce dermis, whole skin, cancellous bone, heart, liver, brain, kidney, pancreas, blood vessel, ureter from a porcine source. The tissues and organs were washed in saline followed by subjecting the tissues to SCCO2 at 100-350 bar carbon dioxide pressure, 20-40°C and 4-12 h finally washed with sodium hydroxide and water. Decellularized tissue and organ scaffolds were stained by hematoxylin and eosin and 4,6-diamidino-2-phenylindole (DAPI) staining and scanning electron microscopy (SEM) depicted complete removal of cells. SCCO2 produced organ scaffold is a bioartificial scaffold that maintains the structure of the extracellular matrix. Our tissue and organ scaffolds are biologically mimetic scaffolds such as biologically active ECM thus creates a in vivo-like microenvironment mimicking biological entities and stimulating cell-specific responses to lead to tissue regeneration and repair. To conclude, we developed and efficient process to produce tissue and organ scaffolds from porcine origin. These organ scaffolds can be used in experimental and clinical tissue engineering and regenerative medicine.

Rhinoplasty is the most difficult aesthetic surgical procedures with a high rate of revision. Rhinoplasty adjusts and reorganizes the defected nose caused by trauma, therapeutic operations including cancer. However, we developed a bioactive scaffold with 3D histotypic cartilage culture using supercritical (SCCO2) carbon dioxide decellularized porcine nasal cartilage graft (dPNCG). dPNCG was produced by proprietary SCCO2 (100-350 bar carbon dioxide pressure, 20-40°C) extraction technology from porcine nasal cartilage. An experimental 3D histotypic culture was engineered using dPNCG, rat adipose-derived stem cells (ADSC) and chondrocytes with different percentage of cells and cultured for 21 days. dPNCG complete decellularization was characterized by hematoxylin and eosin (H&E), DAPI, alcian blue staining, scanning electron microscopy and residual DNA content. A solid mass of 3D histotypic cartilage with significant production of glycosaminoglycans in dPNCG with 100% chondrocytes culture. H&E and alcian blue staining showed an intact tissue mass, with cartilage granules bound to one another by extracellular matrix and proteoglycan, to form a 3D structure. Besides, phenotype chondrogenic markers, type II collagen, aggrecan and SOX-9 were elevated indicating chondrocytes cultured on dPNCG substrate synthesized type II collagen along with extracellular matrix to produce 3D histotypic cartilage. To conclude, dPNCG is an excellent substrate bioactive scaffold that might offer a suitable environment for human nasal chondrocytes to produce 3D histotypic cartilage and a promising potential candidate for cartilage tissue engineering in rhinoplasty.

Tissue-engineered vascular graft commonly comprised of a scaffold, seeded cells, and the appropriate signals to encourage vascular tissue formation. However, we proposed the direct approach to use supercritical carbon dioxide (SCCO2) technology decellularized rabbit blood artery and implant directly into the rat artery to evaluate the main concept of tissue engineering, the decellularization-recellularization approach. Rabbit femoral artery was harvested from a healthy New Zealand white rabbit. SCCO2 extraction technology was used to decellularize the rabbit artery. By subjecting the artery to SCCO2 at 100-350 bar carbon dioxide pressure, 30-40°C and 0.5-2 h finally washed with sodium hydroxide and water completely removed the cells. The decellularized artery was implanted in August Copenhagen Irish (ACI) rats. Doppler ultrasonography depicted implanted decellularized blood vessel showed normal blood flow in all examinations after 12, 42 and 58 days. Recellularization was complete as depicted by hematoxylin and eosin staining. Endothelial cell distribution in the recellularized blood vessel was evaluated by the endothelial marker. Mild expression of inflammatory markers was noticed, indicating regeneration. Cell distribution was noticed in all three layers of the blood vessel, with the expression of alpha-smooth muscle actin. Endothelial markers such as CD34 and vWF were expressed on the implanted artery. To conclude, SCCO2 decellularized rabbit artery direct implantation to rats depicted excellent patency and excellent recellularization with the normal function of the artery.

Osteoarthritis (OA) is the most common articular cartilage degenerative joint disease and a major cause of pain and functional disability in humans. Cartilage tissue engineering (CTE) is to use supercritical carbon dioxide (SCCO2) decellularized porcine cartilage graft as a biomaterial scaffold, plasma rich platelet (PRP) as bioactive molecules, and chondrocytes from rat as the cells to cure the injury and regenerate new cartilage in anterior cruciate ligament transection (ACLT)-induced OA model. We used proprietary SCCO2 (100-350 bar carbon dioxide pressure, 20-40°C) extraction technology to produce decellularized porcine cartilage graft from porcine articular cartilage. SCCO2 decellularized porcine cartilage graft (dPCG) characterized by hematoxylin and eosin and 4,6-diamidino-2-phenylindole (DAPI) staining and scanning electron microscopy (SEM) depicted complete removal of cells. Intra-articular administration of dPCG with or without PRP is efficient in attenuating the progression and repairing the damaged cartilage. In addition, dPCG with and/or without PRP significantly reduced the ACLT-induced OA symptoms and attenuated the OA progression. dPCG reduced pain improved articular cartilage damage in the rat knee characterized by X-ray and micro-CT. Besides, dPCG significantly increased and modulated type II collagen, aggrecan and SOX-9 expression and attenuated the articular knee cartilage damage. To conclude, dPCG attenuated ACLT-induced OA progression with and/or without PRP by elevating the expression of type II collagen, aggrecan and SOX-9. The present investigation might serve as a potential therapy for OA patients and patients with cartilage defect caused by the sport-related injury.

Articular cartilage has limited repair, regenerative capacity and a challenging clinical issue. Thus there is a continued search for the procedures and devices, to explore cell sources and tissue engineering methods for cell-based therapies, to restore articular cartilage. This study aimed to construct a novel 3D composite with decellularized cartilage for the treatment of cartilage defects.

Supercritical carbon dioxide (scCO2) was used to decellularize porcine articular cartilage. The 3D composite was engineered using 50, 100, or 250 mg scCO2 decellularized cartilage scaffolds with PRP, thrombin, and porcine chondrocytes. Expression of SOX-9, collagen type II, and aggrecan was evaluated in the 3D composite employing immunohistochemistry. In addition, 3D composites were made using with and without agarose along with decellularized cartilage scaffolds to elucidate the role of decellularized cartilage matrix on chondrocyte proliferation. Chondrocyte proliferation was optimal in 100mg growth decellularized cartilage, relative to 50 and 250mg. The chondrocyte growth and expression of collagen type II, SOX-9, and aggrecan were significantly elevated in the 3D composite with decellularized cartilage than without decellularized cartilage. The 3D composites with decellularized cartilage with agarose gel, showed exceptional chondrocytes growth, compared to agarose gel without decellularized cartilage. To conclude 3D composite made of decellularized cartilage scaffold acts as a scaffold substrate for the chondrocyte with native type II collagen, thus facilitating ECM production by chondrocytes. This new cell-scaffold construct may provide the basis of a viable chondral graft suitable for in vivo implantation.

Introduction: In the previous study, we aim to study whether titanium affinity biomimetic peptide DOPA-BMP-2 could promote the osteogenesis of bone marrow mesenchymal stem cells (BMSCs) in vitro and accelerates the osseointegration of titanium screws in vivo in osteoporotic rats.

Methods: Titanium sheets and titanium screws were dual-functionalized by soaking to graft DOPA-BMP-2 and DOPA-RGD bioactive polypeptide. The physicochemical properties was explored and the optimal concentration of DOPA-BMP-2 polypeptide and DOPA-RGD polypeptide (promoting cell adhesion) were studied to promote the osteogenesis of BMSCs in vitro. Then, titanium screw coated with dual peptides were implanted into the osteoporotic rats to comprehensively evaluate the osseointegration.

Results: The results of X-ray photoelectron spectroscopy, water contact angle and atomic force microscopy displayed that the DOPA-BMP-2 and DOPA-RGD polypeptides were successfully grafted onto the titanium surface. QRT-PCR, ALP staining and alizarin red staining results further confirmed that the ratio of BMP-2 and RGD at 3:1 (BMP-2:RGD=3:1) had the strongest bone-promoting of BMSCs in vitro. In bone-implant contact (BIC) area of the osteoporotic rats, quantitative parameters of Micro CT showed that the bone volume/tissue volume, trabecular bone number, trabecular bone thickness of dual-functionalized group were higher than other groups, trabecular bone separation and trabecular pattern factor were decreased. The toluidine blue staining and the anchorage force test showed that the dual-functionalized titanium affinity biomimetic peptide promoted osseointegration in vivo.

Conclusions: Biomimetic active peptides and dual-functionalized strategies have successfully promoted osseointegration of titanium implants in osteoporotic rats.

In this study, we prepared a novel targeted and extra stable micellar nanocarrier that can facilitate intracellular drug release. First, ((N-3-sulfopropyl-N, N-dimethylammonium)ethyl methacrylate was synthesized by RAFT polymerization, and it was followed by copolymerization of macroCTA with AEM in the presence of an acid-degradable cross-linker. Then, a peptide estimated by phage display for HER-2 recognition was incorporated into these core cross-linked micelles with carbodiimide reaction. Following this, DOX was loaded to the micelle nanocarriers by dialysis method in varying amounts to reach optimal loading. The resulted formulations were characterized in terms of size and zeta potential values. For polymer characterization, 1H-NMR, 13C-NMR, FTIR, and GPC were used. Size and morphological characterizations of the micelle nanocarriers were performed by Zeta Sizer and TEM, respectively. Analyses demonstrated that micelles with very low size distribution with sizes below 100 nm were obtained successfully. Then, pH-triggered DOX release was achieved due to the acid-degradable cross-links. Afterward, the efficiency of drug-loaded and targeted micelles on SKBR-3 cell lines was determined by using cell viability assay with the healthy breast cells as control (MCF-10A). Drug loaded micelles interacted with SKBR3 and MCF-10A cell lines for toxicity and drug efficiency, and the results were evaluated. According to the in vitro studies, the cytotoxicity of DOX loaded, peptide conjugated micelles were higher than free DOX at the same drug concentration, which indicates the high efficiency and selectivity of a peptide targeted smart nanocarrier system to HER2 positive breast cancer cells. EGGSHELL MEMBRANE AS A BIOACTIVE AGENT IN POLYMERIC NANOTOPOGRAPHIC SCAFFOLDS FOR ENHANCED BONE REGENERATION

Yonghyun Gwon[P][1]

[1] *Chonnam National University*

Corresponding author's email: gyhjhj0716@gmail.com

A bone regeneration scaffold is typically designed as a platform to effectively heal a bone defect while preventing soft tissue infiltration. Despite the wide variety of scaffold materials currently available, such as collagen, critical problems in achieving bone regeneration remain, including a rapid absorption period and low tensile strength as well as high costs. Inspired by extracellular matrix protein and topographical cues, we developed a polycaprolactone-based scaffold for bone regeneration using a soluble eggshell membrane protein (SEP) coating and a nanotopography structure for enhancing the physical properties and bioactivity. The scaffold exhibited adequate flexibility and mechanical strength as a biomedical platform for bone regeneration. The highly aligned nanostructures and SEP coating were found to regulate and enhance cell morphology, adhesion, proliferation, and differentiation in vitro. In a calvaria bone defect mouse model, the scaffolds coated with SEP applied to the defect site promoted bone regeneration along the direction of the nanotopography in vivo. These findings demonstrate that bone-inspired nanostructures and SEP coatings have high potential to be applicable in the design and manipulation of scaffolds for bone regeneration.

NANOSCALE TOPOGRAPHIES TO ENHANCE MESENCHYMAL STEM CELL ADHESION AND REDUCE BIOFILM FORMATION

Matthew Dalby[P][1]

[1] *University of Glasgow*

Corresponding author's email: matthew.dalby@glasgow.ac.uk

Post-operative infection is a major complication in patients recovering from orthopaedic surgery. As such, there is a clinical need to develop biomaterials for use in regenerative surgery that can promote mesenchymal stem cell (MSC) osteospecific differentiation and that can prevent infection caused by biofilm-forming pathogens. Nanotopographical approaches to pathogen control are being identified, including in orthopaedic materials such as titanium and its alloys. These topographies use high aspect ratio nanospikes or nanowires to prevent bacterial adhesion but these features puncture adhering cells, thus also reducing MSC adhesion. Here, we we will describe a number of approaches that can enhance MSC interaction without losing reduction in bacterial adhesion. An example is using poly(ethyl acrylate) (PEA) polymer coatings on titanium nanowires to spontaneously organise fibronectin (FN) and to deliver bone morphogenetic protein 2 (BMP2) to enhance MSC adhesion and osteospecific signalling. This nanotopography when combined with the PEA coating enhanced osteogenesis and reduced adhesion of Pseudomonas aeruginosa in culture. Using a novel MSC–Pseudomonas aeruginosa co-culture, it can also be shown that the coated nanotopographies protect MSCs from cytotoxic quorum sensing and signalling molecules. Such approaches may be useful in development of improved orthopaedic fixation.

In tissue engineering, the inclusion of vascular networks or other nutritional channels has become of major importance, as necrosis would otherwise limit the thickness of engineered tissue to hundreds of micrometers.
In order to fabricate such networks, multiple approaches exist, including soft-lithography, casting approaches and 3D-printing. However, hitherto applied approaches are either limited in production speed, require intensive manual work or entail a limited resolution. Additionally, fabrication of truly biomimetic vascular networks, whose scale span multiple orders of magnitude (micro- to millimeters), is extremely challenging.
To overcome the described limitations, we employed flexographic printing technology for fast and high-resolution fabrication of vascular network mimicking patterns made of gelatin. Dendritic and highly biomimetic hydrogel structures that mimic the vascular network in a human body can be fabricated with high speed (up to 1.5 m/s), on large areas (50 x 100 mm2) and covering a broad vascular size spectrum (30 µm–0.6 mm). Height, width, degree of branching and connectivity of the printed network were tailored by the gelatin concentration (5–30 %), print substrate selection and printing parameters (pressure, anilox shape, temperature).
Following printing the gelatin structures were embedded in various types of hydrogels, including agarose and agarose-gelatin blends, as sacrificial master molds. Bonding of the casted gels onto a substrate led to bioinspired, perfusable networks. In future, these can be applied as nutrient and oxygen providing channels.
In summary, our work is a major step towards rapid, cost-efficient and large-scale fabrication of vascularized tissues, applicable to a variety of hydrogels.

DESIGNING BIOINK AND BIOASSEMBLY PLATFORMS FOR MUSCULOSKELETAL REGENERATIVE MEDICINE

Tim Woodfield[P][1]

[1] *University of Otago Christchurch*

Corresponding author's email: tim.woodfield@otago.ac.nz

Biofabrication technologies, including 3D bioprinting and bioassembly, enable the generation of engineered constructs that replicate the complex 3D organization of native tissues via automated hierarchical placement of cell-laden bioinks, tissue modules, and/or bioactive factors. Photo-initiated radical polymerization combining light and photo-initiators to generate radicals for crosslinking photo-polymerizable macromers, has been widely employed in 3D bioprinting of cell-laden hydrogels. Despite rapid advances in biofabrication technologies, no universal bioink exists. The major challenge for translational regenerative medicine is that the processing requirements (biofabrication window) of current bioinks is narrow, requiring optimization of each bioink for each individual biofabrication technique and specific tissue niche e.g. high viscosity "shear thinning" bioinks necessary for extrusion bioprinting versus low viscosity bioinks for lithography-based bioprinting.

This presentation discusses alternative strategies to provide highly tunable bioinks that 1) promote a specific cell-instructive niche using light activated crosslinking in high throughput modular spheroids, and 2) are printable across multiple biofabrication technologies, including extrusion-, lithography- and microfluidic-based bioprinting.

This talk will describe the design of versatile, photo-clickable bioinks and bioresins for biofabrication of 3D in vitro models targeting cartilage, bone and vascular network regeneration. We describe our experiences in developing hybrid tissue constructs and convergence with 3D spheroid bioassembly platforms for controlling multicellular spheroid fusion, extracellular matrix (ECM) formation and stem cell niche, offering new paradigms for high-throughput screening, "on-chip" and osteochondral tissue repair applications.

Musculoskeletal injuries are one of the main causes of disability worldwide. Soft and hard tissues are integrated through gradient interfaces to form the complex system allowing the body to move. These interfaces are particularly vulnerable to injury and tearing due to biomechanical inconsistency in the connections between soft and hard tissues. Therefore, engineering the musculoskeletal tissue interfaces continues to be a challenge [1]. In this project, I aim at developing polymeric fibrous scaffolds, mimicking native interfaces, with mechanical and biological performance influenced by the scaffold's design and topology. To produce fibrous scaffolds from polycaprolactone (PCL), 3D printing method called Melt Electrowriting (MEW) was used. Mechanical properties of scaffolds with different geometries and pore sizes were analyzed by tensile testing and modelled in computer simulation. Biological performance was investigated through cell attachment and proliferation on the produced scaffolds. Results indicated that the mechanical properties (Young's modulus, ultimate strength, maximum load) of the successfully fabricated scaffolds depend on the design structure. Biological evaluation showed that the cells attach, spread along the scaffolds and proliferate. Computer simulations helped to reveal the stress distribution in the produced scaffolds. In conclusions, MEW allows printing scaffolds with precise architecture. The mechanical properties and cell behavior can be controlled by design. In the next steps, gradient scaffolds will be produced. This study shows that MEW scaffolds have great potential in interface tissue regeneration.

One of the most common health problems in racehorses is Achilles tendon rupture. If Achilles tendon ruptured, it would be difficult or even impossible for the horse to move their feet. Jackfruit sap (Artocarpus heterophyllus) is one of the natural alternative ingredients containing pectin that can act as an anti-inflammatory and has antibacterial substance and cellulose that can act as an adhesive compound. The research purposed to examine the potency of jackfruit sap for healing tendon rupture in the rat as the animal model. Left of Achilles tendon of rats were ruptured 50% using surgery then treated by 1 mg jackfruit sap. Rats have cared during the following 14 days. Nociceptive withdrawal time (NWT) was measured in day 15th then rats were euthanized, and tendon tissue was collected in formaldehyde 4%. Examination of tendon tissue consisted of histopathology, collagen density and thickness, inflammatory cells, expression of IL-1β, TGF-β and VEGF. Results showed jackfruit sap treatment could improve the healing of tendon after ruptured based on increasing NWT, improvement tendon tissue and formation of new collagen. However, the direction of the new collagen was irregular. Rats which given jackfruit sap have reduction IL-1β ($p<0.05$) and elevation ($p<0.05$) of TGF-β and VEGF. The conclusion was the jackfruit sap could be candidate material for bio-sealant to the ruptured tendon

Dinitrosyl iron complexes (DNIC) are endogenous donors of nitric oxide. For more than 15 years, they have been studied to stimulate regeneration. However, the most effective dose and delivery form have not been defined yet. The aim of our research was to develop the aerosol with DNIC and study its effects on regeneration.

We developed a series of aerosols containing DNIC and modeled planar full-thickness wounds in Wistar rats. There were 4 groups of 6 animals. In the control group, the wounds were irrigated with distilled water. In study groups, the wounds were treated with aerosols containing 10, 50 and 100 μg of DNIC. Wound tissues were excised 4 days after the operation and analyzed by histological and morphometric methods.

DNIC aerosol with the dose of 50 μg had the most beneficial pro-regenerative effect on wound healing. In this group, the granulation tissue layer was 140% thicker, the intensity of inflammation was significantly lower than in the control ($p<0,05$). Aerosol with 10 μg of DNIC stimulated cell proliferation and growth of granulation tissue, but it did not facilitate it's the maturity and had no anti-inflammatory effect. Aerosol with 100 μg of DNIC increased the activity of inflammation, and had a less effect on the thickness and maturity of granulation tissue than the aerosol with 50 μg of DNIC. We demonstrated a dose-dependent decrease in the functional activity of mast cells in the experimental groups compared to the control.

DNIC aerosol is an effective delivery form for the treatment of wounds.

Paclitaxel (PTX)-eluting coating of vascular stent prevent neointima growth after stenoticarteries stenting. Matrices produced from 5%PCL/10%HSA/3%DMSO/PTX by electrospinning were shown to be suitable for stent coating as exhibiting long-term PTX release kinetic [1, 2]. Installation of vascular stents considers two-fold increase in stent diameter and, therefore, elongation of the matrices covering the stents. We studied the influence of matrix elongation on its structure and PTX release.

Three different matrices (5%PCL/PTX, 5%PCL/10%HSA/PTX and 5%PCL/10%HSA/3%DMSO/PTX) were prepared using electrospinning on a drum collector. Matrices were fixed between clamps and uniaxially elongated in 2 times and discs cut from relaxed matrcies were incubated for different time intervals (up to 27 days) in PBS or in human blood plasma to evaluate tritium-labeled PTX release in supernatants.

According to SEM data, all matrices were composed of randomly oriented fibers with smooth surface. Matrix elongation results in unequal deformation accompanied by fibers orientation along the applied force vector; breaks and changing the fiber diameter were not observed. Modelling of matrix deformation showed that thickness and specific PTX content do not significantly depend on discs positioning. The elongation has practically no effect on the kinetics and completeness of drug release from matrices.

The data obtained demonstrate that a matrix elongation during stent installation does not lead to fiber breaks and does not interfere with kinetics of PTX release.

Keywords

drug-eluting stents; Paclitaxel; electrospinning

Development of thrombosis- and infection-resistant vascular prostheses is still an unmet clinical need. Here we designed a biodegradable vascular drug-eluting graft fabricated from poly(3-hydroxybutyrate-co-3-hydroxyvalerate) and poly(ε-caprolactone) and modified with iloprost and cationic amphiphile 1,5-Bis-(4-tetradecyl-1,4-diazoniabicyclo[2.2.2]octan-1-yl) pentane tetrabromide (0.25, 0.5 and 1 mg/mL). The surface modification was performed through complexation with polyvinylpyrrolidone, which was polymerized with the luminal surface by means of 15 kGy ionizing radiation. We further evaluated mechanical properties, hemocompatibility, and resistance to Klebsiella pneumonia spp. ozaena No. 5055, Escherichia coli ATCC 25922, Staphylococcus aureus ATCC 25923, Proteus mirabillis ATCC3177, and Pseudomonas aeruginosa. Ionizing radiation and polymerization of polyvinylpyrrolidone did not affect the mechanical competence of the graft. Iloprost/1,5-Bis-(4-tetradecyl-1,4-diazoniabicyclo[2.2.2]octan-1-yl) pentane tetrabromide coating nullified the thrombogenicity of the luminal surface, reducing platelet aggregation by 5-7-fold, and efficiently prevented the growth of microbial pathogens. However, 1,5-Bis-(4-tetradecyl-1,4-diazoniabicyclo[2.2.2]octan-1-yl) pentane at a concentration of 1 mg/mL provoked considerable hemolysis and platelet aggregation. This study was funded by Russian Science Foundation, grant number №20-15-00075.

Many drugs show promising results in laboratory research, but eventually fail in clinical trials. We hypothesize that one main reason for this translational gap is that the cancer models used are inadequate. Most models lack the tumor-stromal cells interactions with their microenvironment which are required for tumor progression. Such interactions do not form in conventional 2D cultures where cells grow on rigid plastic plates. Therefore, there is a need to develop a 3D model that better mimics the tumor microenvironment. Here, we recapitulated the tumor heterogenic microenvironment by creating fibrin GB-bioink consisting of patient-derived glioblastoma cells with astrocytes and microglia. Additionally, perfusable blood vessels were created with sacrificial bioink covered with brain pericytes and endothelial cells. We observed similar growth curves, drug response and genetic signature of glioblastoma cells grown in our unique 3D-bioink platform and in in-vivo studies as opposed to 2D culture. This 3D-bioprinted model could be the basis for potentially replacing cell cultures and animal models as a powerful platform for rapid, reproducible and robust personalized therapy screen and drug development.

Drug-eluting stents (DES) were designed to minimize neointima growth after angioplasty [1]. Sirolimus (SRL) and paclitaxel (PTX) are the most commonly used DES coating drugs now. It was shown that, PCL-based electrospun produced, SRL and PTX enriched matrices exhibit long-term drug release kinetic and are to be used as coatings of DES [2-4]. The retention of drug released from stent coatings by the wall of rabbit iliac artery (IAW) was studied.

DES coated with matrices 5%PCL/10%HSA/3%DMSO/SRL or 5%PCL/10%HSA/3%DMSO/PTX with tritium-labeled drugs in dose of 0.9 and 0.46 μg/cm2, respectively, were produced using electrospinning. Coated stents were installed into freshly obtained rabbit's iliac artery and fixed in special device. The drug release and penetrating through IAW in PBS or in blood plasma (BP) was evaluated by radioactivity of PBS/BP.

IAW retain PTX and decrese release from coating in 3-4 times during first hours and 2-2.5 times during the day. After 24 hours more than half of PTX released from the coating is retained in IAW. Even more efficient retention was observed for SRL; only 12.5% of SRL released from coating into BP pass through the IAW. Retention of drugs by IAW is more efficient when drugs were released in BP with a plateau reached in 9 hours. The retention/accumulation of drugs by IAW provides a prolonged drug release and allows reducing the dose of drugs in stent coatings.

The study was supported by the grants from the Russian Science Foundation no. 18-15-00080 and State Funded Project no. 0245-2021-0007.

Bioactivity of metal ions influences the behaviour of cells like proliferation and differentiation. Here metal ions (Ca2+, Co2+, Cu2+ and Fe3+) were used for cross-linking of chitosan (Chi) and Alginate (Alg) polyelectrolyte multilayers (PEM) by coordination-based intrinsic cross-linking of functional groups like amino and hydroxyl groups. Physicochemical properties of PEM were investigated to characterize layer growth and thickness. Further the quantity of metal ions within multilayers was determined using ICP-MS. The effect of metal ions on surface properties was investigated such as wettability, mechanical properties and topography. The findings indicate that changes in physical properties depend on the type and concentration of metal ion. The adhesion and proliferation studies with murine C3H10T1/2 embryonic fibroblasts demonstrated that coordination-based crosslinking of Chi/Alg PEM with of metal ions had no adverse effect on cell behaviour. Interestingly, PEM cross-linked by copper and iron ions enhanced not only adhesion and proliferation of cells, but induced cell differentiation towards adipocytes. These findings indicate that metal ion-loaded PEM have the potential to guide stem cell differentiation on surfaces of implants and tissue engineering scaffolds.

External auditory canal atresia (EAC) is frequently encountered in clinical practice. Causes of the condition are physical stress, trauma, infection, and ear surgery. Surgery is the treatment of choice; however, is associated with high rate of recurrence [1]. In this study, we artificially created EAC in a rabbit model. We also transplanted oral mucosal cell sheets, which were cultured on temperature responsive inserts, immediately after exfoliating the skin of the external auditory canal to prevent from atresia.
The aim of this study was to explore the possibility of a new therapeutic modality for EAC, and evaluate its effectiveness.

Osteosarcoma is the most diagnosed bone tumour that occurs in children. The use of tissue engineering strategies after malignant tumour resection remains a subject of scientific controversy as standard tissue engineering tools might exert tumour-promoting effects. As a result, there is limited research that focuses on bone regeneration post-resection, which is further compromised following chemotherapy. Due to the increasing interest in developing 3D-culture systems to provide unique means for screening therapies pre-clinical trials, this study aims to develop the first co-culture spheroid model for osteosarcoma to understand the divergent relationship between tumour elimination and bone regeneration. By manipulating the ratio of stromal to osteosarcoma cells the cancer state (early vs. late) was modified, as evident by increased tumour growth rates and altered ALP and VEGF expression levels, which are known clinical prognostic osteosarcoma factors[1,2]. When treated with BMP-2 or PDGF our model indicates, as expected, that osteogenic supplements significantly increase tumour growth in early-stage osteosarcoma. However, osteogenic supplements had no effect on tumour growth when applied to the late-stage osteosarcoma model. Regardless of cancer state, treatment with PDGF significantly increased the release of VEGF, and both osteogenic supplements significantly enhanced mineral formation within the tumour. When treated with chemotherapeutics in combination with osteogenic supplements, both tumour growth and mineral formation was significantly diminished, as previously seen clinically. Using our model, we can begin to understand mechanistically the relationship between stromal and osteosarcoma cells and their response to chemotherapeutics and regenerative cues outcomes that can inform the design of future therapies.

3D bioprinting is changing the way in vitro models are generated to study cell behaviour, tissue properties and biology. The technique is used to fabricate 3D constructs layer-by-layer using living cells with biomaterials. Various biomaterials are utilized to develop bioinks which in return are used to fabricate constructs with biomimetic microenvironment and mechanical properties that are similar to native tissue. In recent years, the development of appropriate bioinks for tissue fabrication has drawn attention towards the decellularized extracellular matrix (dECM). The ECM composition and structure are unique to each tissue and cells and is impossible to replicate using native and synthetic polymers. Despite their excellent biochemical and functional properties, ECM does not possess sufficient mechanical strength to fabricate 3D structures that can retain its shape postprinting. To overcome this hurdle, CELLINK has launched the X-series that uses proprietary Nanocellulose to formulate an ECM containing bioink with improved mechanical properties to bioprint complex 3D structures. The first in the X-series is HEP X, a liver ECM based bioink. Structures printed using HEP X maintained shape and stability throughout 21 days of culture. HepG2 cells biofabricated using HEP X showed high cell viability with expression of liver specific metabolic markers e.g., albumin, alpha-fetoprotein, and E-cadherin. Not surprisingly, expression of albumin and serpina1 increased over time whereas alpha-fetoprotein expression decreased demonstrating that ECM enables liver specific function close to in vivo. Thus, dECM based bioinks are excellent candidates for insitu bioprinting for various applications due to their superior mechanical stability and biochemical properties

Cartilage defects in which the subchondral bone is exposed require surgical intervention to induce repair in order to prevent further degeneration of the joint. The complex depth-dependent structure of articular cartilage (AC), consisting of an arcade-like collagen fibre network, enables it to withstand and distribute the challenging biomechanical loads passing through the joint. While some clinical advances in cartilage repair have occurred, osteochondral (OC) defect repair still remains a significant clinical challenge, with current scaffold and tissue engineering based approaches failing to recapitulate the complex, hierarchical structure of native AC. To address this need, we have developed a bi-phasic extracellular matrix (ECM)-derived scaffold fabricated from solubilized AC and bone. In vitro, porous scaffolds generated from these ECM components were shown to preferentially direct the differentiation of mesenchymal stromal cells (MSCs) towards a chondrogenic or osteogenic lineage depending on the ECM source. In addition, to further enhance tissue deposition and collagen fibre alignment, a novel freeze-drying fabrication method was developed to introduce pore alignment into the scaffolds. Finally, we implanted the scaffolds as an off-the-shelf, cell-free implant into a clinically relevant large animal model (caprine) of OC defect repair. Evaluation at 6 months post-implantation demonstrated that treatment of OC defects with the bi-phasic scaffold enhanced cartilage matrix deposition when compared to empty controls. Furthermore, the structure and composition of the repair tissue in scaffold treated defects was more hyaline-like in nature, consisting of a superficial zone rich in lubricin with aligned collagen fibres.

Tissue engineering (TE) combines both cells' biology and engineering to develop bioactive biomaterials to treat tissue regeneration [1]. Among them, biomaterials with conducting properties have shown promising potential as bioactive cell substrates for tissue regeneration.

Poly (3-hydroxybutyrate-co-3-hydroxyvalerate) (PHBV) is a biocompatible and biodegradable material widely employed in the biomedical field. It has a hydrophobic behavior and excellent mechanical properties. However, it is brittle, highly hydrophobic and shows poor thermostability [2]. Thus, the combination of PHBV with another hydrophilic biomaterial such as poly(vinyl alcohol) (PVA), a synthetic, hydrophilic and biocompatible polymer could be an interesting approach [3]. Additionally, conducting polymers such as polypyrrole (PPy) have attracted great interest in the biomedical field due to its ability to stimulate cell response [4]. Therefore, PHBV/PVA semi-interpenetrating networks (semi-IPN) with electroactive properties can be an interesting approach for TE applications.

Here we describe a novel semi-IPN composed by PHBV and crosslinked PVA in a 30:70 w/w ratio to conform an electroactive hydrophilic network with incorporated conductive polypyrrole nanoparticles (PPy) (up to 15%) [2]. Physicochemical properties have been analyzed by FTIR, DSC, TGA, swelling, water contact angle and dielectric spectroscopy. Electronic microscopy was used to perform a structural analysis.

PHBV/PVA/PPy semi-IPNs present good miscibility, no phase separation and strong interactions between the components. The hybrid hydrogels show increased conductivity with higher content of PPy nanoparticles and higher thermal stability compared to neat components. These properties postulate these nanocomposite hydrogels as promising biodegradable biomaterials for TE applications.

MICROFLUIDIC 3D BIOPRINTING OF A BLOOD BRAIN BARRIER AS A BIOMIMETIC PLATFORM FOR DRUG DELIVERY

Chiara Scognamiglio$_P$[1]

[1] *Istituto Italiano di Tecnologia*

Corresponding author's email: chiara.scognamiglio@iit.it

The majority of cerebrovascular diseases is connected to blood brain barrier (BBB) dysfunctions (1). Their treatment constitutes a major challenge due to the intrinsic properties of the BBB, which strictly controls the passage of molecules from the blood towards the central nervous system (CNS), making inefficient therapeutic drugs delivery (2). Recent studies have highlighted the potential of microfluidics and 3D bioprinting techniques for in vitro models of human blood vessels (3, 4).

We propose a biomimetic 3D printed BBB that provides an innovative platform to assess brain endothelial permeability for disease modeling and drug delivery applications. The microfluidic printhead mounted on a custom made extrusion bioprinter allowed for a continuous and precise deposition of multicellular and multimaterial inks. A blend of alginate and gelatin methacryloyl was used to fabricate a hollow fiber containing human brain-like endothelial cells (hBLECs) and bovine pericytes. We demonstrated the validity of the bioprinted model, checking for cells viability and staining f-actin and anti-zonula occludens-1 (ZO-1) to visualize the actin cytoskeleton and the tight junction at the cell-cell contact. In the presence of astrocytes conditioned medium and shear stress imposed by the flow, cells exhibited BBB phenotypes, among which flow-dependent cell alignment and tight junction formation. The tightness of the barrier is quantified through measurement of the fluorescent dye (40 kDa dextran) diffusion across the endothelial layer as a function of the shear stress exerted on the lumen. We thus show the importance of recreating a physiological shear stress to obtain a stable and tight BBB.

Osteoarthritis (OA) is the most common inflammatory and degenerative joint disease. Mesenchymal Stromal Cells (MSCs), with their immune-regulatory properties and chondro-protective effects, have been considered as a new approach to treat OA. Considering the risk of cell leakage and death after intra-articular injection, we hypothesized that cell encapsulation in cytoprotective hydrogels could overcome these limitations and provide cells with a suitable 3D microenvironment supporting their biological activity. We have generated micromolded alginate microparticles (diameter 150 µm) and demonstrated the long-term viability of microencapsulated human adipose stromal cells (hASCs), as well as the morphological and mechanical stability of the particles. Encapsulated cells maintained their in vitro ability to sense and respond to a pro-inflammatory environment (IFN-γ/TNF-α (20 ng/mL) or synovial fluids from OA patients) by secreting PGE2, IDO, HGF and TGF-β. We then evaluated their anti-OA efficacy in a post-traumatic OA model in adults rabbits (n=24). Eight weeks after anterior cruciate ligament transection, destabilized joints were injected (intraarticular, 26G needle) with 200 µL of either PBS, blank microparticles, non-encapsulated or microencapsulated cells (5x105 cells). Six weeks after injection, a reduced severity of OA lesions was observed in joints injected with hASCs, whether encapsulated or not, as demonstrated by OARSI scoring on safranin-O stained sections. In addition, a significantly decreased expression of the aggrecanase-generated catabolic neoepitope NITEGE, as compared to joints injected with PBS or blank microparticles, was obtained, confirming the therapeutic effect of encapsulated cells on the diseased joint.

Bioprinting of larger tissues and organs presents a tremendous opportunity to challenge the status quo for medical treatments of various illnesses. Necessary for the successful implementation of bioprinting is improving cell survival during the printing process, where cells are subjected to significant shear forces. A possible way to improve cell viability and to expand the bioprinting window is the encapsulation of cells in hydrogels, which can be done using microfluidics (1). This also allows for tailored cell microenvironments and for protection of cells from the immune system. Highley et al. recently proposed the use of microgel bioinks to overcome additional limitations of conventional bioinks, such as poor nutrient/oxygen diffusion (2). However, a limiting factor for the use of microgel bioinks so far is the required combination of microfluidics producing only small quantities, followed by post-chip batch processing such as cross-linking, separation and bioprinting. Here we present a novel approach to this problem by combining on-chip microgel formation, in-flow crosslinking and direct bioprinting of cell-laden microgel constructs. Within this “all-in-one” approach, microgels are formed using a double flow-focusing design, where a 3D contoured narrowing allows for a precise control of achieved droplet sizes. By incorporating an UV-LED at 385 nm into the setup, cross-linking of the microgels is performed in-flow in the microtubing before the microgels are printed directly using a modified FDM printer, resulting in constructs with intrinsic microporosity. These constructs can be manufactured in perfusion chambers, where they can be perfused easily via their porosity and integrated perfusion channels.

Bioengineering has made impressive strides in recent years, yet the commercialization of bio-fabricated tissues and organs is still a great challenge. Precise Bio has taken up the challenge and established an industry-oriented workflow for taking academic products into the market.

To achieve commercial biofabrication, we have developed a high-end laser-based bioprinting method, allowing the deposition of picoliter-size drops of viscous bioink s (100s cP) containing single cells at high density. This continuous laser-induced-forward-transfer (co-LIFT) technique can print multiple bioinks simultaneously at high speed with controlled drop-size and high (>95%) cell viability. The co-LIFT bioprinter is incorporated into a 3D platform combining additional bio-fabrication technologies. We present the development of first bio- fabricated corneal endothelial grafts that are currently in preclinical studies. Other ophthalmologic tissues are in development and this biofabrication platform can be adapted to other tissues and organs.

The biofabricated corneal grafts are indicated for the treatment of corneal endothelial cell dysfunction that leads to corneal edema and blindness. Human donor corneal endothelial cells are expanded under GMP compliant conditions and bioprinted onto an ultra-thin collagen scaffold (10µm) at high cell density (~2700 cells/mm2) while maintaining biological activity. These grafts are easily implantable and reduce corneal swelling in a rabbit model of corneal endothelial dysfunction. Importantly, one donor may produce up to a hundred corneal grafts, thus potentially alleviating the corneal shortage.

Precise-Bio demonstrates here the ability to produce functional corneal endothelial implants, which can be extended to biofabricate other tissues for upscaling towards commercialization.

Biomaterials-based approaches exhibit great promise for regeneration of musculoskeletal tissues [1]. For these strategies, 3D printing techniques can deliver unprecedented control over architecture and properties of biomaterial constructs when combined with innovative material design strategies. Among different biomaterial categories, hydrogels have especially received significant interest for use in 3D printing of tissue engineering constructs [2], as they mimic various aspects of natural extracellular matrix. Unlike conventional (hydro)gels, colloidal gels are entirely assembled from particulate building blocks, enabling their use as modular biomaterial platforms. Although colloidal gels made of polymeric nanoparticles are attractive injectable and self-healing systems for tissue regeneration [3-5], their use as bio-inks for extrusion-based printing is largely unexplored.

Here, we report the development of photo-crosslinkable colloidal gels composed of photo-reactive gelatin nanoparticles for use as bio-inks for extrusion-based 3D printing. These nanoparticles are stabilized with intraparticle covalent crosslinks, and also contain pendant methacryloyl groups. While non-covalent interactions between nanoparticles enable formation of colloidal inks that are printable at room temperature, UV-induced covalent interparticle crosslinks based on methacryloyl moieties significantly enhance mechanical properties of printed constructs. Additionally, the UV crosslinking modality enables remarkable control over swelling, degradation, and biomolecule release behavior of the constructs. Finally, by exploiting the mechanical properties of UV-crosslinked colloidal gels, 3D constructs can be designed with shape memory behavior, returning to their original programmed shape upon re-hydration. Accordingly, these novel colloidal inks exhibit great potential to serve as bio-inks for 3D printing of biomaterials with shape-morphing features for applications such as bone tissue engineering.

3D-printed personalised scaffolds are an attractive approach for mandibular bone repair. The challenging loading environment of this site requires biomaterials with suitable mechanical resilience, which may be provided via the addition of flexible materials such as thermoplastic polyurethane (TPU). This work aims to create a 3D printable personalised scaffold with a configurable layered composition, enhanced mechanical properties and improved cell adhesion. Varying combinations of PLGA (20-30%) and β-TCP (20%) are mixed with or without TPU (0-30%) in ethylene carbonate (EC) to obtain a printable ink (RegenHu Discovery®). Following water-mediated EC removal, surface microporosity and cytotoxicity is assessed using SEM and CellTiter-Blue®, respectively (Figure1A). A 3D model of a mandibular defect is derived from CT scans, then sliced and modified with CAD to obtain LEGO®-like structures. The personalised scaffolds are printed as a series of layers incorporating an interlocking mechanism (Figure1B). Scaffolds with precise and interconnected filaments can be printed using 30% PLGA, 20% β-TCP and 15% TPU. Lower PLGA concentrations (≤20%) in the absence of TPU results in brittle scaffolds. NMR confirms complete EC removal and SEM images show surface microporosity, while no cytotoxicity is reported in 3T3 cells. Large scale personalised mandibular implants can be successfully printed and assembled. We propose a novel 3D printable ink for mandibular bone reconstruction as an alternative to ceramics. Ongoing tests aim to demonstrate that the combination of ink composition, printing strategy and LEGO®-like assembly may confer beneficial mechanical properties suitable for mandibular repair, enhanced cell adhesion and efficient seeding of biologics intraoperatively.

Bone loss represents a major clinical challenge, requiring efficient regenerative therapies. Autografts are considered as the optimal treatment, but their limited availability and associated clinical complications have led to the development of synthetic alternatives, including those made from calcium phosphate (CaP) ceramics [1]. Conventionally, testing new biomaterials for bone regeneration has relied on in vitro studies followed by animal testing [2]. Recent advancements in cell culture platforms such as organ-on-chips (OOCs) have introduced new in vitro strategies to predict in vivo microenvironment [3]. We propose an OOC model to mimic biomaterial-driven bone regeneration. We engineered a microfluidic chip mimicking bone and a bone defect site, which aims to study homing of human bone marrow-derived mesenchymal stromal cells (MSCs) from the "host bone bed" into the "defect site" in the presence of biomaterials. Microfluidic chips were fabricated in polydimethylsiloxane using a two-step soft-lithography process [4]. The chips comprised a central chamber with independent inlet/outlet, mimicking the bone defect site, and two adjacent host bone bed-mimicking channels at opposite sides of the center chamber separated from the same by lines of pillars with a distance between them of 25 µm. MSCs were seeded and cultured in Matrigel® in the side channels. Migration of the MSCs towards the "defect site"-like central chamber was observed overtime using light microscopy. CaP microparticles (average diameter: 38 µm) were homogenously dispersed inside the central chamber of the chip. Next, we plan to study osteogenic differentiation and matrix deposition of migrated MSCs.

In tissue engineering and regenerative medicine, one of the hardest challenges is to create a relevant physical and chemical microenvironment that promotes cell attachment, proliferation and differentiation in order to enable a tissue-specific extracellular matrix formation. In this work, we present a bioink GelXA CARTILAGE for 3D bioprinting with tuned biomechanical properties to stimulate chondrogenesis.First of all, main bioink components, such as GelMA, alginate and xanthan gum, facilitate high resolution bioprinting at ambient conditions and provide the mechanical versatility of crosslinking. The choice between crosslinking methods (a softer ionic crosslinking, medium photocrosslinking or a stiffer one that combines both) allows stiffness adjustment of the cellular microenvironment to resemble different cartilage tissue zones.Strong interaction between chondrocytes and a matrix biomaterial is essential for chondrogenesis — cartilage tissue development — because chondrocytes comprise only 5% of total tissue volume and do not rely on cell-cell interaction. To achieve this, our bioink contains the necessary cell-matrix interaction components: 1) hyaluronan, an essential component of a cartilage ECM, and 2) laminin 521, regulating intracellular signaling in chondrogenesis by promoting cell adhesion to ECM and proliferation. Cell studies with human chondrocytes from femoral head showed that GelXA CARTILAGE successfully support high cell viability, attachment, and elevated expression level of a cartilage-specific proteoglycan aggrecan that is necessary for osmotic resistance against compressive loads and is a perfect sign of a chondrogenesis process.

Bone has multiple mechanical and metabolic functions that are maintained through lifelong remodeling by osteoclasts and osteoblasts. To study this process while addressing the principle of replacement, reduction and refinement of animal experiments (3Rs), human in vitro bone models are being developed. Despite increasing safety, scientific, and ethical concerns [1], fetal bovine serum (FBS), a nutritional medium supplement, is still routinely used in these models. To comply with the 3Rs and to improve the reproducibility of such in vitro models, xenogeneic-free medium supplements should be investigated [1]. Human platelet lysate (hPL) might be a good alternative as it has been shown to accelerate osteogenic differentiation of mesenchymal stromal cells and improve subsequent mineralization [2, 3]. However, for a human in vitro bone model, hPL should also be able to adequately induce osteoclastogenesis and stimulate subsequent resorption. Here, we compared supplementation with 10% FBS vs. 10%, 5%, and 2.5% hPL for osteoclast formation and resorption by monocytes isolated from human buffy coats (N = 3). After 21 days, monocytes cultured with hPL showed a homogeneous and typical morphology for osteoclast, released significantly more TRAP into the culture medium, and were better capable of resorbing an osteo-assay surface when compared to monocytes cultured with FBS. These effects were visible at all hPL concentrations. Hence, hPL should be considered as a good xenogeneic-free alternative to FBS for in vitro bone models, supporting both osteoblast and osteoclast differentiation.

There is high demand for developing biofabrication techniques to produce native-like corneal 3D structures. Unlike conventional methods, 3D bioprinting enables layer-by-layer assembly of cell-laden bioinks [1]. The current challenge is the lack of printable, cell-laden bioinks. Here, human pluripotent stem cell derived limbal epithelial stem cells (hPSC-LESCs) were used for bioprinting corneal epithelium mimicking structures. A novel bioink for extrusion-based bioprinting of hPSC-LESCs was designed and optimized by combining human and recombinant extracellular matrix proteins. Photocrosslinking with ultraviolet (UV) light and protein thiolation were investigated as crosslinking strategies for increased stability. The UV light exposure and the printing substrate were optimized based on the biocompatibility and cellular response. Transmittance and rheological measurements were used to characterize the transparency and rheological properties of the bioink.

The designed bioink possessed shear thinning properties and demonstrated near excellent transparency (65-75%), according to the corneal transparency classification [2]. The UV exposure did not decrease the cell viability (> 88%), however, it increased the crosslinking density and material stiffness. Because softer bioink and MatrigelTM coating promoted higher hPSC-LESC proliferation and further differentiation, bioprinting without additional photocrosslinking on MatrigelTM coated printing substrate resulted in the most stratified epithelium. No significant difference was observed between the bioink with or without the thiolated protein in the rheological measurements.

This was the first study where the stratification of hPSC-LESCs was observed after extrusion-based 3D bioprinting. The novel bioink showed great potential for bioprinting corneal epithelium mimicking structures using hPSC-LESCs and hold great promise in ocular surface reconstruction.

Three-Dimensional (3D) printing is an established manufacturing method(1). However, the use of 3D printing is limited in industry due to few materials available and the long development and optimisation process. A high throughput methodology has been developed allowing to quickly asses the printability and biocompatibility of a large library of materials(2,3). This method is adapted and used here, to screen a library of 64 PCL-based hyper-branched polymers and determine their suitability in articular cartilage regeneration applications.

To screen the polymer library, their printability (Z parameter) for inkjet printing was first assessed using a liquid handler, able to measure viscosity and surface. The high-throughput assessment of mechanical and biocompatible properties were enabled using a microarray strategy. Surface chemical characterisation was carried out using time-of-flight secondary ion mass spectrometry (ToF-SIMS), while localised mechanical properties (elastic moduli) were determined using atomic force microscopy (AFM). Combination of these techniques with cytotoxicity screening led to the selection of three suitable polymers for the targeted application.

Solubility in DMF and printability determination led to the selection of around 60% of the tested library. Subsequently, the polymer arrays were fabricated by contact printing using super hydrophilic/hydrophobic glass slides as substrate. ToF-Sims surface analysis ruled out any chemical contaminations and confirmed the deposition of the desired polymers. Assessment of the mechanical properties and cytotoxicity screening led to the selection of three materials. Preliminary printing essays were undertaken. The polymer library showed interesting mechanical properties matching human articular cartilage (2-7 GPa) and demonstrated the feasibility of manufacturing such scaffolds.

REPLACEMENT OF MATRIGEL BY HUMAN PLACENTA ECM FOR BIOPRINTING APPLICATIONS

Johanna Berg[P][1], Viola Röhrs[1], Johannes Hackethal[2], Jens Kurreck[1]

Bioprinting is a popular technology to generate three-dimensional humanized tissue models, which facilitate human specific research and can help to reduce animal experiments or even replace them. However, cell laden printed biomaterials, called bioinks, often contain the animal derived extracellular matrix (ECM) analogue Matrigel (a). Although frequently used in a wide variety of applications, its xenogenic origin from murine tumor limits the therapeutical potential and relevance for human specific approaches. Due to its complex composition ECM obtained from human placenta has great potential as xenofree ECM analogue in bioprinting strategies (b,c). Here we printed liver cells (HepaRG) in an alginate/gelatin bioink reinforced with either 40 % human placenta ECM; 20 % Matrigel or without further protein supplementation and cultured them for 21 days. Viability measurements and expression of hepato-specific markers (albumin, CYP3A4) showed comparable results between cells printed in Matrigel or placenta ECM conditions. Immunohistochemical analysis showed differences in distribution and morphology of the cells. Cells printed in Matrigel formed less, but bigger clusters of cells whereas cells printed in placenta ECM formed more, though smaller homogenously distributed cell clusters. Interestingly, release of IL-8 initially was lower after printing HepaRG cells under Matrigel conditions and became higher during the cultivation period. Placenta ECM conditioned cells revealed a complementary IL-8 expression profile, with higher release after printing, which became lower during culture. Even though further analysis must be made, placenta ECM reinforced bioinks are a promising approach to bioprint translationally relevant, functional human tissue models.

THE MECHANO-RESPONSE OF TISSUE-ENGINEERED HEPARAN-SULFATE DEFICIENT CARTILAGE: AN ANTI-APOPTOTIC EXPRESSION SIGNATURE AT ELEVATED PROTEOGLYCAN PRODUCTION

Matthias Gerstner$_P$[1], Ann-Christine Severmann[2], Andrea Vortkamp[2], Wiltrud Richter[1]

Purpose: Osteoarthritis (OA), a major cause of disability world-wide, still evades efficient pharmacological or cellular therapies. Severe cartilage degeneration precedes the loss of mobility and disabling pain perception in affected joints. Recent studies showed that heparan-sulfate deficiency (HS^-) protects cartilage from OA in animal models of joint-destabilization, but underlying mechanisms remained unknown (1-3). We aimed to clarify whether low HS-content alters the mechano-response of chondrocytes and to uncover pathways relevant for chondro-protection.

Methods: Tissue-engineered HS^--cartilage was generated from murine rib chondrocytes hypomorphic in HS-synthesizing Exostosin1 (Ext1). Chondrocytes matured in agarose over 2 weeks were exposed to cyclic unconfined compression in a bioreactor. The molecular loading-response was determined by transcriptome profiling, bioinformatic-data processing and qPCR/WB.

Results: During maturation, HS^--chondrocytes expressed 3-6% of wildtype Ext1-levels, raised Sox9, Col2a1 and Acan like controls but synthesized and deposited 50% more GAG/DNA. Their TGF-ß and FGF2-sensitivity was similar to wildtype but the BMP-response was enhanced according to Western Blotting. Loading similarly activated mechano-sensitive ERK and P38-signaling in wildtype and HS^--chondrocytes. Transcriptome analysis reflected regulation of locomotion as major load-induced biological process and similar stimulation of novel mechano-regulated genes Inhba, Timp1, Ngf, Fosl1, Dhrs9 and Itgα5 in both groups was confirmed. Intriguingly, only HS^--cartilage responded to loading by an expression signature related to negative regulation of apoptosis with the apoptosis-regulator Bnip3 being exclusively downregulated in HS^--cartilage.

Conclusion: HS-deficiency enabled an anti-apoptotic impact of loading and enhanced the BMP-sensitivity plus GAG-production of chondrocytes all of which may protect HS^--cartilage from mechano-induced erosion.

Neurospheres created from patient-specific NSCs (neural stem cells) are a promising tool for cell replacement therapy or neurodegenerative diseases modeling. It is known that brain diseases are accompanied by changes in many cellular parameters, including their metabolic activity. In our work, we studied the metabolic status of healthy NSCs and NSCs with Down syndrome cultivated in three-dimensional conditions. To solve this problem, an analysis of the redox ratio (FAD/NAD(P)H), fluorescence lifetimes and fluorescence lifetimes contributions free and bound forms of NAD(P)H was carried out using fluorescence microscopy and FLIM (Fluorescence Lifetime Imaging Microscopy). Evaluation of the redox ratio showed that the values of this parameter are higher in neurospheres created from healthy NSCs, with an average value of 0.13 ± 0.02, compared with neurospheres with Down's syndrome, where hererogenicity is observed for this parameter with an increase from the periphery to the center (0, 05 ± 0.01 and 0.07 ± 0.01, respectively). This indicates that neurospheres with Down's syndrome are characterized by a more glycolytic phenotype than healthy ones. In addition, we demonstrated that NSCs with Down syndrome in the 3D model are characterized by lower a2 values (27.18 ± 1.16) than healthy NSCs cultivated under identical conditions (32.33 ± 1.42), which indicates their more glycolytic status, which is consistent with the redox ratio data. Thus, the metabolic status, assessed by optical imaging methods, can be used as a parameter for non-invasive non-contrast assessment of cells in neurodegenerative diseases modeling.

Skin injuries due to trauma or disease can be healed by the body via a complex series of events but often require clinical intervention. However, current treatment options are frequently not sufficient and evaluation of new treatment concepts remains difficult due to ethical concerns regarding animal models or lack of control over the properties of collagen-based skin equivalents.1 In this work, we are therefore developing 3D skin equivalents based on a highly controllable polyvinyl alcohol (PVA) hydrogel system that is photo-crosslinked by different matrix metalloproteinase (MMP)-sensitive pep-tides (GP and VP).2 The hydrogels were characterized for mechanical properties, and the viability of human dermal fibroblasts as well as matrix secretion were assessed over the culture period of 28 days. Despite using peptides with different MMP-sensitivity, cell-free hydrogels crosslinked with the same peptide concentration shared similar storage moduli, while higher cell viability, enhanced cell spreading as well as higher collagen production was observed in VP gels. These results suggest that the mechanical properties of the PVA hydrogel system are tunable by peptide concentration but are independent on the peptide sequence , providing a versatile platform for research on the biological effects of peptides. The VP peptide, being proteolytically more sensitive to MMPs, facilitated a faster degradation of the hydrogels, which is essential to allow for cell proliferation and spreading within this 3D environment. Further exploration of keratinocyte-fibroblast interactions based on this PVA hydrogel platform with tunable cellular responsiveness and promoted matrix secretion will facilitate the development of 3D skin equivalents.

Background: Critical-sized cartilage defects require therapeutic intervention to promote healing. In our lab, we use tissue engineering strategies to address this by delivering pro-chondrogenic nucleic acid-based therapeutic nanoparticles (NPs) using 3D-printed (3DP) bioinks and scaffolds(1-3). However, clinical translation of these products may prove challenging due to a short shelf-life. Thus, this study aims to investigate lyophilisation as a process to enable stable storage of therapeutic NPs as novel 'off-the-shelf' formulations for incorporation into 3DP bioinks.

Methods: NPs consisting of a glycosaminoglycan-enhanced transduction (GET) peptide non-viral delivery vector complexed with plasmid DNA (pDNA) encoding for the reporter Gaussia luciferase were formulated at increasing charge ratios (CRs - 6, 9, 12) of peptide to pDNA and lyophilised using two respective cycles - a short cycle (SC)(4) and long cycle (LC)(5). NP physiochemical properties were determined. Rat MSCs were then transfected with SC and LC lyophilised NPs (L-NPs) and compared against freshly complexed NPs (F-NPs). Transfection efficiency and cell metabolic activity were determined over 72hrs. Long-term stability studies over 6mnths are ongoing.

Results: There was no significant difference in NP size, polydispersity or charge across groups at each CR. Comparable levels of transfection efficiency were achieved with SC L-NPs, LC L-NPs and F-NPs at CR 6 and 9 with no significant difference in cell metabolic activity.

Conclusions: Lyophilisation shows promise in ensuring stable storage and functionality of therapeutic NPs, paving the way for formulating clinically translatable 'off-the-shelf' gene-activated bioinks and 3DP scaffolds for cartilage repair.

The ability to regenerate damaged cartilage capable of long-term performance in an active joint remains an unmet clinical challenge in cartilage tissue engineering. Biomimetic implants have shown potential to direct high-quality cartilage tissue formation and to modulate key hypertrophic tissue/cellular events associated to endochondral bone formation1. In particular, type I collagen-hyaluronate (CHyA) scaffolds have demonstrated significant chondrogenic regenerative capacity preclinically2 and clinically3. However, the potential of these implants to a chondro-instructive higher quality cartilage tissue regeneration can be enhanced. The aim of this work was to investigate the incorporation of type II collagen (Coll2) (a potential chondro-inductive component4) within type I collagen (Coll1) and CHyA scaffolds and to assess its role in developing high-quality and long-term cartilage tissue formation. Coll1 and CHyA scaffolds in presence or absence of Coll2 were manufactured and cultured in vitro with human mesenchymal stem cells (hMSCs) for 28 days. The incorporation of Coll2 to Coll1 and CHyA scaffolds improved an early cartilaginous tissue formation and reduced hypertrophic tissue/cellular events in cartilage formation. In particular, the incorporation of Coll2 significantly decreased the expression of type X collagen protein by the hMSCs compared to Coll1 and CHyA scaffolds. Moreover, the incorporation of Coll2 to Coll1 scaffolds in combination with hyaluronate (HyA) led Coll2-CHyA scaffolds to the greatest expression of type II collagen protein by the cells. In summary, the incorporation of Coll2 to CHyA scaffolds demonstrated to improve cartilage regeneration and to indicate Coll2-CHyA scaffolds as prospective biomimetic implants capable to regenerate damaged cartilage for long-term performances.

Astrocytes (AC) and Schwann cells (SC) are mutually repulsive glial cell populations of the central and peripheral nervous system, respectively. They juxtapose at spinal nerve root entry zones or in areas of spinal cord following severe traumatic injuries, where they establish a barrier that allows regenerative axonal growth from the AC to the SC territory but not in the other direction. The confrontation assay reproduces some of these growth inhibitory cell-cell interactions in vitro and is frequently used to test the barrier-modifying properties of potential therapeutic agents. However, so far only moderate success has been achieved. Here, the effectiveness of highly orientated electrospun polycaprolactone (PCL) nanofibers in over-riding this barrier is demonstrated. The elastic band spacer (EBS) technique was used to set up confrontation assays between AC and SC in the absence or presence of PCL nanofibers. The interface established between AC and SC in the absence of nanofibers showed only minor cell intermingling and acted as effective barrier to neurites derived from early post-natal dorsal root ganglia attempting to cross from the SC into the AC territory. In the presence of nanofibers, however, AC and SC adopted highly orientated morphologies and intermingled extensively, blurring the otherwise defined interface. In consequence, substantial numbers of neurites were able to cross the interface and extend for long distances into the AC territory. This observation reflects the first demonstration of non-functionalized nanofibers providing a bioengineered nanotopography that can over-ride the mutually repulsive nature of these cells in a model of nervous tissue scarring.

Mesenchymal stromal/stem cells (MSC) hold great promise as treatment for osteoarthritis (OA) due to their immunomodulatory and regenerative capacities. Growing evidence shows that part of these effects are induced by extracellular vesicles (EVs). Here, we investigated whether MSC-derived EVs have anti-inflammatory and pro-regenerative properties in a rat high fat diet model for OA.

36 male rats were fed a high fat diet for 24 weeks and received groove surgery in week 12 to induce OA. One week after surgery rats were treated with either PBS, 2 million MSCs or EVs derived from 2 million MSCs. Pain behavior was monitored during the study and uCT scans were made at week 0 and week 24. Knee joints were harvested for histology to determine the OARSI histopathological score for rats.

Pain behavior showed no difference between the three treatment groups. On uCT the mean osteophyte number was slightly lower in the MSC group and cartilage mineralizations were observed in 9 of 12 animals in the PBS and MSC group and in 5 of 12 animals in the MSC-EV group. Total mineralization diameter was lowest in the MSC-EV group, but not statistically significant. Histological evaluation is ongoing.

In conclusion, we see little significant differences between treatments on uCT or von Frey test. However, we observe a large spread in the MSC and MSC-EV treated groups, possibly indicating that individual animals are responding differently. Before solid conclusions can be drawn a complete picture of the joint damage including cartilage and synovium is needed.

It is widely accepted that the molecular composition of the extracellular matrix (ECM) and its inherent topographical cues influence cell migration in important processes such as wound healing and functional tissue regeneration. Current tissue engineering strategies for the repair of neurotmesis-type injuries of the peripheral nervous system (PNS) include directional cues (e.g. micro- or nanofibers) for orchestrating efficient regenerative growth. Further developments in such bioengineered materials require the use of quantifiable in vitro assays that are suitable for demonstrating the effectiveness of changes in ECM composition and/or application of topographical cues. Most popular in vitro migration assays monitor cell movement into a well-defined cell exclusion zone (CEZ) but are either not ideally suited or have not been tested for their ability to preserve the ECM substrate or its topographical features. The present investigation introduces the elastic band spacer (EBS) technique, an easy to use, economical and highly standardized migration assay based on the use of commercially available elastic bands for the generation of well-defined CEZs. The EBS technique preserves the ECM substrate of poly-L-lysine/fibronectin-coated glass coverslips as well as 2.5D nanotopography provided by arrays of adherent electrospun polycaprolactone (PCL) nanofibers whereas commercial adhesive silicon inserts and the popular scratch assay cause substantial disruption of the substrate. Application of the EBS approach in CEZ assays in the absence or presence of PCL nanofibres was validated monitoring the migratory behaviour of perineurial cells and Schwann cells, both of which are known to play important roles in PNS regeneration.

LINKAGE OF BMP-2 AND NANOPARTICLES FOR ENHANCED BONE REGENERATION: BMP-2 DOSE FINDING AND BIOCOMPATIBILITY TESTING OF NANOPARTICLES

Lena-Christin Ingwersen[P][1], Doris Hansmann[1], Rainer Bader[1], Anika Jonitz-Heincke[1]

Bone morphogenetic protein (BMP-)2 promotes osteogenic differentiation [1] whereas this can mainly be observed in clinical trials for doses in the milligram range [2]. Tissue engineering strategies aim for carrier systems for BMP-2 delivery to reduce negative side effects of high BMP-2 doses like ectopic growth and carcinogenicity [2,3]. The aim was to find appropriate BMP-2 doses and nanoparticles with a high biocompatibility for linkage and a controlled BMP-2 release.
The effect of BMP-2 (0.1, 1 or 10 µg/ml) was tested in human osteoblasts (n=6) for up to seven days. Metabolic and alkaline phosphatase (ALP) activities and gene expression of collagen 1 (COL1A1), ALP, BMP-2 and osteopontin (OP) were analyzed. In addition, the biocompatibility of silica and PLA nanoparticles (both: 500 nm diameter) in osteoblasts was determined via gene expression analysis, ALP activity and interleukin (IL)6 and 8 protein quantification.
Mainly exposure to 10 µg/ml BMP-2 resulted in significantly decreased metabolic ($p=0.012$) and increased ALP activity ($p= 0.012$). COL1A1 expression was decreased and ALP-, BMP-2- and OP-mRNA (all: $p=0.028$) were increased. While PLA nanoparticle biocompatibility analysis showed only a slight effect on gene expression and protein secretion in osteoblasts, silica nanoparticles induced a strong immune response at both gene expression and protein level with respect to IL6 and IL8 secretion.
Due to the good biocompatibility of PLA nanoparticles and the osteoinductive effect of low dose BMP-2, these parameters will be used for linkage to ensure a controlled release which will be evaluated in further studies.

Keywords

BMP-2; osteogenic differentiation; nanoparticles

DESIGNING AN IN VITRO ANGIOGENESIS MODEL FROM PORCINE ARTERIAL ECM HYDROGEL FOR LONG-TERM HIGH THROUGHPUT RESEARCH

Tzila Davidovp[1], Marcelle Machluf[1]

[1] *Technion - Biotechnology and Food Engineering*

Corresponding author's email: tzila937@campus.technion.ac.il

Angiogenesis is a developmental process that plays a fundamental role in tissue development and different abnormalities and is, therefore, extensively studied worldwide to provide deep understandings of its ruling mechanisms. Low-cost high throughput research of angiogenesis is applied in In vitro models that offer the benefit of the use of human cells while sparing animal lives. Nevertheless, only temporal vessel formation is available in current in vitro models and, consequently, limited to a few days' assays. Considering these limitations, this study examines the hypothesis in which the mimicking of the physiological artery microenvironment can provide longer and more reliable angiogenesis processes in vitro. To this end, the development of a porcine arterial extracellular matrix (paECM) hydrogel is presented, followed by its characterization in terms of composition, structure, and mechanical properties that confirms the preservation of important characteristics of the arterial ECM. This unique hydrogel was then tailored into an angiogenesis model comprising endothelial and supporting cells, in a configuration that allowed high throughput quantitative analysis of cell viability and proliferation, cell migration, and apoptosis, revealing the advantages of paECM over frequently used biomaterials. Particularly, when applied with well-known angiogenesis effectors, the model enabled to measure and reflect the expected response of the effectors. Hence, validating its efficacy and establishing its potential as a promising tool for angiogenesis research.

ENGINEERING PORCINE EXTRACELLULAR MATRIX HYDROGELS AS A TISSUE-SPECIFIC BIOACTIVE MICROENVIRONMENT FOR REGENERATIVE MEDICINE

Tzila Davidov[1], Marcelle Machluf[1]

[1] *Technion - Biotechnology and Food Engineering*

Corresponding author's email: tzila937@campus.technion.ac.il

Injectable cell delivery systems for regenerative therapy offer a minimally invasive administration while shielding and retaining the transplanted cells. Furthermore, the use of biomimetic delivery systems can increase cell survival and re-acclimating in the tissue. Due to its unique bioactivity, porcine extracellular matrix (pECM) —the natural bed of cells in the tissues—holds a great promise as a biomaterial for cell delivery. Our aim was, therefore, to develop tissue-specific pECM-based injectable systems for cell delivery. ECM, isolated from different porcine tissues was enzymatically processed into thermally induced pECM hydrogels, which were further assessed to investigate their distinctive properties, and their consequent ability to support cells for biomedical applications. In terms of composition, each hydrogel had preserved the main collagens and GAGs of its original tissue. Nevertheless, the collagenous profile varied between the different pECM hydrogels leading to microstructural differences in porosity and fiber size distribution. The rheological properties of the hydrogels were also evaluated, revealing soft gel behavior that varied in strength according to the pECM tissue of origin. These hydrogel characteristics highly affected their interactions with cells demonstrated through the different morphology and viability of mesenchymal stem cells (MSCs). Most importantly, the different hydrogels guided a tissue-specific spontaneous differentiation of human-induced pluripotent stem cells (hiPSCs), demonstrated through immunostaining and CEL-Seq analyses for tissue-specific gene expression.

To conclude, pECM-based cell delivery systems benefit unique, tissue-specific attributes that affect their properties and interactions with resident cells and generate a natural supportive bed for improved cell function and in vivo transplantation outcomes.

Vascularization of engineered scaffolds remains a critical obstacle hindering tissue engineering translation from the bench to the clinic. We previously demonstrated the robust micro-vascularization of collagen hydrogels with induced pluripotent stem cell (iPSC)-derived endothelial progenitors; however, physically cross-linked collagen hydrogels compact rapidly and exhibit limited strength [1]. We have synthesized an interpenetrating polymer network (IPN) hydrogel comprised of collagen and norbornene-modified hyaluronic acid (NorHA) to address these challenges [2]. This dual-network hydrogel combines the natural cues presented by collagen's binding sites and extracellular matrix (ECM)-mimicking fibrous architecture with the in situ modularity and chemical cross-linking of NorHA. We modulated the IPN hydrogel's stiffness and degradability by varying the concentration and sequence, respectively, of the NorHA peptide cross-linker. Rheological characterization of the photo-mediated gelation process revealed that the IPN hydrogel's stiffness increased with cross-linker concentration and was decoupled from the bulk NorHA content. Conversely, the swelling of the IPN hydrogel decreased linearly with increasing cross-linker concentration. Collagen microarchitecture remained relatively unchanged across cross-linking conditions, although the addition of NorHA delayed collagen fibrillogenesis. Upon iPSC-derived endothelial progenitor encapsulation, robust, lumenized microvascular networks developed in IPN hydrogels over two weeks. Subsequent computational analysis showed that an initial rise in stiffness increased the number of branch points and vessels, but vascular growth was suppressed in high stiffness IPN hydrogels. These results suggest that an IPN hydrogel consisting of collagen and NorHA is highly tunable, compaction resistant, and capable of supporting vasculogenesis.

Guided bone regeneration (GBR) is an attractive technique for restoring oral bone defects, where an occlusive membrane provides space maintenance required to seclude soft tissue infiltration. However, bone regeneration can be impeded by a lack of an adequate tissue vascularization and/or by bacterial contamination. A bone inspired coating made of calcium phosphate-chitosan-hyaluronic acid was built on one side of a GBR collagen membrane. The resulting hybrid coating is composed of amorphous calcium phosphate and carbonated poorly crystalline hydroxyapatite, wrapped within chitosan/hyaluronic acid complex. Hybrid coated membrane possesses excellent bioactivity and capability of inducing an overwhelmingly positive response of stromal cells and monocytes in favor of bone regeneration [1,2,3,4]. Furthermore, the hybrid coating disturbs the cell wall integrity of Gram-positive and Gram-negative bacteria. Its combination with stromal cells, able to release antibacterial agents and mediators of the innate immune response, constitutes an excellent strategy for fighting bacteria [5]. A preclinical in vivo study was therefore conducted in rat calvaria bone defect for 8 weeks. µCT reconstructions showed that hybrid coated membrane favored bone regeneration (two-fold increase in bone volume / total volume ratios vs. uncoated membrane). The histological characterizations revealed the presence of mineralized collagen (Masson's Trichrome and Von Kossa stain) which was not fully organized (second harmonic analysis), but immunohistochemistry analysis highlighted a bone vascularization. Finally, Raman spectroscopy and biomechanical characterizations are in progress. This bioinspired hybrid coating provides a suitable environment for bone regeneration and vascularization, as well as an ideal strategy to prevent bone implant-associated infections.

Upon reaching an injured site, mesenchymal stem cells (MSCs) are known to regulate the innate immune response of host and exerting antibacterial effects. However, few studies reported that bacteria as commensal Cutibacterium acnes (C. acnes) hidden from the immune response, inside MSCs, could cause implant-associated infection1,2. The present study hypothesizes that bone marrow could be contaminated during bone surgery with C. acnes and MSCs might serve as a protective niche for C. acnes.

Human bone marrow MSCs were challenged with two clinical and one laboratory C. acnes strains at MOI 30:13. Whatever their origin, C. acnes were able to invade MSCs, inducing the potential transition of commensal C. acnes to an opportunistic pathogen (i.e. by increasing biofilm formation and resistance of macrophage phagocytosis). Although direct and indirect antibacterial effects of MSCs secretome were not enhanced following C. acnes infection, C. acnes strains affect MSCs paracrine activities by promoting the secretion of immunomodulatory mediators and pro-healing growth factors: following 48h post-infection, a significant increase in IL-6, IL-8, PGE-2, VEGF, TGF-β and HGF release in infected MSCs supernatant was observed. IL-1$\beta$and TNF-α were not detected in all studied conditions. Moreover, an increase in OPG production suggested that MSCs/C. acnes interaction hinders bone homeostasis.

These results showed a direct impact of C. acnes on bone marrow MSCs, providing new insights into the development of C. acnes during implant-associated infections. Additional experiments using osteoblasts or osteoclasts co-cultures are required to state about the effect of C. acnes infection on bone healing and remodelling.

Collagen hydrogels, fabricated from low concentrated collagen solutions, are characterized by poor mechanical properties and low physical stability1. To circumvent these drawbacks, high collagen concentrations can be used but this increases cell mortality due to poor diffusion of nutrients and oxygen2. Moreover, cells such as cardiomyocytes or neurons only grow and organize themselves on anisotropic substrates3,4. The aim of this study was to develop a novel 3D printing technique using dense collagen solutions to design macroporous and anisotropic hydrogels. By modification of the extrusion velocity and the gelling method, diameter of aligned fibrils and hydrogel mechanical properties could be tuned. The phosphate buffer enabled anisotropy occurrence as observed by polarized light and SHG microscopy. To increase mechanical properties, the phosphate buffer gelation was combined with ammonia vapors to reach Young's moduli of physiological extracellular matrices (10 kPa). Fibroblasts seeded on top of anisotropic hydrogels aligned along the axis of 3D printed constructs. In addition, the process enabled to generate an intrinsic porosity of 20-40 µm in diameter between the different layers. This porosity is an asset for vascularization or neuronal guidance. To increase the scaffold porosity, the addition of macroporous channels with sacrificial matrix printing or needles molding created larger channels ranging from 100 to 500 µm. These bigger channels were adequate for the 3D organotypic organization of cardiomyocytes. Taken together, these results demonstrate the usefulness of 3D printing of dense collagen solutions to develop anisotropic and porous biomimetic scaffolds for tissue engineering applications.

Keywords

3D printing; anisotropy; porosity

Volumetric muscle loss (VML) is the traumatic or surgical loss of skeletal muscle beyond the inherent regenerative capacity of the body, generally leading to severe functional deficit. Formation of appropriate motor innervations remain one of the biggest challenges for both autologous grafts as well as tissue-engineered muscle constructs. We have recently fabricated Innervated Tissue Engineered Muscle (InTEM) comprising networks of spinal motor neurons and skeletal myocytes on aligned nanofibrous sheets. Pre-innervation resulted in formation of neuromuscular junctions in vitro as well as promoted myocyte fusion. Subsequently, the InTEMs were implanted in a rodent VML model and exhibited structural integrity and cell survival up to three weeks post repair. InTEMs significantly increased satellite cell density, neuromuscular junction maintenance, graft revascularization, and muscle volume over three weeks as compared to myocyte-only constructs and nanofiber scaffolds alone. These pro-regenerative effects can potentially enhance neuromuscular regeneration following VML, thereby improving the levels of functional recovery following these devastating injuries. Considering that bulk restoration is a major challenge following VML, we are working towards scaling up the InTEMs to fabricate thicker constructs by stacking multiple layers of cell laden nanofiber sheets. Further, we demonstrate fabrication of InTEMs using primary human skeletal myocytes and iPSC derived motor neurons to augment potential clinical translation of InTEMs using patient specific cell populations. These human InTEMs are being studied in a clinically relevant delayed repair model of VML so as to provide trauma surgeons, a patient specific solution to repair VML grade musculoskeletal injuries and facilitate functional restoration.

Photocrosslinking enables precise control over shape fixation in extrusion-based 3D bioprinting. However, most photocrosslinking processes entail propagation of free radicals with potential toxicity or longer-term impact on cell function. The aim of this study was to introduce a bioink undergoing a rapid photoinitiator-free photocrosslinking process without propagation of free radicals. The system is based on the coumarin derivatives of hyaluronic acid (HA) and gelatin (Gel), undergoing photodimerization.

Coumarin-modified HA and Gel characterized via NMR were used to prepare a range of formulations for an optimization parametric study; crosslinked HA was added as viscoelastic enhancer. Rheological properties (viscosity curve, elastic recovery, gelation time) were assessed using the AntonPaar Rheometer. Printability was assessed (3D Discovery, RegenHU) evaluating filament formation, uniformity and spreading, and the ability of the printed filament to support itself when printed over pillars (2-8 mm). Cytocompatibility was tested according to ISO 10993-5:2012 with Alamar blue on Balb/3T3 cell line.

The dimerization mechanism of coumarin moieties upon near-UV irradiation (365 nm) via photocycloaddition reaction did not form any by-products. Shear thinning behavior and instantaneous elastic recovery has been proven for several formulations. Upon extrusion, a uniform filament with little spreading was achieved, thus indicating high shape fidelity. Cell viability ranged between 77% (undiluted samples) and 100%. High cell viability was shown after encapsulated in different formulations. Differentiation of human mesenchymal stromal cells in these bioinks towards different lineages is currently under investigation.

The photo-initiator free bioink platform here introduced expands the possibilities of using biofabrication approaches for soft tissue engineering.

Ascending thoracic aortic aneurysm (TAA) is a high incidence pathology, still lacking decryption of the underlying detrimental molecular mechanisms guided by cell-extracellular matrix (ECM) interaction [1]. In this work, we compared different decellularization methods of thoracic aorta (TA). TA samples obtained from healthy donors (n=4, cryopreserved specimen from tissue biobank) or patients affected by TAA undergone surgical aortic replacement (n=3) were treated using either i) snap freezing (24-48hours), ii) anionic detergent (sodium dodecyl sulfate, SDS, 48-72hours 1%w/v), iii) non-ionic detergent (24hours, Triton-X100, 0.1%w/v) followed by SDS (24hours, 0.1%w/v) [2] or iv) snap freezing (24hours) followed by SDS 1%w/v. Decellularization efficacy was evaluated in respect to cell removal and ECM integrity. At this aim, we performed nuclei (DRAQ5) and ECM component (vitronectin, collagen) immunofluorescence, histological analysis (haematoxylin & eosin, Masson's Trichrome) and immunohistochemistry (hydroxyproline). Results lead to identification of one protocol (48hours- SDS1%W/v) able to efficiently remove the cellular component, preserving ECM structure and geometrical organization. Finally, we verified that the selected protocol did not diminish tissue mechanical response, as demonstrated by the absence of statistically relevant differences between native and decellularized tissue in elastic moduli measured by tensile test in aorta radial direction (T-test: E1 p=0.64, E2 p=0.33). On the other side, decellularization procedure induced an increase in tissue permeability , thus supporting its exploitation as novel scaffold for in vitro study of the interaction between aorta resident cells and ECM, in the contest of TAA pathological mechanisms (e.g. mechanotransduction pathways).

Joint diseases such as osteoarthritis are highly prevalent and are often accompanied with synovial inflammation (synovitis), cartilage degradation, and pain. Currently, neither effective disease-modifying drugs nor efficacious and safe medications for long-term pain management are available. To address this unmet medical need, we propose to develop an innervated, human cell-derived microphysiological system for understanding joint pain mechanisms and developing pain medications.Polydimethylsiloxane-based microfluidic chips were fabricated to culture three-dimensional synovium and cartilage tissues engineered from human mesenchymal stem cells (hMSC). Given their crucial role in inducing “synovitis”, macrophages derived from human peripheral blood monocytes were co-encapsulated in the synovial tissue with hMSCs-derived fibroblasts. The real-time synovium-cartilage crosstalk was enabled by a “simulated synovial fluid (SSF)” shared by these two tissues. A separate neuron chamber that housed human or rodent dorsal root ganglion neurons was connected to the synovium chamber via microchannels, through which the neurites extend to innervate the synovium. Of note, neurons were indirectly influenced by cartilage and SSF through synovial tissues. “Synovitis” was induced by polarizing the macrophages toward the proinflammatory M1 phenotype or challenging synovium with the pro-inflammatory cytokine interleukin-1β. The inflamed synovium caused cartilage degradation and the generation of pain mediators, including Prostaglandin E2, tumor necrosis factor-α, and C-telopeptide of type II collagen, in the SSF. Furthermore, the inflamed synovium evoked an increase in calcium efflux in a subpopulation of neurons.These results indicate that this novel innervated, human cell-derived system can be potentially employed for understanding inflammation-mediated joint pain and developing effective pharmaceutic interventions.

The informed consent process for upper extremity (UE) Vascularized Composite Allotransplantation (VCA) has not been standardized. Information provided to patients varies, which may contribute to individuals being inadequately informed and under-prepared for decision making. Therefore, this study examined psychosocial factors affecting decision-making about UE VCA. We conducted in-depth interviews among people with acquired UE amputations. Open-ended questions assessed psychosocial factors informing decision making about UE VCA. Thematic analysis was used to analyze qualitative data. To date, 18 people completed in-depth interviews (82% participation rate), including 3 undergoing UE VCA evaluation. Most were male (78%), had a mean age of 48 years, had a unilateral amputation (78%), and had undergone amputation a mean of 10 years earlier. Fifty percent were 'completely' or 'a lot' willing to pursue VCA. Psychosocial factors influencing decisions to pursue VCA included: regaining functionality and the associated independence; increasing social and physical confidence; and enabling more active parental involvement in childrearing. Psychosocial factors and concerns influencing decisions not to pursue VCA included: health or limb function becoming "worse off" from UE VCA; the rigorous commitment required for undergoing UE VCA and rehabilitating; and having already adapted to life without upper limb(s). Participants would ethically justify getting an UE VCA if the UE VCA success rate was high and risks were low, and if participants currently struggled with managing daily tasks. Preliminary findings suggest that people with UE amputations hold concerns that diminish enthusiasm for UE VCA. Addressing psychosocial concerns may foster informed decision making about UE VCA.

The macrophage is a type of phagocyte that plays a critical role in the immune system. It is well known that macrophage is polarized to tumor-associated macrophage (TAM) and promotes cancer progression and drug resistance in the tumor microenvironment(TME). Although this increasing knowledge on macrophage in the TME, there are technical hurdles to develop in vitro models to simulate immunocompetent TME. Here, we propose simple strategies to develop the 3D breast cancer tumor microenvironment with M2 macrophages via induced GM-CSF and G-CSF expression. To develop in vitro immunocompetent TME for breast cancers, we first formed the 3D multicellular cancer spheroids containing invasive human breast cancer (MDA-MB-231) and THP-1 driven M0 macrophages. Next, we analyzed the 3D multicellular cancer spheroids and found that the 3D architecture of cancer cells induces M2 polarization of macrophages in in vitro immunocompetent TME for breast cancer. Then, we demonstrated enhanced expression of GM-CSF and G-CSF via 3D breast cancer spheroids increases transcript activation of pSTAT-3, pp38, pNf-kB, thereby inducing M2-like macrophage polarization. Finally, we confirmed the enhanced drug resistance by M2-like macrophage polarization in in vitro 3D immunocompetent cancer model. The simple strategy to form in vitro 3D immunocompetent TME developed in this study will contribute to many biological fields constating academies and industries for precise evaluation of cancers.

When we talk about cell culture, we can discriminate between 2D and 3D models. In 2D models, biologists culture cells onto flat glass slides and, although this approach is easy to handle and cheap, it often leads to the formation of unrealistic cell monolayers which do not reproduce the complex 3D spatial configuration that we find in the brain. For this reason, during the last two decades, novel strategies started to emerge and led to the creation of biomimetic 2.5D and 3D cell microenvironments [1]. Among the available fabrication techniques, two photon direct laser writing [2,3] allows the creation of complex architectures by photopolymerizing extremely confined volumes (voxels) via focusing femtosecond laser pulses onto an organic photosensitive pre-polymer material. In this work we report the development of 2.5D and 3D constructs to unveil the behavior of primary microglia cells extracted from primate models. Within ex-vivo models, microglia preserve their natural ramified “resting” state but as soon as they are cultured in a 2D environment, they often assume an “activated” amoeboid configuration. Here we show how artificial structures can promote a higher ramified configuration in vitro

The design of functional scaffolds as transplantable platforms for tissue repair and regeneration requires gaining precise control of surface properties. Here, we propose a new methodology to fabricate hierarchical multiscale nanotopographic scaffolds with controlled hydrophilic properties by employing capillary force lithography in combination with plasma modification. Using our method, we developed biodegradable and biocompatible polymer (i.e., polycaprolactone (PCL))-based multiscale nanotopographic scaffolds with natural extracellular matrix-like hierarchical structures along with flexible and controlled hydrophilic properties by treating nitrogen and oxygen gas plasma. In response to multiscale nanotopography and chemically modified surface, the proliferation and osteogenic mineralization of cells were significantly promoted. Furthermore, the multiscale nanotopographic scaffolds promoted regeneration of the rotator cuff tendon tissue and the calvarial bone tissue in vivo in rat models. Overall, the PCL-based multiscale nanotopographic scaffolds could accelerate soft and hard tissue regeneration. Thus, our proposed methodology was confirmed as an efficient approach for the design and manipulation of scaffolds having a multiscale nanotopography with controlled polymeric surface property.

Cancer metastasis is the major cause of death for malignant tumor nowadays. In the process of cancer metastasis, cancer-associated fibroblasts (CAFs) play a key role in the tumor microenvironment, inclusive of extracellular matrix (ECM) deposition, angiogenesis, tumor proliferation as well as metastasis, and chemoresistance. Nevertheless, many distinct features and interaction between CAFs and cancer cells in the tumor microenvironment, termed the niche, remains unclear. To investigate the mechanism of how CAFs regulate cancer invasion, as well as the estimation of invasion behavior a variety of cancer cells, this research aims to establish a complex biomimetic tumor microenvironment via a nanomaterial based interface with CAFs. In this study, we induced a phase transformation in graphene oxide (GO), leading to different degrees of cluster of oxygen groups and dissimilar efficiency of growth factors conjugation. We found that the GO interface results in ECM deposition, such as collagens, from CAFs, which can be enhanced when the interface is conjugated with platelet-derived growth factor (PDGF), epidermal growth factor (EGF) and transforming growth factor-β (TGFβ). Furthermore, the nanomaterial based interface with CAFs affect the motility features of cancer cells, including migration rate and orientation. Apart from this, clinical samples will be next added into our work to further investigate the cell-cell interaction. Overall, we demonstrate the potential of CAFs with GO for cancer invasion mechanism research, which may possibly be applied in potential drug development targeting CAFs and achieve personalized precision medicine in the future.

Tissue engineered skin constructs are valuable tools for academic and industrial research, to investigate skin physiology and disease, and provide a predictive platform for pre-clinical studies. We have developed advanced, complex skin equivalents that resemble the structure and function of human skin, and have multifaceted applications in skin health research.

To mimic the dermal composition in vitro, primary fibroblasts were incorporated within the porous, polystyrene Alvetex® Scaffold, to synthesise endogenous extracellular matrix proteins. The dermal compartment supports the formation of a differentiated, stratified and keratinised epidermis, with mature barrier properties. Neonatal, young and ageing cells have been used to bioengineer age-specific skin models. Additional cell types such as melanocytes and immune cells have also been successfully incorporated to generate complex skin constructs.

Bioengineered skin equivalents recapitulate the microanatomy of human skin in vitro. Ageing skin equivalents demonstrate an age-related phenotype, with epidermal thinning and reduced synthesis of extracellular matrix proteins.

Complex skin constructs with additional cell types have been generated, with correct strata-specific localisation and functionality. Uniformly pigmented skin constructs contain melanocytes localised to the basal layer, which successfully transfer melanin to neighbouring keratinocytes. These skin models exhibit a darker pigmentation in response to ultraviolet radiation. Immune-competent skin constructs contain Langerhans cells in the epidermis, which are responsive to allergens and irritants.

The advanced, complex skin constructs have been tailored for downstream academic and industrial applications, such as investigating the molecular mechanisms of skin ageing, photoprotection research and determining the efficacy of actives in skin care formulations.

One of the determining factors for the survival of severe burn patient is the rapid wound coverage and definitive closure of burn lesions. Despite the great diversity of approaches, the prognosis for severe burns remains unsatisfactory today with poor skin engraftment that often results in a pathological scar. Since their discovery, Mesenchymal Stromal Cells (MSCs) have aroused growing therapeutic interest for skin repair, thanks to their trophic, their immunomodulatory, their cell matrix remodeling, and their pro-angiogenic properties. The discovery of their plasticity with regard to various environmental stimuli has more recently opened up new therapeutic perspectives, such as priming strategies. Recently, our laboratory showed that IL-1β priming of MSC improves their wound healing potential in a model of skin excision.
In this study, we investigated whether IL-1β-primed MSC could improve autologous skin graft take in a severe burn rat model. Syngeneic IL-1β-primed MSC, derived from bone marrow, were evaluated in a 3rd degree rat burn model. The development of this model was inspired on surgical management of severe burn patient. This treatment consisted in a rapid excision of burned tissue and autologous split-thickness skin graft application to ratio 1:6 concomitants with the subcutaneous injection of MSC. Histology and immunohistochemistry analysis were used to monitor skin graft take, re-epithelialization, epidermis and dermis remodeling, angiogenesis and inflammation. We hope this animal model will help find an innovative MSC based-therapy for severe burn patients.

Introduction: Extracellular vesicles (EVs) are membrane-enclosed vesicles that are secreted by cells and mediate cell–cell communication. EVs may provide opportunities for new tissue engineering (TE) approaches to mimic both the microscopic and molecular in vivo environment and to enhance tissue repair.

Methods: EVs were isolated from the conditioned media of normal oral fibroblast cells in culture. After characterising the size and protein abundance of EVs, they were incorporated into polycaprolactone electrospun scaffolds using conventional adsorption and covalent-attachment based methods. The number of EVs attached to the scaffolds and their release kinetics was examined using nanoparticle-tracking analysis (NTA). The influence of myofibroblast-derived EVs on cell migration was studied using scratch assays.

Results: EVs were successfully isolated by UC and SEC as assessed by NTA and determination of presence of EV marker proteins (CD9, CD63 and CD81). Our functionalisation comparative study indicated that the use of conventional adsorption (achieved after PCL activation) may offer a novel and simple approach for the homogeneous incorporation of EVs. For these cases, NTA showed slow release of 40% of EVs from the scaffolds over 21 days. Myofibroblast-derived EVs significantly increased fibroblast activation and migration compared to untreated controls.

Conclusion: Here we provide evidence that electrospun scaffolds can be functionalised with EVs and provide sustained slow release, offering an opportunity to develop novel, cell-free and tuneable approaches to tissue engineering. We also showed that myo-EV may have a role in wound healing, and that incorporation of myo-EVs in scaffolds may have potential as a regenerative medicine approach.

Purpose: This study aims to clarify the effect of high mobility group box 1 (HMGB1) in promoting healing in a mouse distraction osteogenesis (DO) model.

Methods: The effects of HMGB1 on the proliferative and migratory ability of human bone marrow mesenchymal stem cells (hBMSC) were evaluated in vitro. Osteogenic differentiation capacity was evaluated by alkaline phosphatase (ALP) and Alizarin Red S staining. Moreover, DO was performed on the tibia of the mice. The experiments were divided into three groups: HMGB1 with scaffold transplantation group (HMGB1 group), phosphate-buffered saline (PBS) with scaffold transplantation group (control group), and no transplantation group. New bone and callus formation were evaluated by microCT and hematoxylin and eosin staining. The angiogenesis was evaluated by immunofluorescence on days 10 and 20.

Results: HMGB1 enhanced the migration, mineralization ability, and ALP activity of hBMSC in vitro. HMGB1 group showed more bone formation than the other two groups. In addition, HMGB1 group has been shown to promote angiogenesis in the DO gap. Furthermore, the local HMGB1 application promotes bone healing by accelerating angiogenesis during the DO healing process.

Conclusion: HMGB1 is suggested to have a regenerative activity according to the acceleration of angiogenesis to shorten the healing period during DO.

Tissue regeneration often combine growth factors, cells and biomaterials. Gene therapy is considered to overcome growth factor limitations. pDNA, carried by viral vectors is traditionally used in gene therapy. This often results in risk for mutagenesis. Alternatively, mRNA has been proposed. Chemical modifications to mRNA (cmRNA) can increase its stability and biocompatibility. In order to transfer mRNA to cells, lipid vectors are commonly used. In this study, we evaluated the performance of diverse lipids in delivering cmRNA in vitro.

Lipoplexes were produced by using cmRNAs coding for Metridia Luciferase (MetLuc) and eGFP that were mixed with 6 different lipids. Ratios of cmRNA:Lipid tested were in the range of 0.5:1 to 1:11 (w/v). Doses of cmRNA starting from 0.78 pg/cell up to 50 pg/cell were investigated. For transfection, A549 and HEK293 cells were used. MetLuc expression was assessed by coelenterazine assay at 24-, 48-, and 72-hours post-transfection. PrestoBlue was performed to evaluate cell viability after transfection. Optimal cmRNA concentration at the best performing cmRNA:Lipid ratios were selected to transfect hMSCs. In hMSCs, MetLuc and eGFP expression was evaluated up to 7 days post-transfection. eGFP was assessed by flow cytometry and fluorescent microscopy.

Overall, concentrations of cmRNA >25 pg/cell in ratios >1:5 (cmRNA:Lipid) lead to increased cytotoxicity and decreased functionality. Using 6.25 pg cmRNA per cell in a 1:4 ratio with NL37 and 3D Fect showed to be the most efficient and biocompatible transfection condition. This was confirmed in hMSCs with prolonged expression up to 5 days.

AIR PULSE STIMULATION DEVICE DEVELOPMENT FOR 3D BIO PRINTING RECONSTRUCTED TISSUE

Hugo Marchal-Chaud$_P$[1]

[1] *VetAgro Sup_ Ecole vétérinaire de Marcy l'Etoile (FRANCE)*

Corresponding author's email: hugo.marchalchaud@gmail.com

Several mechanical stimulations have been used to improve the properties of tissue engineered constructs (TEC). The objective of the study was to develop a contactless stimulation process applied during the maturation of a 3D bioprinted dermal tissue. Our hypothesis was that air pulses would induce enough mecanotransduction to modify the mechanical, morphological and structural TEC properties. A dedicated air pulse stimulation device (APS) was developed and validated. The APS delivered an impinging jet with controlled pressure, airflow, speed and impinging height to transmitted waves through the object. The APS was designed by CAD and the 3D printing was manufactured in Acrylonitrile butadiene styrene to be adaptable to every culture plate with a switchable diameter of stimulation. The APC was also designed to ensure the tissue sterility during the stimulation. Range stimulation parameters were determined based on the literature and experimentally by testing the impact on acellular 3D bio-printed construct. Numerical simulation based on both the experimental outlet speed and the mechanical properties of the tissue measured by DMA (Dynamical mechanical Analysis) was perfomed.

Tissues frequently exhibit cellular organization that directs their development and function, and thus it is important to replicate these structural features when seeking to engineer tissue grafts or biological models [1]. We have previously shown that ultrasound standing waves can be used to rapidly and remotely form tunable arrays of viable cells for the engineering of aligned skeletal muscle [2]. Here, we have applied a similar methodology to generate 3D arrays of articular chondrocytes for the engineering of cartilage with deep-zone cytoarchitecture.

We fabricated acoustic cell patterning devices with pairs of piezotransducers to generate programmable ultrasound standing waves. We used these devices to pattern chondrocytes en masse into organized arrays predicted by pressure field modeling. The acoustic patterning process was rapid and reproducible, forming chondrocyte arrays with uniform separation (~111 µm) in under 5 s. Chondrocytes exposed for up to 10 min of ultrasound exhibited no measurable differences in membrane viability or metabolic activity, and retained their capacity for secreting cartilaginous extracellular matrix.

We next acoustically patterned chondrocytes throughout the 3D volume of agarose hydrogels, which we put through an established course of cartilage tissue engineering. Over the course of 35 days, the chondrocytes secreted large quantities of type II collagen and sulfated glycosaminoglycan while remaining in their acoustically-patterned configuration. To the best of our knowledge, this is the first example of an acoustically-patterned cartilage tissue and the first instance in which the deep-zone structure of cartilage has been engineered in vitro.

Tissue engineering is a promising area of regenerative medicine, which aims to repair, replace, and regenerate injured tissues and organs. For this purpose, scaffolds and biological constructs are fabricated to mimic the extracellular matrix of natural tissues. 3D bioprinting is a versatile technology to fabricate these structures. Nowadays, open-source 3D printer projects have made it possible to spread bioprinting at the laboratory scale. Hence, hardware and software developments are required to adapt the available projects to the bioprinting field. In this research, the software BioScaffolds PG V2.0 was developed to generate tool-paths for scaffold fabrication starting from parameterized geometries. The software was programmed using the VB.NET language and is compatible with the Fab@Home and RepRap variants open-source 3D printers. This tool allows obtaining tool-paths to fabricate scaffolds in the 3D printer platform, Petri dishes, and tissue culture plates. Moreover, it works independently from Computer-Aided Design (CAD) software. Consequently, the user can quickly define all the scaffold parameters to obtain a tool-path for bioprinting. The software was initially validated using CAM (Computer-Aided Manufacturing) simulations of the tool-paths. Next, tests were performed using a Fab@Home and a RepRap-based 3D printer with a piston-driven system. A shear-thinning ink was formulated for the validation stage. Finally, a hydrogel-based bioink was used to perform the bioprinting validation. After the validation process, it was concluded that the developed software is a powerful laboratory tool for bioprinting.

Formula of an elixir for oral cavity on the basis of biologically active substances of bee products and natural compounds was developed, which requires detailed study. The study was carried out on a rounded aseptic plane wound.

Animals were divided into 4 groups: group 1 – a model of a plate wound with an untreated surface, group 2 (control) – the wound treated with sterile 0.9 % sodium chloride, group 3 (main) – the wound treated with the new elixir, group 4 (comparative) – the wound surface treated with comparator agent –"Phytopropolis".

Positive dynamics of wound healing was revealed visually in animals that received topical application of hygiene products based on propolis, which was confirmed by a quantitative calculation by the planimetry method.

The difference at the area of wound defect of the animals was determined on the 3rd day of the experiment. On the 7th day, it was determined that the wound area in the main group was significantly reduced as compared to the control and comparison groups. On the 14th day, the reduction of the wound area in the main group was significantly more pronounced as compared to other experimental animals and almost complete healing was observed. The difference in changes at the wound area in rats of the main and comparative group was on the 3rd day – 25.7 %, on the 7th day – 37.5% and on the 14th day – 45.2%.

Reparative activity of the new elixir was determined on the model of wound process.

Keywords

Introduction: Engineered, autologous nasal cartilage grafts have been used recently in a first-in-human clinical trial (ClinicalTrials.gov: NCT01605201) Feasibility and safety were demonstrated, and the first promising clinical and radiological results were recorded up to two years postoperatively (1). We here report on clinical and radiological outcomes five years after implantation.Methods: 10 patients of phase I clinical trial were examined clinically and radiologically after a minimum of 5 years postoperative. Adverse events (AE) were collected. Clinical assessment was made using the KOOS questionnaire, and radiological results were evaluated using the MOCART scoring system. Results: Mean follow up was 63 months postoperatively. Mean age at implantation was 38.8 years, total size of treated cartilage lesions was in average 3.6 cm2. There were no serious adverse reactions 5 years postoperatively.Improvements of KOOS scores from preoperative (66.1) to 2 years (88.5) remained stable at 5 years (90.6). Subscales for Sports and QoL further improved from 2 years (78.00 and 68.13) to 5 years (84.50 and 79.38). Radiological analyzes showed improvements of joint effusion and bone marrow edema, but with overall slightly reduced MOCART scores from 58.8 (2 years) to 51.3 (5 years).Conclusion: This study confirms the safety and feasibility of treating focal cartilage lesions of the knee joint with tissue engineered, autologous nasal cartilage grafts at midterm. Patients benefit at 2 years is maintained over 5 years. Comparative studies with bigger cohort are required to better assess efficacy in comparison to standard therapies.

There are currently no sufficiently effective treatments for ischemic stroke, that leads to the development of innovative approaches such as cell therapy. The aim of the research was to study therapeutic effects of mesenchymal stem cells (MSCs) transplantation on stroke model in rats.

The studies were performed in male rats, which underwent a transient bilateral 20min. ischemia-reperfusion of internal carotid arteries. After modeling the pathology animals were injected with human UC-MSCs (1x106cells) into the femoral vein. Control animals received 0.2 ml of saline. The neurological status of the animals was assessed before ischemia induction and after cell transplantation on days 7 and 14.

Stem cell transplantation in experimental group promoted mortality reduction and animals life prolongation. At the 12th hour of observation (critical period in the development of experimental pathology) mortality in experimental group was 10% vs. 45% in control group ($p<0,05$). On the 7th day, the average score according to the Stroke-index McGrow scale was 7.14 ± 0.19 points in experimental animals vs 11.79 ± 0.48 in control group; on the 14th-4.86 ± 0.15 vs 9,14 ± 0.30($p <0.05$). MSC transplantation achieved active orientation restoration and research behavior indicators of animals. Cytofluorimetric study showed that experimental cell therapy reduced the intensity of nuclear DNA fragmentation in sensorimotor cortex neurons.

Thus, human umbilical cord MSC transplantation lowered mortality, alleviated neurological symptoms and normalized behavioral responses, ie, led to a significant regression of neurological deficits in rats with experimental ischemic stroke.

Corneal transplantation continues to be one of the leading treatments against vision impairments that affect million people worldwide. However, the shortage of donors shows the need of substitutes that mimic the native tissue to promote cell growth and the subsequent tissue regeneration. The current study has focused on the in vitro assessment of protein-based biomaterials that could be a potential source for corneal scaffolds. Collagen and soy protein isolate (SPI) were used to prepare films by compression molding, while solution casting was employed to prepare gelatin films cross-linked with lactose or citric acid. The physical characterization of the films showed transmittance values that met the light transmission needs of the cornea and the in vitro degradation profile revealed a progressive decomposition of the biomaterials in enzymatic and hydrolytic solutions, which could promote the simultaneous integration with the native tissue. Cell viability of human corneal epithelial cells (HCE) and 3T3 fibroblasts was above 70% when exposed to SPI and gelatin films, even after 72 h. Live/dead assays and SEM analysis demonstrated the adhesion of both cell types to the matrixes, with a very similar morphology and arrangement to that observed in controls. Besides, both cell lines were able to proliferate and migrate over the films to a cell-free area, simulating the cell repopulation that would happen in a wound. These results demonstrated that the studied biomaterials could be potential alternatives applicable in corneal bioengineering. Research study supported by grants from the Basque Government (RIS3, 2020333027) and UPV/EHU - ICQO (US19/18).

Introduction

Neovascularization of implants used as scaffolds is crucial for the regeneration of large tissue defects. Hence, the formation of vascular networks is of utmost importance. Photocrosslinkable hydrogels show promise as matrix for the ingrowth of neo-vessels. We integrated the mimicry of placenta, a highly vascularized organ, within gelatin (Gel)-hydrogels. Different Gel-modifications, including Gel-norbornene (Gel-NB) [1] and Gel-allyl glycidyl ether (Gel-AGE) [2] were in situ crosslinked enabling fabrication of complex structures either by extrusion-based 3D-bioprinting or by two-photo-polymerization.[3]

Methods

Gel was modified with 5-norbornene-2,3-dicarboxylic anhydride,N-hydroxysuccinimide-activated 5-norbornene-2-carboxylic acid (Gel-NBs), or allyl glycidyl ether (Gel-AGE) with degrees of modification. Hydrogel formation was monitored by photorheology using lithium phenyl-2,4-6-trimethylbenzoylphosphinate, as photoinitiator and D,L-dithiothreitol or ethoxylated trimethylolpropane tri(3-mercaptopropionate) as crosslinker in aqueous solution (2.5-10 wt%).[4].

Results

Mechanical properties (shear moduli 10-1000 Pa) and swellability (5-40 fold) of the hydrogels depend on the type/degree of modification. Hydrogel vascular network formation with HUVECs was observed when placenta-specific factors were incorporated.

Discussion and Conclusions

The formation of vascular networks could be observed with the prepared hydrogels. For the 3D fabrication of vascularization promoting hydrogel constructs, suitable system is to be found by variation of parameter (modification, crosslinker, gel content etc.).

Introduction

Biodegradable scaffolds for tissue engineering are getting more and more important, including vascular grafts with small-diameter.1 It is often reported, that materials like thermoplasts show good degradation behaviour. In contrast to that the mechanical properties are not sufficient for the intended application. Here, we introduced new hard-block degradable thermoplastic polyurethanes (TPUs) based on a variety of cleavable chain-extenders.2-4 These new materials provide new insights especially on the improvement of mechanical properties for thermoplasts.

Methods

TPUs, based on new developed cleavable chain-extenders, were processed via electrospinning, resulting in highly-porous tubes.2-4 The material itself was characterized in terms of biomechanical properties, degradability, biocompatibility and were tested in vivo.

Results

Different hard-block degradable TPUs were prepared by varying the hard-block components and by adjusting the ratio of these. These novel materials were compared in terms of mechanical properties, degradability and biocompatibility. There is a wide consensus that the mechanical properties are controlled by the hard-blocks and therefore by the choice of isocyanate and chain-extender. Since most biodegradable TPU concepts are based on ester-cleavage of soft-blocks, this concept was adapted for hard-block degradable TPUs by integration of cleavable chain-extenders. Furthermore, the mechanical properties of the materials were improved by introducing moieties, which also have the ability to form strong microcrystalline structures.

Discussion and Conclusions

During this study, we found a combination of TPU components, which results in small-diameter vascular grafts with superior mechanical properties, biocompatibility and degradability in vitro and promising performance in vivo.

Most bone injuries heal without any complication, however, there is an increasing number of cases where bone lesions result in delayed healing or non-union. Current treatments such as autografting and bone graft substitutes containing growth factors have limitations, due to donor site morbidity and dose-related safety concerns, respectively. Additionally, current clinically available bone graft substitutes lack control of spatial architecture to anatomically match defect sites after complex fractures. The aim in this study was to engineer a biomaterial-ink composed of osteoinductive calcium phosphate and matrix biopolymers for delivery of chemically modified RNA inducing nerve, vessel and bone formation using 3D-printing. To this end, a 3D-printed matrix of tyramine modified hyaluronan (HA-Tyramine), combined with a range of nano-hydroxyapatite (nanoHA) particles, was developed. A parametric study comparing formulations with a range of 0-30% w/v nanoHA (size: 10-50x50-400 nm) showed that, the biomaterial-ink formulations of 3.5% w/v HA-Tyramine with 1 U/mL horseradish peroxidase (HRP), 0.17 mM (5.78 ppm) H2O2, and 0.02% w/v Eosin Y are extrudable using a 1.35 mm diameter nozzle. Extrusion of these formulations resulted in the formation of a continuous strut, with good shape retention and without waviness. Swelling and mechanical properties were dependent on nanoHA content. The range of compositions identified will be assessed for in vitro osteogenesis (cell viability, gene expression, protein production and mineralization) using human mesenchymal stem cells (hMSCs). To conclude, this study presents a 3D-printed biomaterial-ink with nanoHA that has the potential as a bone graft substitute for bone regeneration in trauma and osteoporotic patients.

Stromal vascular fraction (SVF) cells, isolated from adipose tissue by enzymatic digestion, represent an attractive cell source for bone tissue engineering. They are easily accessible, abundant and include stromal, endothelial and hematopoietic cells[1]. Previous studies from our laboratory have shown the capacity of expanded-SVF cells to form bone through endochondral ossification (ECO)[2], but little is known about the specific mechanisms involved. Here, we studied the role of in vitro expansion, passaging and accessory cells in ECO by SVF cells.

We compared SVF cells and monolayer-expanded SVF cells, called adipose stromal cells (ASCs). Endothelial and hematopoietic cells were depleted from SVF-cells and ASCs with MACS microbeads. Thereafter, cells were cultured in collagen sponges with growth factors to generate cartilaginous templates (CT) in vitro or analyzed by mass spectrometry. SVF cells showed superior chondrogenic potential when compared to ASCs, as demonstrated by higher amounts of glycosaminoglycan (GAG) and by increased histological quality of the CT. The depletion of endothelial and hematopoietic cells showed limited effects on chondrogenesis. ASCs presented a highly different proteomic profile when compared to SVF cells, notably for pathways related to energy metabolism like glycolysis, TCA cycle and lipid metabolism.

This study evidences the role of metabolism in ECO by adipose-derived cells. Next steps will assess whether a more physiological cell culture environment would better preserve the specific metabolic status of SVF cells and thereby retain their chondrogenic and hypertrophic differentiation potential when expanded. Moreover, we will assess if better CT quality results in an improved remodelling in vivo.

Traumatic brain injury (TBI) is the leading cause of mortality and disability among both young individuals and elderly subjects. Systemic inflammation has been shown to play a dominant role in TBI [1]. Furthermore, during aging, the immune system undergoes a functional priming towards a proinflammatory state that aggravates TBI outcome and response to therapy. Cells from the mesenchymal region of the amniotic membrane (hAMSC) and the conditioned medium generated from their culture (CM-hAMSC) act on cells of the immune system belonging to both innate (dendritic cells, monocytes and macrophages) and adaptive (T and B lymphocytes) immunity, controlling inflammation, proliferation, and cytokines production [2].

Considering the role of the immune system in TBI, we aimed to investigate the immunological changes that occur in peripheral blood mononuclear cells (PBMC) collected 6-24h after TBI in young (18-45 yo) and aged (>65 yo) patients, and how CM-hAMSC acts on these PBMC. Preliminary results show that PBMC from TBI patients have a significantly lower yield and viability after thawing when compared to age-matched controls. Moreover, TBI induced a significant reduction in the frequency of T cells, and an increase of monocytes, compared to healthy donors. Differences in the CD4/CD8 ratio, in the composition of Th subsets (Th1, Th2, Th17, Th22) and in memory T cell subsets (central and effector memory) were observed, and further studies are ongoing to determine the effect of CM-hAMSC on PBMC. Our results could help to better understand the contribution of systemic immune changes to TBI evolution and response to therapy.

INTRODUCTION

Trabecular Meshwork (TM) cells serve as a biological filter by phagocytosing debris accumulated in aqueous humor. The number of TM cells decreases with age and more so in the Primary Open Angle Glaucoma. A cell-based functional restoration of TM, therefore, represents a new therapeutic approach. This study examines different protocols in the ability of induced Pluripotent Stem Cells (iPSCs) to differentiate into functioning TM cells.

METHODS

The following four methods I) TM cell-conditioned media (CM), II) Co-culturing iPSCs with TM cells using a transwell membrane, III) Co-culturing iPSCs with TM cells using the double surface of transwell membrane IV) Culturing iPSCs on TM Extracellular Matrix (ECM) with TM-CM were used to differentiate peripheral blood mononuclear and fibroblast dermis cells originated two human iPSC lines.

RESULTS

Culturing iPSCs on TM Extracellular Matrix (ECM) with TM-CM was identified as the best method for differentiation of iPSCs into TM cells. The differentiated cells demonstrated TM morphological characteristics (elongated, spindle-shaped) and gene expression of specific TM cell markers, Chi3l1, AQP1 and MGP significantly greater than to iPSCs ($p<0.005$) but not different than control TM cells ($p>0.05$). Differentiated iPSCs had undetectable expression levels of pluripotency genes; Sox2 and Oct4.

DISCUSSION

The study suggests that the TM ECM plays an important role in differentiating human iPSCs into TM cells. Generating a source of iPS derived TM cells has the potential for future drug screening or transplant approaches.

CONCLUSION

iPSCs became differentiated to TM-like cells after sustained exposure to ECM of TM cells and CM together.

The glass transition temperature of a polymer is one of the most important parameters to consider in the development of new polymeric biomaterials or understanding their behavior. It determines its use temperature, physical and mechanical properties, and material processing conditions. However, it still remains one of the most significant unsolved problems in condensed matter physics [1].

Computer simulations provide many important insights at the molecular level in materials science, offering significant new knowledge about the performance of polymeric biomaterials [2]. In this context, computer simulations can be considered as a bridge that connect microscopic dynamics (such as interaction between atoms or molecular geometry) to macroscopic properties of polymeric systems such as the glass transition temperature, diffusion coefficient or viscosity [3].

The complex behavior of the material around the glass transition has been reproduced by a Non-Markovian computational model, reducing the system under study to a nanoscale region formed by a cluster of a small number of molecular groups coupled to their environment. Dynamic heterogeneity was implemented in this model through the existence of slow and fast regions which can change randomly with two different potential barrier heights [4]. This minimal stochastic model developed for small open regions reproduces the main phenomena found in the glass transition and can be useful as a basis for the development of more specific models that allow understanding the complex behavior underlaying the glass transition and structural relaxation processes.

Introduction:

Annually, millions of people die because of liver failure, while the waiting duration for a donor liver is around 12 months.[1][2] Here, we developed hybrid 3D-printed scaffolds to serve liver tissue engineering(LTE) applications. Gelatin and dextran were used as starting material, crosslinked using two different chemical approaches to explore their effect on cell response and GelMA served as benchmark[3].

Materials and methods:

Thiolated gelatin(GelSH)[4] was combined with norbornene-functionalized dextran(DexNB)[5] followed by a radical step-growth thiol-NB crosslinking. In parallel, oxidized dextran(Dexox) and gelatin were crosslinked using a Schiff-base mechanism. Both materials were characterized on 2D-and 3D-level and compared with GelMA regarding their physico-chemical properties (swelling, gel fraction, mechanical properties) and in vitro biocompatibility (cell proliferation, live-dead staining). The 3D-scaffolds were developed using indirect 3D-printing[6].

Results and discussion:

On a 2D-level, GelMA and DexNB-GelSH were superior over Dexox-gel as their crosslinking kinetics were significantly faster and they mimicked natural liver tissue (NLT) to a greater extent with respect to swelling and mechanical properties.

On a 3D-level, DexNB-GelSH scaffolds exhibited a compressive modulus of 4.8±1.6kPa which is in excellent agreement with that of NLT(i.e. 1–5kPa)[7] as compared to GelMA which resulted in a modulus of 8.5±1.9kPa. However, the in vitro biocompatibility of both materials was comparable.

Conclusions:

DexNB-GelSH scaffolds are promising hybrid materials to support LTE as they exhibit similar physico-chemical properties compared to NLT (cfr. compressive modulus and swelling ratio), while cell viability and proliferation were preserved. Further analyses evaluating the preservation of cell functionality are ongoing.

Glass-ceramics based on the CaO–P2O5–SiO2–MgO system have presented biocompatible phases as hydroxyapatite (HA), tricalcium phosphate (TCP), and TCP with magnesium substituting partial calcium (TCMP). The β-TCMP phase with whitlockite structure has interesting biological features and mechanical properties, meeting the bioactivity requirements for bone restoration. In this work, a 3CaO·P2O5-SiO2-MgO glass was submitted to different heat treatments of 4h at temperatures from 775 to 1100 ℃. After that, samples were mechanically characterized. It was observed a direct correlation between the induced crystalline phases and the increase of temperature treatment, resulting in a rise of bending strength (70 – 120MPa). Likewise, the elastic parameters were determined (Elasticity modulus = 92 – 162 GPa, Poisson's ratio = 0.26 – 0.27). From that, numerical simulation using the finite element method (FEM) was proposed to interpret the mechanical response of these bioactive glass-ceramic implants' as a function of its intrinsic geometry parameters and the application of masticatory loads. A geometry implant model of Ø4.1 - 4.8 mm, 0.8 mm thread pitch, containing 11,146 knots (45,286 elements), and a bone structure (cortical + spongy) with 31,200 knots were developed using CATIA V5 software. These models were used to simulate human adult male mandible, implanted in the third molar region, through the HyperWorks and Abaqus software. Finally, loads between 100 – 300N were simulated using FEM at different application angles, replicating an adult's effort. Results were discussed according to the crystalline phases, the amount of residual glass, and normative requirements for the use of dental implants.

Ceramic composites based on (Ce, Y)-TZP/Al2O3 system have great potential for applications as dental implants due to their excellent mechanical properties associated with high resistance to hydrothermal degradation. In this work, hydrothermal degradation and preliminary biological evaluation of a ceramic composite of the CeO2-Y2O3-ZrO2-Al2O3 system were investigated as a function of surface roughness. Compacted samples were sintered at 1500 °C - 2h and then submitted to different surface treatments: Group 1 composed of samples with smooth surfaces, Group 2 composed of rough surfaces (sanding with 45 µm diamond sandpaper). Samples were characterized by X-ray diffraction and optical profilometry and them subjected to hydrothermal degradation tests in autoclave (134 °C - 2 bar) for a maximum of 10h, using artificial saliva. To assess indirect cytotoxicity, samples were immersed in the culture medium for NIH-3T3 cells for 72 hours. Furthermore, cell adhesion and proliferation were investigated using MG63 cells (human osteosarcoma) after 3, 7, 14, and 21 days of culture. Cytotoxicity, adhesion, and cell proliferation were examined by the Methyl Tetrazolium salt (MTS) and Alizarin Red, using a confocal laser microscope. The results indicated that the materials have high resistance to degradation, having low monoclinic phase concentrations only on surfaces with high roughness (45 µm). The (Ce, Y)-TZP/Al2O3 composites are not cytotoxic. The rougher sample shows the best cellular adhesion and proliferation, leading to a mineralized matrix formation after 21 days. These results clearly suggest that the new (Ce, Y)-TZP/Al2O3 brand is strong and highly biocompatible and warrants further study.

THE EFFECT OF DIFFERENT MOLAR RATIOS OF PEGYLATED FIBRIN ON ISOLATED OVARIAN STROMAL CELLS

Arezoo Dadashzadeh$_P$[1], Saeid Moghassemi[1], Christiani Andrade Amorim[1]

[1] Pôle de Recherche en Gynécologie, Institut de Recherche Expérimentale et Clinique, Université Catholique de Louvain, 1200 Brussels, Belgium

This study aimed to assess the influence of two formulations of PEGylated fibrin on the survival and proliferation of ovarian stromal cells. To this end, a total of 2.4×104 cells were equally divided into two groups according to the molar ratios of PEGylated fibrinogen (PEG:Fib): 10:1 and 5:1. After polymerization with 50 IU/ml thrombin, the cells embedded in the hydrogels were in vitro cultured for five days. Histological and immunohistological analysis of hydrogels before (day 0) and after in vitro culture was performed. Cell density dynamic (Cd) was calculated by the following formula:

Cd= (density of day 5-density of day 0)/(density of day 5)×100

Our results show that while more elongated cells were observed in the PEG:Fib 5:1 hydrogel, rounded shape cells were more often found in the other group (Fig. 1). This could be due to the higher availability of bioactive sites in PEG:Fib 5:1, which fewer PEG molecules have interacted with the fibrin domains. The average proportions of Ki67-positive cells were high in PEG:Fib 10:1 and 5:1 groups, around 24% and 22%, respectively. Additionally, more caspase 3-positive cells were also seen in also appeared PEG:Fib 10:1 scaffold. On the other hand, PEG:Fib 5:1 indicated a considerable Cd compared to PEG:Fib 10:1 (Fig. 2). In conclusion, increasing the molar ratio of PEG:Fib can decrease the availability of bioactive sites of fibrinogen, which may be masked or bound by PEG molecules and affect the cellular behaviors in terms of proliferation, apoptosis, and morphology.

Human mesenchymal stroma cells (MSC) are a promising cell source for generation of engineered cartilage. However, during in vitro differentiation MSCs develop along the endochondral pathway and become hypertrophic, which is undesired for cartilage regeneration. The signaling mechanisms regulating hypertrophic differentiation are not fully understood. We recently demonstrated during in vitro chondrogenesis of MSCs, expression of non-canonical WNT11 increased along with hypertrophic markers, while no typical canonical WNT ligand was found to be upregulated. Aim of this study was to illuminate the role of non-canonical WNT11 for hypertrophic differentiation of MSCs compared to a canonical WNT ligand. Understanding the role of canonical and non-canonical WNT signaling for endochondral differentiation, will allow improved articular cartilage neogenesis suitable for clinical regeneration of stable cartilage tissue. MSC in vitro chondrogenesis was treated with recombinant WNT11 protein, canonical WNT3A or the canonical WNT-antagonist DKK1 from day 14 on. Chondrogenic and hypertrophic markers were assessed on mRNA and protein levels on day 28. WNT3A-stimulation enhanced expression of hypertrophic markers MEF2C, ALPL, IBSP and IHH at maintained COL2A1 levels. Enhanced ALP enzyme activity and higher IBSP protein levels confirmed the pro-hypertrophic action. Accordingly, DKK1-treatment significantly suppressed hypertrophic markers, demonstrating that canonical WNT signaling is driving hypertrophy. WNT11-stimulation reduced ALPL expression and ALP enzyme activity only slightly but significantly. In conclusion, non-canonical WNT11 is no main driver of hypertrophy during chondrogenic differentiation of hMSCs. Excessive canonical WNT signaling, from a yet unidentified ligand, is the critical factor driving hypertrophic differentiation of hMSCs and preventing stable chondrogenesis.

Control of cell-surface interaction is necessary for tissue engineering applications such as cell sheets, intelligent cell culture surfaces, or functional coatings. The cell morphology measured through cell aspect ratio (CAR) can indicate ideal candidates for these various applications thus reducing the time taken for the screening and development process. The cell aspect ratio of primary porcine dermal fibroblast (PDFs) (3 biological replicates) were tested on ten different surfaces comprising components of the natural extracellular matrix of tissues. Characterisation followed with proliferation and cell migration assays, which clearly highlighted an optimal morphology for increased cell proliferation and migration. If the CAR was 0.1 (very elongated cell), the cell migration and proliferation were extremely reduced compared to those in 0.2-0.3 CARs. The same was evidenced in PDFs with a CAR of 0.4+ (very rounded cell). These results suggest a prime cell shape for PDFs to migrate and proliferate, which is a key aspect in tissue engineering applications requiring control of cell-surface interaction. This project shows the beneficial use of testing the cell morphology on prospective prototypes for screening, eliminating those that do not support an optimal cell shape. In addition, the technique used to calculate CAR provides a useful, simple alternative to monitor morphology if DAPI staining is not available.

Evidence suggests skeletal muscle (SkM) myotube derived extracellular vesicles (EVs) drive SkM processes, indicating their regenerative potential. However, therapeutically aligned studies are limited by the ability to efficiently obtain high yield purified populations from minimal sample volumes in a cost-effective manner. This study compared isolation methods to understand EV output variation using Nanoparticle tracking analysis (NTA), BCA protein assay, western blots (CD9, CD63, Alix, Annexin A2), ExoELISA's (CD63 and CD81) and nano flow cytometry (NanoFCM) (CD9, CD63, CD81). To further understand advantages and limitations (e.g. efficiency, cost, scalability, purity) a survey was internationally distributed via Qualtrics within the EV community. EVs were isolated from C2C12 mouse myoblast cells by ultracentrifugation (UC), polyethylene glycol (PEG) precipitation, Total Exosome Isolation Reagent (TEIR), an aqueous two-phase system (ATPS) utilising PEG and dextran, and size exclusion chromatography (SEC). ATPS was repeated with multiple washes of the top PEG phase for additional purification. TEIR displayed the highest particle concentration (1.15E+09) followed by UC (8.46E+08) and PEG precipitation (7.11E+08), with purity (particles per µg protein) 7.16E+05, 1.22E+06 and 6.90E+05 respectively. SEC and ATPS showed lower sample purity, 1.12E+05 and 1.99E+05 and particle counts of 4.57E+08 and 6.31E+08 respectively. ATPS with repeat washes displayed the lowest particle counts (2.71E+08) and highest purity (2.01E+06). EV markers were present in all isolations but with distinctly variable profiles. This high-throughput comparison study indicates that methods withdraw myogenic EV-enriched fractions with variable purity and marker profiles. This could have significant implications for defining SkM processes and EV applications in tissue engineering.

INVERSE EFFECTS OF CALCIUM ON CARTILAGE MATRIX PRODUCTION BY ARTICULAR CHONDROCYTES VERSUS MESENCHYMAL STROMA CELLS: IMPLICATIONS FOR OSTEOCHONDRAL CARTILAGE ENGINEERING

Tim Hammersen[P][1], Severin Zietzschmann[2], Wiltrud Richter[1]

[1] *Research Center for Experimental Orthopaedics, Heidelberg University Hospital, Heidelberg, Germany*

[2] *Clinic for Orthopaedics and Trauma Surgery, Heidelberg University Hospital, Heidelberg, Germany*

Purpose: Treatment of articular cartilage lesions often reveals mechanical failure at the graft-to-host tissue junction. Osteochondral tissue-engineering (TE) constructs composed of a resorbable calcified bone-substitute with a cartilage-mimetic scaffold on top showed better tissue integration and mechanical stability than non-zonal repair strategies. However, little is known about how elevated calcium ion-release from a bone-substitute affects differentiation of chondrogenic cells and whether articular chondrocytes (AC) or mesenchymal stroma cells (MSC) are more sensitive to such conditions. Aim of this study was to compare the influence of elevated [Ca2+] on differentiation and cartilage matrix production of AC and MSC to identify the ideal cell source for zonal cartilage TE.

Methods: Human AC and MSC were seeded in collagen type I/III scaffolds, cultured for 35 days under chondrogenic conditions at standard (1.8mM) or elevated (8.0mM) extracellular CaCl2 and assayed for GAG and collagen-type II production by radiolabel-incorporation, ELISA, qPCR and Western blotting.

Results: In cartilage engineered from ACs, elevated calcium significantly reduced GAG-synthesis, GAG/DNA and collagen-type II deposition and downregulated chondrogenic marker gene expression. Opposite, calcium significantly upregulated GAG- and collagen-deposition in the MSC group where chondrogenic and hypertrophic markers remained unchanged. Selective PTHrP-induction by calcium-treatment in AC suggests their enhanced sensitivity to calcium via the calcium-responsive PTHrP pathway compared to MSC.

Conclusion: Overall, it is important to consider the origin of the chondrogenic cell source for multilayered cartilage TE and we propose to separate an AC-layer from calcified structures by an intermediate layer of MSC.

HIGH-THROUGHPUT PRODUCTION OF HIPSC-DERIVED VASCULARIZED MYOGENIC SPHEROIDS FOR 3D BIOPRINTING

Jasper Smet$_P$[1], Heidi Declercq[1], Lieven Thorrez[1]

[1] *Tissue Engineering Lab, Department of Development and Regeneration, Faculty of Medicine, KU Leuven, campus Kulak, E. Sabbelaan 53, 8500 Kortrijk, Belgium*

Corresponding author's email: jasper.smet@kuleuven.be

Despite decades of progress, tissue engineering (TE) remains severely hampered by the incompetence to generate complex histoarchitectural features including vascular networks (1).

The 3D bioprinting of spheroids is ideally positioned to overcome these obstacles since it allows the directed assembly of microtissues that resemble the target tissue structurally and functionally (2). Therefore, we previously employed a high-throughput non-adhesive agarose microwell system for the generation of printable vascularized spheroids comprising adult endothelial cells, fibroblasts and adipose tissue-derived mesenchymal stem cells (MSCs) (3). These spheroids could fuse and inosculate their individual capillary-like networks (3) and confirmed their potential as microvascular building blocks in 3D extrusion printing (publication in preparation). We intend to exploit this strategy for the engineering of a human induced pluripotent stem cell (hiPSC)-derived vascularized muscle model. Therefore, we now created vascularized myogenic spheroids composed of hiPSC-derived ECs (Stem Cell Institute, KU Leuven), hiPSC-derived MSCs (Cellular Dynamics) and hiPSC-derived myoblasts (iXCells Biotechnologies). Upon application of the most optimal coculture ratio, the cells managed to form uniform and viable spheroids with dimensions compatible with 3D extrusion printing (Ø around 130 µm). Immunohistochemical, transmission electron microscopic and confocal fluorescence microscopic analyses indicated that the ECs were able to sort into capillary-like networks. Similar to our previous experiments, the presence of hiPSC-derived MSCs appeared indispensable for an optimal spheroid stability and vascularization. In future work, these vascularized microtissues will be implemented in 3D bioprinting to fulfill the need for vasculature within the low-micron range (<10 µm) in our muscle model.

Introduction

The efficacy of tissue-engineered (TE) cartilage scaffolds(1,2,3), an alternative to traditional cartilage repair techniques, can be augmented by adding tissue-specific matrix-components(3,2,4) and growth factors(5) to biomaterials. Proteoglycan-4, PRG4, is a superficial-zone cartilage protein and a synovial fluid constituent, with critical roles in boundary lubrication and joint homeostasis(6,7,8,9). Intra-articular supplementation of PRG4 is chondroprotective(10,11,12,13), shown to preserve cartilage volume(10,11), improve damage scores(12), and maintain biomechanics(13) in models of injury. Therefore, the hypothesis of this study was that the addition of PRG4 to TE cartilage scaffolds would enhance the lubricating function of biomaterials and therefore healing potential.

Methods

Recombinant-human (rh)-PRG4 was provided by Lμbris Biopharma(14). Collagen-glycosaminoglycan (coll-GAG) scaffolds were prepared by lyophilization(15) of a collagen I, hyaluronan, and rhPRG4 slurry at varying concentrations. Mesenchymal stem cells were cultured on collagen-GAG scaffolds. Biological assessments included: proliferation (Quant-iT PicoGreen), metabolic activity (alamarBlueTM), GAG synthesis (Blyscan, Biocolor), and cell infiltration (immunohistochemistry: hematoxylin & eosin, safranin-o). The coefficient of friction (COF) of scaffolds in PBS was characterized with an adapted scaffold-on-glass test(16,17,18).

Results

Coll-GAG-rhPRG4 scaffolds had significantly reduced COF compared to controls (0.068 ±0.01 vs. 0.118±0.02, $p<0.001$), and decreased compressive stiffness. The rhPRG4 released from scaffolds was intact (460kDa) and protein released completely from materials in seven days. The addition of rhPRG4 to Coll-GAG scaffolds did not negatively effect cell proliferation or metabolism.

Discussion & Conclusion

rhPRG4 added to Coll-GAG scaffolds through bulk-incorporation had significantly reduced friction and gradual protein release times. The Coll-GAG-rhPRG4 material is a biomechanically-enhanced biomaterial for cartilage repair application.

BIOMIMETIC HYALURONIC ACID-BASED HYDROGELS TO INVESTIGATE ROLE OF TUMOR BIOPHYSICAL PROPERTIES ON GLIOBLASTOMA (GBM) PROGRESSION

Alireza Sohrabi[P][1], Jesse Liang[1], Austin Lefebvre[2], Michael Condro[1], Harley Kornblum[1], Michelle Digman[2], Stephanie Seidlits[1]

Glioblastoma (GBM) is the most common, lethal type of brain cancers with 5-years survival of 5%. The unique microenvironment of GBM is one of the main factors in tumor aggression. Specifically, similar to other solid tumors, GBM cells experience different biomechanical forces than cells in a healthy brain tissue. Our micro-compression mechanical analysis (using AFM) of GBM tumors shows a stiff core (5-6 kPa Young's modulus), a softer tumor edge (1-2 kPa Young's modulus), a very soft non-tumor brain tissue (0.5-0.8 kPa Young's modulus). To understand how this biomechanical landscape affects GBM cells, GBM spheroids were encapsulated in biomimetic hyaluronic acid-based (HA) hydrogels, mimicking stiffness of a tumor and neighboring brain tissue. In soft hydrogels, GBM cells migrate away from original spheres whereas we did not witness any migration in stiff hydrogels. RNA-sequencing analysis revealed overexpression of mitochondrial genes in stiff conditions, involved in oxidative phosphorylation (OXPHOS), when compared to soft hydrogels. This data suggests GBM cells in soft hydrogels undergo aerobic glycolysis (GLY). We then performed fluorescence-lifetime imaging microscopy (FLIM) to measure amount of bound NADH (OXPHOS) vs. unbound NADH (GLY). FLIM data revealed higher presence of bound NADH in GBM cells encapsulated in stiff hydrogels which in turn suggests more OXPHOS metabolic activity. On the other hand, more unbound NADH was observed in soft hydrogels suggesting more GLY metabolic activity in soft hydrogels. In sum, we find that a softer microenvironment (like normal brain) promotes GBM cells migration and a switch to a more malignant metabolic pathway.

Market authorization of mesenchymal stromal cells (MSCs) has yet to be achieved in the United States, and lack of regulatory approval could be due to MSC preparation techniques. Fetal bovine serum (FBS) has been used for MSC preparation in recent US clinical trials and also for MSC therapeutics with current foreign market authorization. Likewise, FBS is almost exclusively used in animal models. We hypothesize that the use of FBS results in recipient immune targeting of therapeutic MSCs, thereby preventing their clinical effect. In the equine model, we evaluated the effect of FBS in MSC preparation by performing repeated intra-articular injection of MSCs cultured with and without FBS. First, we validated the use of bone marrow supernatant (BMS) in vitro as a replacement for FBS, and noted an increased rate of MSC isolation but no difference in MSC expansion or characteristics. Supplementation of MSC with FBS caused local inflammation, antibody mediated MSC cytotoxicity, and reduced synovial MSC concentration, despite a lack of change in anti-bovine antibodies in recipients. These adverse effects and immune targeting were ameliorated with the replacement of FBS with BMS. For the first time, we show that FBS supplemented MSCs are targeted by the recipient immune system resulting in local inflammation, cytotoxicity, and reduced efficacy. Fetal bovine serum should no longer be utilized in clinical study, and the use of FBS in pre-clinical and historical clinical studies should be considered when interpreting results. Bone marrow supernatant as an FBS replacement should be further investigated.

DIFFERENTIAL REGULATION OF PI3K/AKT SIGNALING BETWEEN ENDOCHONDRAL DIFFERENTIATION OF MESENCHYMAL PROGENITOR CELLS AND NON-HYPERTROPHIC MATURATION OF ARTICULAR CHONDROCYTES

Introduction: Re-directing mesenchymal progenitor cell (MPC) chondrogenesis towards a non-hypertrophic articular chondrocyte-(AC)-like phenotype is important for facilitating cartilage repair with MPC. PI3K/AKT signaling promotes proteoglycan-deposition and chondrocyte hypertrophy in the growth plate. AKT inhibition during early MPC chondrogenesis suppressed proteoglycan-deposition according to our previous data, but later AKT inhibition and effects on hypertrophy remained uninvestigated. Aim was to uncover PI3K/AKT-pathway activity during chondrogenic (re-)differentiation of MPC and AC and illuminate functional consequences.

Methods: Human expanded MPC and AC were subjected to standard chondrogenic pellet culture and assayed for expression of AKT-related genes at day 28 as well as pAKT/AKT pathway activity via Western-blotting at day 1, 3, 7 and at weekly intervals until day 42. Differentiation was assessed histologically and via DMMB-assay.

Results: MPC started into chondrogenesis with significantly lower pAKT and AKT levels and expressed AKT-activators PDPK1, JUN, JUNB, JUND, STAT3 and AKT1 lower, but the AKT-inhibitor PTEN higher than AC. While AC rapidly silenced AKT-activity at switch to differentiation culture, AKT pathway activity raised in MPC parallel to hypertrophic markers reaching significantly higher pAKT levels from d21 on. In line, AKT-related PDPK1, JUNB and JUND expression was significantly enhanced compared to AC. Late AKT suppression during MPC chondrogenesis from d21 on reduced SOX9 protein levels, SMAD2/3 signaling and chondrogenic differentiation.

Conclusion: Selective upregulation of AKT-pathway activity only in MPC parallel to hypertrophy suggests its relevance for MPC mis-differentiation. Crosstalk of the AKT-pathway with TGFβ signaling is currently followed up as a putative mechanism of potential pro-hypertrophic AKT action.

Preclinical assays often fail to predict drug action, resulting in high clinical trial failure rates. Cellular models can screen for cardiotoxicity, but oftentimes utilize complex 3D systems that—while predictive—are challenging to deploy at sufficient scale. Widespread adoption of engineered muscle tissues (EMTs) has been hindered by traditional fabrication methods that require extensive bioengineering and by measurement methods that involve low-throughput approaches. We designed, optimized, and validated a novel method to fabricate and measure the contractility of 24 3D EMTs in parallel.

Our tissue casting approach improves success rate to >95% (n > 30) and produces consistently-sized constructs with a standard deviation of +/- 9% of the mean across 6 experiments. The substrate features an embedded magnet; as tissues contract, the magnet's displacement is quantitatively detected in a highly-parallel manner using specialized sensors. We detected 24 contractions simultaneously with a rate of measurement 100Hz, which is suitable for measuring various aspects of contractility such as upstroke velocity and decay time.

This method can measure drug-induced changes to EMT contractility, such as doxorubicin, a structural cardiotoxicant. Treated EMTs showed no differences over controls at acute (30 min) or daily timepoints to Day 2 post exposure. The highest dosed (1 μM) tissue began to slow at Day 4 ($p < 0.01$) and Day 5 ($p < 0.0001$) until complete cessation of twitching by Day 6. We will also present data showing phenotype stratification across EMTs from healthy and diseased individuals, demonstrating the potential of the platform to be used in drug discovery studies.

In-vivo embryogenesis demonstrates a flawless example of self-organization using a combination of diffusible morphogens and the physical effect of the endometrial constraint as guidance for germ layer differentiation. Modulating physical environmental factors has supported the growth and development of a pre-gastrulation mouse embryos in-vitro. Although information is available on how diffusible morphogens affect gene expression and signalling dynamics, the mechanistic role in inducing these events is poorly understood. Due to ethical limitations with human embryos, in-vitro models present a better platform to understand the contribution of mechanical stress towards the differentiation and self-organization capacity of pluripotent stem cells. Previous studies have demonstrated a role of geometry in germ layer organization of ESCs in response to BMP4 induction. Here, we present an in-vitro gastrulation model, which uses polyacrylamide hydrogels as culture substrates to present physical factors like stiffness and geometry to the cells creating a self-sufficient system for differentiation and spatial organization using iPSCs, without the need of using exogenous induction. We demonstrate that substrate stiffness and geometry control iPS cells differentiation into a SOX17+ endodermal and a T/Brachyury+ population, which represents primitive streak/mesoderm by fluorescence imaging and qPCR results.These colonies confine the cells causing cytoskeleton mediated nuclear shape alterations, inducing the signalling dynamics to create these gastrulation-like events, enhanced in a 3-D environment, implicating the crucial role of mechanics of the culture substrates. This model presents a simple approach to understand how iPSCs interpret their physical microenvironment to alter cell identity and spatial organization, which better represents the in-vivo environment.

The involvement of the microvasculature in many (patho-)physiological processes inspired the interest to engineer in vitro models that allow to dissect these complex biological processes with spatiotemporal resolution. Current state-of-the-art in vitro engineered human microvasculature is based on perfusable microvascular networks (MVNs) within microfluidic devices. Unfortunately, these MVN suffer from pruning and network retraction upon spontaneous vasculogenesis, leading to non-functional luminous structures.

To address this limitation, we developed cell culture methodologies by introducing a biophysical stimulus based on macromolecular crowding (MMC) into MVN cultures, composed of umbilical vein endothelial cells (HUVECs), forming the inner lining and mesenchymal stem cells (MSCs), taking up pericyte function. In both experimental groups MVNs formed within the first 2 days, exhibited patent lumina and were outlined with a basement membrane. Noteworthy, MVNs cultured without MMC regressed immediately after being formed while MMC led to perfusable MVN with a retention up to day 10. Quantification of major basement membrane components revealed an enrichment of collagen IV and laminin α5 in MMC supplemented MVN cultures. A functional contractility assay further confirmed a reduced contractility of MSCs and HUVECs in three-dimensional cultures.

Taken together, current data indicate that MMC stabilized MVN by promoting the formation of a robust basement membrane around microvessels and by toning down cell contractility that generally drives microvessel retraction. The here established platform integrates two key technologies based on MVNs in microfluidic devices and MMC and enables the modeling of various microvasculature-related (patho-) physiological processes with a close resemblance of physiological cellular composition.

A long-term serial cell expansion can induce stem cell senescence, which can cause a progressive decline in stem cell function and stemness, highlighting the need to identify specific biomarkers for senescent cells. Reactive oxygen species (ROS), known as one of factors responsible for senescence, rather requires low levels of ROS to maintain quiescence and self-renewal. Based on this, we exposed the tonsil-derived mesenchymal stem cells (TMSC) to a low level of ROS using sustained ROS releasing hydrogel and identified the new senescence biomarker and its effects on stem cell function as well as its expressional changes. Changes of transcriptomic and proteomic profiles of TMSCs were evaluated using control (5 – 8p) and culture-aged senescent TMSCs (20 – 25p). G-protein was identified as an MSCs specific hallmark of senescence. Changes of intracellular location of G-protein from cytosolic to the peri-nuclear region as well as significantly decreased cytosolic expression with replicative senescence. Next, cell surface G-protein expressing cells (CS-G-pro(+)) sorted by magnetic-activated cell sorting (MACS) method presented were applied for further experiment. The CS-G-pro(+) cell showed superior ability not only in differentiation ability but also in mitochondria metabolic efficacy and proliferation. In the calvarial defect rat model, bone regeneration efficacy was high when mixed with ROS releasing hydrogel. Taken, we suggest that the G-pro as an effective senescence biomarker of MSCs and ROS releasing hydrogel can control its regenerative potential as well as the proliferation of MSCs by regulation of the G-pro intracellular distribution.

The success of cell-based approaches for the treatment of cartilage or fibro-cartilaginous tissue defects, requires an optimal cell source with chondrogenic differentiation ability that maintains its differentiated properties and stability following implantation. For this purpose, the aim of this study was to evaluate the use of endostatin (COL18A1), an anti-angiogenic factor, which is physiologically involved in meniscus development for cell differentiation. Neonatal porcine meniscal cells not yet subjected to mechanical stimuli were extracted, cultured in fibrin scaffolds, and treated for two different times with different concentrations of COL18A1. At the end of the treatments, the scaffolds were subjected to biochemical, molecular, and histochemical analysis. The results showed that high concentrations of COL18A1 increased the production of glycosaminoglycans (GAGs), without particular variations in the cellularity index (DNA content) compared to the untreated experimental group (UNT), resulting in an increase in the GAGs/DNA ratio. These data were supported by the molecular analysis of type II collagen (COL2A1, marker of cartilaginous-like tissue), SRY-Box Transcription Factor 9 (SOX9, early marker of chondrogenicity) and type I collagen (COL1A1, marker of fibrous-like tissue), where the expression of COL2A1 and SOX9 increased with increasing endostatin concentration and the expression of COL1A1 decreased compared to UNT group. Histological studies (Safranin-O staining) confirmed that high concentrations of endostatin were more effectives, laying the foundations for researches evaluating the involvement of this anti-angiogenic protein in the differentiation of avascular tissues.

It is estimated that about 0.5% of the world's population will require an articular cartilage intervention at some point in their life. [1] Current treatment options for osteochondral (OC) lesions are only marginally successful, and if left untreated, lead to osteoarthritic joint disease, one of the major sources of disability world-wide. [2] Many of the common surgical approaches to treat cartilage lesions such as microfracture, are dependent on the efficient migration of cells from the underlying subchondral bone to ensure successful regeneration of the tissue. However, the extent of cell migration and hence the clinical outcome, is highly variable. [3] To overcome this critical limitation, it is necessary to study the chemical and physical properties that would induce bone marrow mesenchymal stem cell (BMSCs) migration in a 3D matrix. We propose a simple and fast method to produce macroporous annealed particle hydrogels by mechanical disruption of HAMA hydrogels [4] and secondary crosslinking them using a cell-friendly transglutaminase enzymatic reaction [5]. This design presents enough void space that can naturally facilitate the endogenous migration of BMSCs. Microgels with different diameters (Ø = 48 ± 17.5 µm and 12.8 ± 5.2 µm corresponding to a void space of 25% and 35 %, respectively) and different degree of substitution (10% and 50% corresponding to a compression modulus of 7.2 ± 0.4 and 20.4 ±1.7 KPa, respectively) were evaluated. We believe these advanced, yet biocompatible materials, provide an ideal 3D environment for promoting cell migration and differentiation leading to a fully functional OC repair.

DELAYED THE ESRD PROGRESSION BY TRANSPLANTING 3D PRINTED OMENTAL PATCH

Hyunoo Jo[P][1], Boyun Kim[1], Jina Ryu[1]

[1] ROKIT HEALTHCARE, Inc

Corresponding author's email: whgusdn4@rokit.co.kr

Chronic kidney disease (CKD), caused by various causes, leads to the end-stage of renal diseases (ESRD). Dialysis and kidney transplant are the only treatments existed in the market for ESRD. Currently, there is no practical renal replacement therapies. We developed a new treatment using autologous omental tissue that can delay the progression of ESRD. Omentum is one layer of the peritoneum, known for a rich source of biological materials that enhance tissue growth and has rich matrix. Also, growth factors such as bFGF, PDGF, HGF, and VEGF in the omentum can play a key role in renal regeneration. We prepared the bio-ink using a micronizing omental tissue, then printed it in the form of a therapeutic patch. A 3D printed omental patch was applied to Kidney of CKD rat model. We transplanted the omental patch to a renal subcapsular layer in unilateral ureteral obstruction (UUO) rat, and kidneys were histologically analyzed after two weeks of transplantation. Reduced glomerulosclerosis and tubular injury were observed in the omental patch UUO group compared to the untreated UUO group. Also, high cellular proliferation was observed in regions near the patch. Next, we selected a 5/6 nephrectomy CKD model to determine the effect of omental patch on renal function. The untreated 5/6 nephrectomy group showed a higher BUN and Creatinine range, while the omental patch 5/6 nephrectomy group showed a normal range in BUN and Creatinine. Therefore, we confirmed that the omental patch delays ESRD progression by providing protective effects to kidney disease.

3D BIOPRINTING OF HYALURONAN-TYRAMINE MICROGEL BIOINKS WITH TUNABLE POROSITY FOR AURICULAR CARTILAGE REGENERATION

Killian Flegeau[P][1], Marcy Zenobi-Wong[1]

[1] *Department of Health Science and Technology, ETH Zurich, Zurich, Switzerland*

Corresponding author's email: killian.flegeau@hest.ethz.ch

Microtia is a congenital deformity affecting 1 of every 7,000 births worldwide and causing psychological morbidity1. Autologous rib cartilage graft remains the “gold standard” but is associated with high co-morbidity and risk of failure. 3D bioprinting of tissue-engineered cartilage was proposed to recreate the complex auricular shape but suitable bioinks combining printability and supporting maturation to functional tissue remain scarce. Granular hydrogels, made of annealed microgels, are excellent candidates combining injectability and porosity2. In this study, we evaluated the use of sized microgels as bioinks with tunable porosity for auricular cartilage regeneration. Enzymatically crosslinked hyaluronan-tyramine (HA-Tyr) hydrogels were fragmented using grids with aperture of 40, 100 or 500 µm. Microgel bioinks mixed with 10 mio/mL auricular chondrocytes suspension were microextrusion printed (discs of 8x2 mm) with excellent viability (>75% at D1), self-healing and shear-recovery properties, and stabilized by secondary crosslinking of tyramine residues. Scaffolds were matured for 3 weeks in vitro and subcutaneously implanted for 6 weeks in nude mice. Decreasing microgels size resulted in increased porosity (from 8 to 21%) and initial stiffness (from 5.5 to 10 kPa) and favored cell invasion of acellular constructs in vivo. Cells uniformly spread between the microgels in 40 µm samples but clustered in larger 100 and 500 µm microgels, resulting in micro-pellet formation. Cartilage maturation was confirmed in vitro with stiffening of the gels (100 kPa), upregulation of key chondrocyte genes, and deposition of collagen II and glycosaminoglycans. Altogether, secondary crosslinked HA-Tyr microgels are promising bioinks for auricular cartilage regeneration.

Near-field electrospinning (NFES), is a powerful technique for direct-writing of micro/nanofibers, with the potential of creating detailed structures. This ability opens an interesting perspective for the position-controlled deposition and precise integration of aligned individual fibers which greatly expands their application in various fields [1]. However, the utilization of these structures, is limited by the maximum achievable height of controlled fiber deposition, beyond which the structure becomes increasingly disordered [2]. The aim of this study was to investigate the impact of distance between adjacent fibers on the deposition of fibers and their alignment by increasing the constructed layers. For this purpose, a 2 ×2 cm network-like pattern by inter fiber distance in the range of 0.1 to 1 mm was designed and a network of polycaprolactone (PCL)-gelatin composite was fabricated up to 50 layers. The operational conditions were investigated and optimized as follow; voltage of 1200 v, the feed rate of 14 mm/s, nozzle-to-collector distance of 1 mm and flow rate of 10 µL/h. According to experimental data, the alignment index defined as actual distance relative to the theoretical pre-defined distance was approached to 1 by increasing the inter fiber distance from 0.3 to 1 mm. The random orientation of the printed fibers at distances less than 0.3 mm can be attributed to the charge build-up on the deposited polymer producing unwanted coulombic forces [3]. This study demonstrates the practical limits of inter-fiber distance and necessity of electrostatic control on the level of orientation that can be achieved via NFES method.

3D scaffolds are becoming more and more important in the field of regenerative medicine due to their ability to mimic the physiological microenvironment. In this field, Raimondi and colleagues applied two-photon polymerization (2PP) to fabricate the "Nichoid", able to maintain and stimulate the stemless of cells[1, 2]. To investigate the Nichoid's influence on cellular response, murine neural stem cells (NSCs) where expanded inside the micro-scaffold [2] and analysed through a whole transcriptomic approach [3]. Nichoids were fabricated by 2PP. 10000 NSCs were expanded inside the engineered niches and in control conditions for 7 days and then analysed through RNA-Seq. We demonstrate that the Nichoid impacts the biological and genetic response of stem cells, as genes strongly connected to mechanobiological functions emerged. We fully dissected this mechanism highlighting how the changes start at a membrane level, with subsequent alterations in the cytoskeleton, signaling pathways, and metabolism, all leading to a final global modification of gene expression. Our findings highlight the Nichoid's ability to induce changes in cultured stem cells at any molecular level without any other chemical agents, allowing recreating the stem cells adhesion, proliferation and cell signaling that best mimics physiological conditions. We highlight the Nichoid's importance for regenerative medicine approaches based on the development of stem cell therapies.

ENZYMATICALLY CROSSLINKED ZWITTERIONIC MICROGELS FOR BIOPRINTING OF MACROPOROUS SCAFFOLDS

Maryam Asadikorayem$_P$[1], František Surman[1], Patrick Weber[1], Marcy Zenobi-Wong[1]
[1] *Tissue Engineering + Biofabrication Laboratory, Department of Health Sciences and Technology, ETH Zürich*
Corresponding author's email: maryam.asadikorayem@hest.ethz.ch

Zwitterionic hydrogels have high potential for various biomedical applications, due to their biocompatibility and low biofouling properties [1, 2]. However, the current methods used for preparation of zwitterionic hydrogels are limited and their potential in innovative biofabrication methods such as bioprinting has not been explored yet. Here, we present a novel and scalable strategy to make zwitterionic microgels that are printable and can be enzymatically crosslinked to make stable, macroporous constructs. Bulk hydrogels are produced via photopolymerization of zwitterionic carboxybetaine acrylamide monomer using gelatin methacryloyl as crosslinker and tyramine acrylamide as functional comonomer to allow for secondary crosslinking via horseradish peroxidase and H2O2. To introduce printability as well as macroporosity of the final construct, the bulk hydrogel is mechanically fragmented into microgels of 100–40 µm in size. This microgel bioink showed optimal shear thinning and shear recovery properties required for extrusion printing with high shape fidelity. Enzymatic crosslinking of microgels resulted in a macroporous structure, optimal for facilitated diffusion and cell-cell interaction [3, 4]. In vitro experiments with human chondrocytes showed excellent biocompatibility with more than 90% viability and enhanced tissue maturation. Moreover, cells were encapsulated in the pores between microgels and bioprinted with retained high cell viability. Bioprinting of cell-laden microgel bioink was demonstrated by creating a 3D ear model which after enzymatic cross-linking, resulted in a mechanically stable construct in culture media. This versatile and highly biocompatible platform material shows great promise for bioprinting of diverse zwitterionic monomers which can be used for multiple tissue engineering applications.

The increasing prevalence of osteoarthritis and the modest efficacy of available treatments represent an incentive to develop new therapeutic strategies. However, the lengthy and increasingly expensive process of pharmaceutical innovation and the significant percentage of failed pre-clinical trials demonstrate an urgent need for realistic tools for in vitro drug screening. In this context, starting from previously optimized bioreactor [1], we developed a new millifluidic bioreactor able to accommodate biphasic cell construct perfused by two separate culture media in order to reproduce the crosstalk between articular cartilage and subchondral bone, while providing an accurate assessment of the mechanism of action and potential drug toxicity. The implemented CFD analysis and biological tests validated the designed biphasic bioreactor capability in guaranteeing cell viability, continuous optical monitoring, no mixing of fluids in the culture chamber hosting each tissue phase. Moreover, we validated the designed device in inducing two specific differentiation pathways in the same chamber. These results confirmed the new biphasic bioreactor as a suitable device for multiphasic tissue culture, where optical accessibility for real-time monitoring at the tissue interface is a fundamental requirement to capture potential interactions of candidate treatments in drug screening and toxicity assessment. Once scaled for high throughput, our biphasic bioreactor will be an essential step in developing new strategies to prevent and treat joint diseases.

POROUS BIODEGRADABLE MICROCARRIERS FOR IPSC-DERIVED CARDIOMYOCYTE EXPANSION & DIFFERENTIATION

Annalisa Bettini$_P$[1], Daniel Stuckey[2], Richard Day[1]

[1] *Centre for Precision Healthcare, UCL Division of Medicine, University College London, London, WC1E 6BT, UK*

Cell therapy is a potential novel treatment for cardiac regeneration. Numerous studies have attempted to transplant cells to regenerate myocardium lost during myocardial infarction. To date, only minimal improvements to cardiac function have been reported in clinical trials. This is likely to arise from low cell retention following delivery and high cell death after transplantation.

The current study aims to improve intramyocardial delivery of viable cells by using an injectable biodegradable substrate that supports cell attachment and growth of cardiomyocytes derived from induced pluripotent stem cells (iPSC).

Highly porous microcarriers <250 µm were fabricated from 2% (w/v) 75:25 poly(DL-lactide-co-glycolide) using Thermally Induced Phase Separation (TIPS). Pre-incubating the microcarriers with recombinant human vitronectin (VTN-N; 0.5 µg/ml) resulted in an increase in iPSC attachment (93.4% vs 2.9% control; attached cells as % of seeded cells, n=5, $P \leq 0.0001$). The attached cells proliferated (doubling time≤24 hrs, n=3). iPSC attached to the microcarriers retained their pluripotent phenotype, demonstrated by positive expression of markers, SOX2, OCT4, TRA-1-60, and SSEA4. Pluripotency was further demonstrated by differentiation of TIPS-iPSC into a mixed cardiomyocyte-like population exhibiting a beating phenotype for up to 40 days in culture.

This work demonstrates that TIPS microcarriers offer a supporting matrix for culturing and differentiating iPSC and may provide an injectable biomaterial for cardiac regeneration.

Efficacy of cell therapies are often diminished by low cell retention. A method to visualise the location of grafted cells and biomaterials after delivery could be used to optimise therapies by verifying injection success, retention of the therapeutic and distribution of the product. To address these challenges an injectable cell-substrate consisting of highly porous microspheres containing the computed tomography (CT) contrast agent barium sulphate (BaSO4) was developed.

Porous microspheres (<250 µm) were fabricated via Thermally Induced Phase Separation (TIPS) using a 2% (w/v) 75:25 poly(DL-lactide-co-glycolide) polymer solution containing a 20% (w/v) colloidal suspension of particulate BaSO4. Culture media conditioned with BaSO4-loaded microspheres (46.87 mg/ml) showed no significant toxicity when cultured with L929 fibroblasts for up to 7 days (maximum toxicity 12% vs 5% matched control media, n=4, $p<0.01$).

Suspensions of BaSO4-loaded microspheres generated high CT contrast in vitro (2023.6 Hounsfield Units) and were then tested in vivo. Three 50 µl injections of BaSO4-loaded microspheres (46.87 mg/ml in 60% GRANUGEL®; 21G needle) were delivered into the myocardium of Sprague Dawley rats under real-time ultrasound-guidance (n=6). Whole body CT scans revealed BaSO4-loaded microspheres at the injection site within the myocardium at 1 hour, 2, 4 and 6 days after injection. A low level of microspheres were visualised in off-target organs including lung, brain and liver (confirmed by histology), indicating some material was lost during injection.

These findings suggest that BaSO4-loaded microspheres can be used as a novel tool for optimising delivery techniques and tracking persistence and distribution of implanted products.

Bioengineered corneas have been fabricated using a variety of synthetic or natural materials to transplant corneal keratocytes.1 However, control of keratocyte phenotype remains a challenge. If a regenerative construct activates a fibroblast-like phenotype then unfavorable ECM akin to scar tissue is produced which will adversely affect transparency and ultimately impair vision. All trans-retinoic acid (RA), as a supplement, has been shown to promote favorable non-scarring phenotype and keratocyte proliferation.2 We hypothesize that supramolecular materials formed via host-guest inclusion of retinol and cyclodextrin can recapitulate dynamics of the ECM but also act as an injectable drug-delivery scaffold. Herein, we confirm the complexation between retinol and ?-cyclodextrin (?CD) and proceed to use this interaction to build a supramolecular system with ?CD-functionalized alginate. We present host-guest complex characterization, synthesis of functionalized alginate, tunable stiffness of hydrogel, and cumulative release of retinol. In addition, we show supramolecular hydrogel behavior for example self-healing and shear thinning character from this interaction through rheological tests. A supramolecular environment built with bioactive molecules like this could facilitate corneal keratocyte proliferation but also be used for other tissue applications where tissue remodeling and tissue integration could be enhanced with antioxidant delivery.

Osteoarthritis (OA) is the most frequently encountered chronic joint disease worldwide affecting more than 25% of the adult population. Joint injury, as a result of trauma, inflammation or infec-tion, leads to superficial and deep joint surface defects, which are risk factors in the development and progression of OA. Engineering precise osteochondral/joint tissues for the regeneration of such defects could mitigate this clinical and societal challenge. However, engineering suitable im-plants remains a challenge due to the complex structural organization and functionality of native joint tissue.
»JOINTPROMISE« aims to develop an automated process pipeline for precision manu-facturing of functional 3D living implants of the required structural complexity, paving the way for the creation of a tissue-engineered prosthesis to treat patients suffering from end-stage osteoar-thritis. The »JOINTPROMISE« platform will additionally boost productivity by transforming existing laboratory-scale Tissue Engineering processes into robust, large-scale and cost-effective production methods.
We elaborated the concept of a multistep automated platform for manufacturing high-complexity Joint-ATMPs by the production of progenitor cell aggregates and their subsequent maturation into microtissues, functioning as building blocks for the assembly of joint implants by multi-step 3D bio-printing. This concept will be implemented by building up an end-to-end automated pro-duction pipeline for Joint-ATMPs. After proving feasibility, safety and indications of clinical efficacy in large animal models, our Joint-ATMPs open up new possibilities in treatment of deep joint sur-faces to building a biological prosthesis for end-stage OA.
This project received funding from the European Union's Horizon 2020 research and innovation programme under grant agreement no 874837.

4D BIOPRINTING WITH AUTOLOGOUS ADIPOSE TISSUE DERIVED ECM BIOINK ENABLES COMPLETE RE-EPITHELIALIZATIOIN OF CHRONIC DIABETIC FOOT ULCER WOUND WITHIN 4 WEEKS

Jeehee Kim$_P$[1]

[1] *ROKIT HEALTHCARE, Inc*

Corresponding author's email: Jeehee.kim@rokit.co.kr

The medical industry has been globally exploding together with innovative drugs and medical devices development. The latest biological research accelerates to discover new approaches of cell and gene therapy for repairing damaged human body. The fourth industrial revolution combined life, engineering and digital science strategically disrupts the traditional pharmaceutical medicine market to open a new era in healthcare business. Indeed, advances in three-dimensional (3D) bioprinting technology and their various applications in tissue engineering provide emerging solutions of precision medicine and customized healthcare. Since 3D bioprinting fabrication is the best way to recapitulate complex and functional human tissue and organ, we have developed the therapeutic 3D bioprinter called INVIVO to use in skin, cartilage, and cardiac regeneration. To find advanced treatment method particularly for wound healing, we tested our own 3D bioprinting system with autologous fat tissue for diabetic foot ulcer (DFU) treatment. The extracellular matrix (ECM) derived from nano-fat consisting of supportive proteins, growth factors and cytokines, has been reported as an important player to provide efficient 3D environments during cell proliferation and differentiation. In the clinical study, we printed minimally manipulated autologous ECM (MA-ECM) with bio-inks to apply onto the chronic wound site. Most of DFU patients showed significant reduction of wound size with distinct epithelization process only after a week treatment of 3D bioprinting MA-ECM. Therefore, we suggest 3D bioprinting system with MA-ECM as an alternative method for dressing materials that successfully promote the mechanism of skin reconstruction for DFU treatment.

Mesenchymal stem cells (MSCs) , experience influential microenvironmental conditions, which induce specific metabolic profiles that affect processes of cell differentiation and dysregulation of the immunomodulatory function. Reports focusing specifically on the metabolic status of MSCs under the effect of pathophysiological stimuli - in terms of flow velocities, shear stresses or oxygen tension – do not model heterogeneous gradients, highlighting the need for more advanced models reproducing the metabolic niche. Organ-on-a-chip technology offers the most advanced tools for stem cell niche modelling thus allowing for controlled dynamic culture conditions while profiling tuneable oxygen tension gradients. However, current systems for live cell detection of metabolic activity inside microfluidic devices require the integration of microsensors. The presence of such microsensors pose the potential to alter microfluidics and their resolution does not enable intracellular measurements but rather a global representation concerning cellular metabolism. Here, we present a metabolic toolbox coupling a miniaturised in vitro system for human-MSCs dynamic culture, which mimics microenvironmental conditions of the perivascular niche, with high-resolution imaging of cell metabolism. Using Fluorescence Lifetime Imaging Microscopy (FLIM) we monitor the spatial metabolic machinery and correlate it with experimentally validated intracellular oxygen concentration after designing the oxygen tension decay along the fluidic chamber by in silico models prediction. Our platform allows for the metabolic regulation of a metabolic profile to MSCs, mimicking the physiological niche in space and time, and its real-time monitoring representing a functional tool for modelling perivascular niches, relevant diseases and metabolic-related uptake of pharmaceuticals.

HUMAN SALIVARY GLAND RESIDENT EPITHELIOMESENCHYMAL STEM CELL DERIVED EXTRACELLULAR MATRIX (ECM) IMPROVED ORGANOID FORMATION AND MATURATION

Yeo-Jun Yoon[P][1], Joshua Jaeyun Kim[2]

[1] *Yonsei University College of Medicine*

[2] *ROKIT HEALTHCARE, Inc*

Corresponding author's email: joshua@rokit.co.kr

Salivary gland organoids have therapeutic potential for treating salivary gland hypofunction. We developed salivary gland organoid, in which bone marrow stem cell (BMSC)-derived extracellular matrix (ECM) supports formation of salivary gland organoids and growth of acinar cells. We tested the regenerative potential of salivary gland organoids after transplantation into SCID mice model for Sjögren syndrome. Compared to the Matrigel conditioned media group, organoid grown with human primary BMSC derived ECM group was not only equivalent in growth rate, but also superior in ductal cell marker K5/K7 expression level at the basal/ luminal position of the organoid. Furthermore, AQP5, a pro-acinar marker, was identified, and Amy1 was present in the cytosol. In Amy1 measurement, Amy1 activity per unit cell was higher than that of Matrigel group. Furthermore, in the evaluation of other salivary gland functional markers such as BHLHA15, MUC7, KRT7, ACTA2 and CCND1, salivary gland organoid grown with BMSC ECM showed 2 folds or more functional enhancement compared to Matrigel group. Next, we implanted fully matured salivary gland organoid grown with BMSC ECM into SCID mice. Salivary gland organoid transplants showed salivary gland architectures at 2 weeks after implantation and contributed structural and functional rescue of salivary gland dysfunction in SCID mice. In conclusion, salivary gland organoid using primary human parotid gland grown with BMSC ECM successfully recapitulated the specific characteristics of human salivary gland. We expect this salivary gland organoid offers opportunities not just as a practical research tool but as a clinically translatable solution for medical treatment.

WHOLE HUMAN EXTRACELLULARMATRIX (ECM) DERIVED FROM NEONATAL DERMAL FIBROBLAST CULTURE ACHIEVED COMPLETE BURN WOUND REGENERATION WITHOUT FORMING SCAR

Joshua Jaeyun Kim$_P$[1]

[1] *ROKIT HEALTHCARE, Inc*

Corresponding author's email: joshua@rokit.co.kr

WHO reports over 11 million people suffer from sever burn wound not only in traumatized body condition but also in post injury psychological trauma. Currently, there is no one time treatment that prevent further infection and promotes scarless skin regeneration at the same time. We derived human whole dermal ECM from neonatal dermal fibroblast culture and prepared in lyophilized powder form for burn wound treatment. In porcine model, 4cm x 4cm burn wounds (between 2nd and 3rd degree burn) were created. ECM powder dissolved in saline was sprayed directly on the derbidemented wounds. Re-epithelialization was achieved in 14 days and 35 days follow up showed fast skin regeneration pattern without contraction compared to control group (no treatment). At day 35, ECM treated group showed complete re-epithelialization with hair without scar while control group showed scar formation due to contraction. Furthermore, proteomic analysis showed ECM applied group had minimal amount of collagen type I content similar to that of normal undamaged skin. In histological analysis, rich collagen type III, which is main collagen type in dermis, was found in newly formed dermis of ECM treated group. However, collagen type I was main collagen type in control group. We also confirmed the reformed basedment membrane. Moreover, in immunohistological analysis, CTGF (connective tissue growth factor associated with fibrotic tissue formation) level was 4 folds less than scar formed control group. We confirmed that whole human ECM from matching tissue type cell provided a regeneration niche that is a minimal requirement for dermal regeneration.

CHITOSAN-NANOCRYSTALLINE CELLULOSE SCAFFOLDS FOR BONE TISSUE ENGINEERING: EFFECT OF TWO DIFFERENT CROSSLINKING AGENTS ON THE PHYSICOCHEMICAL PROPERTIES OF THE SCAFFOLDS

Fatemeh Doustdar$_P$[1], Ali Olad[1]

[1] *University of Tabriz*

Corresponding author's email: f.doustdar@tabrizu.ac.ir

In the current study, the porous scaffolds based on chitosan and nanocrystalline cellulose polymers were fabricated for bone tissue engineering through the freeze-drying method. The effect of calcium cation as an ionic crosslinking agent and glutaraldehyde as a covalent crosslinking agent on the different features of the scaffolds was investigated. The accuracy of the syntheses was approved using the FTIR technique. The morphological and mechanical properties of scaffolds were evaluated through SEM imaging and tensile tests, respectively. Moreover, the water uptake capability of the scaffolds was investigated in PBS buffer (pH=7.4). The SEM images showed that the scaffolds are highly porous which provides proper surroundings for cell growth, cell migration, and transmission of nutrients and waste to or from cells. In addition, the scaffold which crosslinked by glutaraldehyde possesses a more uniform structure with bigger pores compared with the scaffold crosslinked by the calcium cation. Moreover, tensile tests represent that Young's modulus of glutaraldehyde-crosslinked scaffold is 2.5 folds greater than that of the ion-crosslinked scaffold. It can be concluded that the glutaraldehyde-crosslinked scaffold has better mechanical properties and a more stable 3D network. Furthermore, the water absorption capacity of the glutaraldehyde-crosslinked scaffold was higher than that of the ion-crosslinked scaffold. This can be attributed to the stable structure of the glutaraldehyde-crosslinked scaffold which can absorb and retain greater amounts of water. In this research, the glutaraldehyde-crosslinked scaffold showed better physicochemical properties than the calcium cation-crosslinked scaffold.

Recently, tumor research focused onto microgravity cell cultures, analyzing the epigenetic effects in malignancy cellular behavior [1]. Nowadays, no dynamic culture system in use with microgravity conditions showed the capability to generate truly in vitro 3D tissue models by having a controlled geometry at the cellular scale [2]. Those systems, engineered to reach orbiting laboratories, as into the International Space Station, are limited to non-frangible substrates due to regulations. Therefore, we developed high resolved (~100 nm) synthetic 3D cell culture scaffolds [3] suitable to microgravity and zero-gravity applications. They are fabricated on a commercial non-frangible cyclic-olefyn-copolymer by the two-photon polymerization (2PP) into a biocompatible photoresist [4, 5].

Given the gap between mechanical properties, the 3D model stability under the stress conditions involved by the flexibility of the substrate, was computationally evaluated first. Then, we developed a brand-new protocol for substrate preparation and polymerization.

This study proved the feasibility of the 2PP microfabrication of biocompatible scaffolds on deformable non-frangible substrates, thus representing a great promise in 3D cell culture substrates production for microgravity and zero-gravity applications.

The trabecular meshwork (TM) is an essential tissue in the eye that facilitates aqueous humour outflow and filtration. In glaucoma patients, TM cellularity decreases, and extracellular matrix (ECM) accumulates, disrupting aqueous humour outflow and causing a rise in intraocular pressure. This damages optic nerves and leads to irreversible blindness(1). Adult stem cells in the TM (TMSCs) may offer a solution this problem, as they proliferate in response to damage caused by laser trabeculoplasty(2). We investigate the possibility for TMSCs to differentiate on ECM deposited by glaucomatous TM cells and therefore the potential to repopulate the TM in glaucoma patients.

Primary TM cells were cultured from dissected donor TM tissue. TMSCs were isolated over 7 days by sphere culture, a method encouraging growth of stem cells whilst initiating apoptosis of differentiated cells. Spheres were differentiated on ECM deposited by glaucomatous (GTM3) and normal (NTM5) immortalised TM cell lines for 7 days.

TMSC spheres successfully attached to tissue culture plastic (TCP) as well as the GTM3 and NTM5 ECM coating within 24 hours. Irrespective of ECM coating, spheres differentiated into cells with TM cell morphology. However, after 5 days, cells on GTM3 ECM had similar morphology to that of healthy primary TM cells and spheres were absent, whereas structures resembling spheres remained on TCP and NTM5 ECM coated wells.

TMSCs appear to differentiate at different rates on ECM from GTM3 compared to NTM5. Further studies will compare TM cell markers with primary cells; as well as assess TM phagocytic function.

Tissue engineering strategies leveraging cellular self-organisation (SO) are capable of producing hyaline-like cartilage grafts [1,2], although recapitulating the spatial organisation of the tissue's collagen network remains a challenge. Additionally, current methods to securely fix such engineered tissues within joint defects are inadequate, leading to graft loosening and implant failure [3]. This study seeks to address both challenges by developing a 3D printed device capable of firstly guiding the SO of jetted MSCs to generate a structured engineered cartilage, and secondly, securely fixing such grafts into the subchondral bone. First, a monolithic polycaprolactone implant composed of an overlying microwell array (designed to direct engineered tissue growth) and an underlying anchoring pin was fabricated by fused deposition modelling. Biofabrication of the cartilage graft involved the automated deposition of MSCs into microwell arrays of the implant via inkjet bioprinting. Inkjetting enabled the accurate deposition of high cell numbers (up-to 264 x 106 cells/mL) in low media volumes (< 1 µL) into individual microwells. Within these microwells, in the absence of any adhesive sites, cells self-organised and in chondrogenic culture conditions formed a thick and biomimetic cartilage. The engineered tissue was rich in cartilage matrix-specific extracellular matrix (ECM) components and importantly exhibited a 'Benninghoff' collagen architecture. Finally, we demonstrated that in dynamic culture conditions, using a custom bioreactor, the quality of the engineered cartilage could be enhanced (to near native levels of cartilage ECM components), forming a thick (>1 mm thick) spatially organised tissue.

Cancer is the second leading cause of death worldwide. Despite the huge efforts to find effective treatments, failure rate is still high [1]. Bioprinted cancer models represent a significant improvement for drug discovery by mimicking the complex physiological 3D architecture [2]. Matrigel is the most common basement membrane used in vitro as substrate for 3D cell culture, as it is very similar to the physiological one [3]. However, its use is challenging due to its physico-chemical properties. Therefore, it is often used in combination with other polymers. To obtain the desired constructs, extensive knowledge of materials properties is strictly necessary.

To retrieve these characteristics, we performed rheological measurements in order to estimate the dynamic viscosity. Considering the wide range of possible shear rates acting on fluids, we started measuring viscosity at shear rates ranging from 0.1 to 100 [1/s]. Moreover, we also investigated the mechanical behaviour of hydrogels, evaluating their storage and loss moduli (G' and G'' respectively). All measurements were performed at 4, 20 and 37 °C. Preliminary results showed high variability in matrigel samples due to batch differences. This aspect significantly impairs filament extrudability and bioprinted fiber homogeneity. To overcome this limitation, matrigel dilutions with PBS and combinations with alginate/gelatin blend (4.5%/6.5% w/v in PBS) at different ratios increased reproducibility and improved bioprinting process, but impaired scaffolds mechanical stability. Therefore, we will evaluate swelling/degradation properties within three weeks to further characterize hydrogels capability to retain their structures over short and long time period cultures.

Autologous osteochondral transplantation (AOT) has been shown to outperform other clinical joint repair strategies[1,2], and is the only treatment that consistently resurfaces the joint with a hyaline cartilage tissue. However, several shortcomings limit AOTs universal uptake[3]. This project sought to use two phenotypically distinct populations of cartilage microtissues as biological 'building blocks' to fabricate biomimetic osteochondral plugs capable of regenerating critically sized synovial joint defects. The chondral region of the implant was engineered using stable cartilage microtissues that were combined, allowed to fuse, and self-organize (SO) into a homogenous hyaline-like cartilage tissue. Hypertrophic cartilage microtissues, primed to recapitulate the developmental process of endochondral ossification, were used within the osseous region of the implant. The engineered implant was evaluated in a pre-clinical, large animal (caprine) model. A novel method for forming phenotypically distinct cartilage microtissues, in a medium/high-throughput fashion was developed. The hypertrophic cartilage microtissues were rich in sGAGs and mineral, while the hyaline-cartilage tissues were rich in type II collagen with little evidence of hypertrophy. These distinct microtissues were spatially localised into chondral and osseous phases of a 3D-printed polymer implant that further functioned to guide the SO process, supporting the generation of a zonally defined collagen network in the chondral layer. After 6 months in vivo bone ingrowth into the osseous region was observed, stabilizing the implant, and facilitating the chondral region of the implant to support the restoration a near-normal articular surface. The cartilage repair tissue was superior to empty control defects, where little spontaneous regeneration was observed.

The set- up of advanced in vitro model of bone and cartilage defects and fractures is a topic of growing interest for the evaluation of regenerative processes and innovative therapeutic solutions. However, despite the increasingly availability of biomaterials and therapies, there is still a relevant blank in the preclinical evaluation models. Few tissue models of osteochondral defects are described in literature, using mainly animal tissues, and without definition of a reference culture set-up (1).

Aim of the study is to develop 3D tissue models that simulate osteochondral defects in vitro, to be used to assess the regenerative potential of biomaterials/bank products, cells, growth factors or combination of them.

Cylindrical osteochondral tissue samples were harvested from the femoral head of cadaver beating heart donors. From each sample, a smaller inner portion was extracted; to fully characterize the model, autograft (inner core of the same donor), allograft (inner core from different donor) and empty tissue explants (without inner core) were cultured for 8 weeks in dynamic culture condition.

Osteochondral tissue samples showed stable viability, without significant fluctuations and regardless of the experimental group. Microtomographic images showed signs of integration of the graft, mainly along the lateral contact surfaces between graft and defect. Molecular and histological analyses are in progress to evaluate both regulation of genes related to bone and cartilage metabolism and integration.

The proposed 3D human tissue culture promises to be reliable and replicable, capable of mimicking an osteochondral defect condition for the preliminary evaluation of treatments and therapies.

Introduction:

Women with dense breast tissue are at an increased risk of developing breast cancer. This is attributed to the increased periductal collagen stiffness and organisation present in dense breast tissue[1]. The mechanical cues present in stiff breast tissue can stimulate pro-oncogenic behaviour in mammary epithelial cells (MECs) via mechanosensitive signalling pathways[2]. However, these pathways are ill-defined.

Investigating mechanosignalling events between MECs and their environment requires a mechanically tunable and defined model of the human mammary gland. Biomaterials currently used to model the mammary gland suffer from limitations that inhibit their ability to recapitulate the native breast environment, highlighting the need for a biomaterial that meets our requirements[3].

Methods:

PeptiGel® Alpha4 (Manchester BIOGEL), a self-assembling peptide hydrogel that supports MEC viability[4], was used. Non-malignant, human MECs (MCF10a) were encapsulated in Alpha4 for 12 days before being probed for markers of acinar development. Modifications made to gels included diluting them with PBS and mixing in laminin 111.

Results:

Alpha4 supports the development of clusters that deposit a laminin-rich basement membrane but lack other markers of acinar development. Functionalised Alpha4 gels yielded softer gels that increased MCF10a viability and cluster formation. However, these modifications did not stimulate acinar development.

Conclusion:

We show that Alpha4 supports MCF10a cluster formation and basement membrane deposition as well as being amenable to chemical and mechanical tuning. These results suggest that, with further optimisation, Alpha4 can be used to make an accurate model of the human mammary gland which will help us define MEC-matrix interactions.

Mesenchymal stem cells (MSCs) are the most promising source for cell-based therapies, not only for their potentiality in differentiation and tissue regeneration but also for their immunomodulatory and anti-inflammatory effects and their marked trophic activity [1]. In the panorama of three-dimensional culture systems for stem cells expansion, a particular scaffold called NICHOID was developed, an innovative engineered niche fabricated via two-photon polymerization of a negative hybrid photoresist (SZ2080), conceived to emulate the native microenvironment [2]. The ability of NICHOID to maintain stem cells pluripotency without adding exogenous factors have already been assessed [3][4]. Here we resolved to investigate the effect of 3D NICHOID on the whole transcriptome of MSCs. For this purpose, two versions of NICHOID were fabricated, the 3D and a single-layered one, used as flat control. Rat bone marrow MSCs (rBMSCs) were cultured on both structures, their morphology and viability assessed and RNA extracted after 4 days. Later, differential expression and enrichment analyses were carried out. Results showed that rBMSCs were vital in both conditions but displayed a different morphology, which translated into a total of 603 differentially expressed genes and several interesting deregulated pathways. These evidences proved that NICHOID, thanks exclusively to its tridimensional pattern and to the forces it exerts on cells, is able to maintain, beyond pluripotency, other peculiar features of MSCs.

Increased expression of T-type calcium channel (TTCC) in cancer has paved the way for TTCC blockers to be tested for their anticancer activity. Various studies have shown that blocking TTCCs reduces cancer cell viability. TTCC blockers also provide a possible role as an adjuvant. It is well-known that drug-drug interaction can alter the actions of each other or cause adverse effects. Therefore, using in silico study, binding sites of a TTCC blocker and the paclitaxel (PTX)- a tubulin-binding agent, at the TTCC were studied. The combination index was calculated using in vitro assay to study the interaction between the two drugs.

Molecular docking results showed that both drugs could bind with a good binding affinity with the TTCC at the same sites, thus exhibiting competition for the same sites. However, the TTCC blocker exhibited a higher binding affinity as compared to the PTX.

Further, molecular dynamics analysis confirmed that the TTCC blocker bound at the active site of the TTCC and resulted in the formation of the stable protein-ligand complexes. In vitro study showed the antagonistic interaction between the drugs when given together for the combination treatment. However, the sequential treatment, where the TTCC blocker was removed before adding the PTX, reduced cancer cells' viability further, even at a low TTCC blocker's concentration. Hence, we conclude that the TTCC-TTCC blocker complex is more stable than the TTCC-PTX complex, and sequential treatment can be used to circumvent the competitive antagonistic interaction between the two drugs.

Osteoarthritis is a degenerative condition of the Articular Cartilage (AC) occurring due to age, trauma, or repetitive injury. The current treatment provides short-term benefits that have given rise to Tissue Engineering. 3D-printing has surfaced as a promising strategy to engineer mechanically functional scaffolds for cartilage tissue engineering. An advantage of 3D-printing is that the architecture of the scaffold can be controlled and can be mechanically reinforced with networks of stiffer polymers such as Polylactic-co-glycolic acid (PLGA) to engineer composites that are both mechanically functional and supportive of new tissue deposition by resident cells. PLGA has gained considerable interest due to its biocompatibility, tailored biodegradation for cartilage regeneration, and so on. However, synthetic polymers have poor cell adhesion properties which are overcome by natural polymers. Alginate is a naturally derived polysaccharide and a versatile biomaterial owing to its excellent biocompatibility, printability, and ability to support the differentiation of encapsulated cells. Here, a new class of functionalized alginate and PLGA have been developed for the 3D-printing of composite scaffolds. The scaffold loaded with Mesenchymal cells are also found capable of supporting robust chondrogenesis. Immunohistochemical analyses of the scaffolds revealed enhanced type II collagen fibril and cartilage tissue formation. Finally, it is demonstrated that this network of composite 3D-printed PLGA fibres with Alginate showcased a compressive modulus comparable to the native AC. In conclusion, an innovative 3D-printed composite scaffold of PLGA infused with Alginate for cartilage regeneration has been presented.

Treatment options for triple-negative breast cancer (TNBC) are limited to chemotherapy (1). Current cancer models include 2D cell culture and mice models but are unable to accurately mimic human TNBC (2). This highlights the need for the development of a representative in vitro model to study TNBC behaviour and identify new treatment targets. This project aims to develop a collagen-based model composed of components of breast tissue including hyaluronic acid (HyA) and chondroitin sulphate (CS), both elevated in tumours, to investigate their role in the epithelial-mesenchymal transition (EMT) process, which promotes TNBC cell migration and invasion.

Collagen-based slurries comprised of three different concentrations of HyA or CS were freeze-dried and crosslinked using previously optimised protocols (3). Scaffold characterisation was performed using SEM, porosity, pore size analysis and mechanical testing. AlamarBlue, dsDNA and live/dead assays were performed to assess the metabolic activity and growth of TNBC cell lines, MDA-MB-231 and MDA-MB-436. The effect on EMT is being assessed using qPCR and western blot analysis.

Results showed that all scaffolds exhibited characteristics conducive to cell growth. Different concentrations of HyA or CS did not affect cellular growth though cells were more metabolically active in HyA versus CS scaffolds. The effect on EMT is currently being analysed.

In conclusion, we have successfully fabricated suitable scaffolds to model different TNBC tumour microenvironments and assess the EMT process. These scaffolds have huge potential to be used as efficient 3D drug testing platforms.

This work was funded by the Health Research Board Investigator Led Project [ILP-POR-2019-023].

SPHEROIDS AS VASCULARIZED BUILDING BLOCK UNITS FOR BONE TISSUE ENGINEERING

Filipa Teixeira$_P$[1], Lorenzo Moroni[1], Carlos Mota[1]

[1] Maastricht University, MERLN Institute for Technology-Inspired Regenerative Medicine, Complex Tissue Regeneration Department, Universiteitssingel 40, 6229 ER Maastricht, The Netherlands

Corresponding author's email: f.castroteixeira@maastrichtuniversity.nl

Spheroids represent an attractive building block unit for bone tissue engineering (TE), especially when pre-vascularized. These allow to create and mimic the in vivo 3D microenvironment, mainly the cell-to-cell and cell-to-extracellular matrix (ECM) interactions and fusion. It is precisely this fusion capacity that makes spheroids a promising building block for bottom-up TE approaches. Bioprinting is one of the approaches where tissue spheroids have been largely investigated to form 3D complex-shaped constructs for tissue and organ regeneration [1]-[4]. The ability to promote adequate vascular morphogenesis in spheroids is a complex process, which is still not completely understood.

In this study, we aim to use vascularized spheroids for bone TE, and evaluate the potential of endothelial cells and their role in osteogenic differentiation. First, we investigated the culture conditions to generate vascularized spheroids using human mesenchymal stromal/stem cells (hMSCs) and human umbilical vein endothelial cells (HUVECs). Spheroid fusion in suspension or in hydrogels were investigated to access the assembly into a larger tissue intermediates to form 3D complex vascularized macro-tissue. Results show that the hMSCs/HUVEC ratio strongly influences the stability and compactness of microtissues. Furthermore, cell viability is largely influenced by the ratio and size of the microtissues. Future studies will aim at inducing differentiation to these microtissues and their bioprintability for the creation of vascularized bone implants.

Keywords

Spheroids; Vascularization; Bone tissue engineering

In recent years, the design of photoactivatable materials has stimulated a widespread use of light-mediated biofabrication techniques,1 which present powerful tools to mimic multiscale tissue organization, with resolution ranging from nanometer to centimeter. However, most of the work has been done with homogenous, bulk hydrogel compositions, hence overlooking the potential of three-dimensional microarchitecture in directing cell fate. In certain tissues, such as muscle, cell alignment plays a fundamental role in physiological tissue function. Our group has developed a simple method to create microarchitected hydrogels,2 which provide physical guidance for oriented cell growth and tissue development and a vastly improved mass transport, therefore helping to overcome nutrient diffusion, a major and common obstacle for the realization of centimetre-sized grafts. Aligned microgels are generated by sizing a cell-laden bulk hydrogel through grids with apertures ranging from 20 to 100 µm. A second light-driven crosslinking step stabilize the aligned microstructures. Here we first report C2C12 myoblasts fusion and maturation in aligned myofibers, resulting in a contractile construct. In addition, we investigated the influence of various size of Gel-MA based microgels (20, 40, 70 and 100 µm) on the oriented and functional maturation of wild type primary mouse myoblasts. The importance of cellular crosstalk in the mature and contractile construct was also assessed by the introduction of other cell types, such as endothelial and satellite cells. Finally, the potential use of this system as an in vitro disease model has been evaluated with myoblasts from a mouse model of Duchenne Muscular Dystrophy.

Dental pulp (DP) and periodontal ligament (PDL) cells derive embryologically from the interaction between cells from the neural crest and the underlying mesenchyme. Given the limited availability of dental pulp cells (DPCs), there is a need to find alternative cells sources for endodontic tissue engineering applications. Mesenchymal stem cells (MSCs)-like populations have been isolated from both DP and PDL. However, these population are very heterogenous and present dissimilar differentiation potential.

This study aimed at evaluating the odontogenic potential of 3 specific subpopulations (SSEA-4+, CD90+, and nestin+), isolated from human PDL fibroblasts (PDLFs) using magnetic sorting. These cells were cultured on basal and osteogenic α-MEM for 7 and 14 days. Cultures were assessed in terms of proliferation, ALP activity, mineral matrix deposits, calcium content, and gene expression.

Results showed that the SSEA-4+ cell population was more prone to differentiate into the odontoblast phenotype and deposit more mineralized matrix compared to a non-sorted population or DPCs from the same donor.

We concluded that the SSEA-4+ PDLF cells population could differentiate into the odontogenic pathway, whereas CD90+ and nestin+ PDLFs were more similar to the original fraction. Furthermore, our studies show that SSEA4+ cells can be homed directly from bulk PDLFs into hydrogels using magnetized files. Overall, these results allow us to propose SSEA-4+ PDLFs as a potential alternative to DPCs for tissue engineering approaches aiming endodontic treatments.

A NOVEL BIOENGINEERED TISSUE MODEL FOR THE DEVELOPMENT OF PHARMACEUTICALS IN THE TREATMENT OF HUMAN INFLAMMATORY BOWEL DISEASE

Claire L Mobbs[P][1,2], Stefan A Przyborski[1,2]

[1] *Durham University*

[2] *Reprocell Europe*

Corresponding author's email: claire.l.mobbs@durham.ac.uk

Inflammatory bowel diseases (IBD) are complex pathologies with an increasing worldwide prevalence. It is therefore essential to better understand the cellular interactions underpinning these diseases. However, modelling IBD in vitro is difficult due to their complex aetiology. The scarcity and short-lived nature of IBD tissue ex vivo, low similarity between animal and human tissue, and absence of physiologically relevant in vitro models impedes research progression.[1][2] Most research efforts have focused on immune-mediated barrier damage, neglecting other critical mediators of the inflammatory response, including fibroblasts. There exists irrefutable evidence that fibroblasts are not just bystanders in mucosal inflammation but are pivotal participants in orchestrating the immune response.[3]

We have bioengineered a highly reproducible, in vitro model that better recapitulates aspects of the IBD intestinal mucosa. These constructs utilise a porous polystyrene scaffold to construct lamina-propria-like compartments with an overlying epithelium. Subepithelial fibroblasts within the lamina-propria secrete endogenous ECM, alongside a co-cultured viable immune component that simulates the mass immune-cell infiltration observed in IBD.

These IBD models can be treated with stimuli to produce an inflammatory environment. Mimicking an inflammatory phenotype induces endogenous cytokine secretion, impacts barrier function, as well as stimulating lamina-propria inflammatory events such as ECM-remodelling. This in vitro system allows for investigation into complex interplay between epithelial, mesenchymal and immune cells and the resultant effects on barrier function, thus simulating key aspects of IBD. These results demonstrate the potential for this novel bioengineered system to be used for pharmaceutical compound testing in a controlled, reproducible and physiologically relevant environment.

Human meniscus presents a peculiar time-dependent response to loads - which is related to the interaction between solid (extra-cellular matrix with collagen fibres network) and fluid phase -, that makes it a key player in knee biomechanics. Although the importance of meniscus pathophysiology, a complete assessment of the relation between structure and function is not yet achieved. Thus, the purpose of this study was to elucidate the contribute of solid and fluid phase in response to compressive load. Mechanical tests were performed on cubic samples, harvested from anterior horn, central body and posterior horn of 7 human lateral menisci, where radial, circumferential and vertical directions were clearly identified. Fibril-network-reinforced biphasic model was fitted to experimental data achieved through unconfined compression tests, in order to estimate fibril modulus Ef, matrix modulus Em and hydraulic permeability k of the tissue. Histological analyses were performed taking care to visually maintain the information about the orientation adopted during mechanical test. Tissue porosity and collagen fibres arrangement were evaluated. Regional and strain-dependent parameters for a fibril-reinforced biphasic model of the lateral meniscus tissue were proposed, specifically isotropic in the horns and transversely isotropic (i.e. isotropy plane formed by radial and vertical directions) in the body. Fibres orientation and percentage of porosity on various regions and planes supported the differences highlighted in the compressive responses. The mechanical and histological observations of this study support the functional characterization of the meniscal tissue, crucial for modelling the tibio-femoral contact and for the realization of constructs for meniscal replacement.

The decellularized extracellular matrix (dECM) is used as a bioink for 3D bioprinting or as a hydrogel for studying the physiology of tissues. In this study, we obtained dECM from goat digital flexor tendon using physical and chemical methods. The dECM was subjected to enzymatic digestion and the final hydrogel was termed as tendon-derived ECM (tdECM). The tdECM was characterized for its physicochemical properties using Fourier Transform Infrared Spectroscopy (FTIR) and Scanning Electron Microscopy (SEM). Collagen, dsDNA, GAGs, and protein contents were quantified using spectrophotometric assays. The cell viability and proliferation of mouse fibroblast cells (L929) and human umbilical cord-derived mesenchymal stem cells (UMSCs) encapsulated in the tdECM hydrogel inside the microfluidic device was checked using Calcein-AM/PI. The FTIR data showed prominent peaks of amide group indicating the presence of collagen. The SEM data showed intact fiber morphology after the decellularization process. There was 94% reduction in double-stranded DNA (dsDNA) content, hence, proving the effectiveness of the decellularization technique. There was no significant difference in the collagen content of tdECM as compared to the native tissue. The GAGs and protein contents were reduced due to the decellularization process but were in the acceptable range. Over 90% cell viability in L929 and UMSCs was observed both qualitatively and quantitatively. In conclusion, we demonstrate the effectiveness of the decellularization process using a combination of physical and chemical methods followed by tdECM biocompatibility in a microfluidic device to understand the stem cell behavior in a 3D condition.

CASTING OF HUMAN SIZED MULTI-LAYERED EARS FOR THE TREATMENT OF MICROTIA

Enrico Tosoratti[P][1]

[1] *Tissue Engineering + Biofabrication Laboratory, ETH Zürich, Switzerland*

Corresponding author's email: enrico.tosoratti@hest.ethz.ch

Tissue-equivalent implants are necessary for the treatment of craniofacial deformations such as microtia. However, biofabrication of multi-material constructs remains challenging due to the complex and layered structure of anatomical tissues[1,2].

Additive manufacturing technologies can help in the biofabrication of tissue-equivalent implants. Our technique for the biofabrication of heterogeneous multi-layered implants uses diffusion induced gelation and involves the computational design of multi-part molds, termed metamolds[3], that respect the geometric and topological constraints involved in the process of casting. Metamolds are fabricated using biopolymers and are preloaded with a crosslinker of interest. The subsequent casting of the implant into consecutive metamolds allows for the precise generation of multi-layered hydrogels with elevated precision (50 µm). The mechanical stability and bonding between adjacent layers are achieved using an enzymatic-based strategy triggered by the elution of 100 mM CaCl2 and 0.1% H2O2 from the metamolds. The porosity of the construct is increased by fabricating the core material using entangled microstrands[4] and including sacrificial microstrands in the outermost layers.

As a proof of concept, three-layered anatomical human-sized ears were generated using different biomimetic hydrogels. The cartilage structure was formed using auricular chondrocytes embedded in an HA-tyramine/alginate-based hydrogel. The perichondrium layer was formed using chondroprogenitor cells within a densely crosslinked collagen-tyramine gel. Finally, fibroblasts and endothelial cells were encapsulated within a loose collagen gel to resemble a layer of connective tissue. Samples were cultured for nine weeks and analyzed via mechanical testing and immunochemistry showing excellent cell viability and maturation.

INTRA-ARTICULAR TRIAMCINOLONE ACETONIDE-LOADED LIPOSOMES DO NOT AFFECT THE PROGRESSION OF JOINT DAMAGE IN A RAT METABOLICALLY ACCELERATED GROOVE MODEL OF OSTEOARTHRITIS

J. L. Rios[1], H. M. de Visser[1], G. Geusebroek[2], G. Storm[2], N. Dupuis[2], S. G. Plomp[2], K. Warmink[1], N. Eijkelkamp[1], M. Tryfonidou[2], P. R. van Weeren[2], H. Weinans[1], N. M. Korthagen[2,3]

We evaluated the effect of slow-release anti-inflammatory treatment (triamcinolone acetonide loaded liposomes [TAA-L]) in a model mimicking metabolically accelerated post-traumatic osteoarthritis. Wistar rats were fed a high-fat diet, twelve weeks after diet-onset, bilateral osteoarthritis was induced employing small grooves at the femoral condyles1. At 13 and 19 weeks, rats received an intra-articular injection with TAA-L in their left knee (30µg or 100µg TAA). Saline or empty liposomes were injected intra-articular in the right knee. At week 24, rats were euthanized, and knees were harvested for histology (OARSI score) and microCT images (subchondral plate thickness and osteophytes). Preliminary results show no difference between groups for the OARSI cartilage (average ±SD: 4.7 ±2.3 out of 15; p=0.5) and subchondral bone scores (average ±SD: 1.2 ±0.4 out of 5; p=0.5), nor for subchondral plate thickness (average ±SD: 272 ± 30 µm, p=0.2) in the tibial lateral plateau. Interestingly, none of the rats that received TAA-L injection at a dose of 30 µg presented signs of synovial inflammation (OARSI score 0), while control knees treated with saline, empty liposomes, or 100 µg TAA-L presented signs of synovial inflammation in 50% of the rats. In conclusion, TAA-L did not prevent joint damage progression in our metabolically accelerated groove model of osteoarthritis, but 30µg TAA-L reduced synovial inflammation. Thus, low doses of TAA-L might be a strategy to reduce joint (synovial) inflammation and possibly related joint pain, therefore, further investigation of the potential dose-response analgesic and anti-inflammatory effects is recommended.

ADAPTING NEW OTOLOGIC DEVICES TO THE CLINICAL ENVIRONMENT – THE NEXT GENERATION OF TYMPANIC MEMBRANE REPAIR

Elaine Horn-Ranney[P][1], Sithara Nair[1], Bethany Young[1]

[1] *Tympanogen, Inc.*

Corresponding author's email: elaine@tympanogen.com

INTRODUCTION: Perf-Fix light-curable gel patch is a highly regenerative and non-ototoxic biomaterial intended to replace traditional tympanoplasty with a cost-effective in-office procedure while regenerating native tympanic membrane (TM) architecture, thereby eliminating a common surgery and its complications for thousands of patients annually. Mechanistic, usability, and regulatory design criteria for Perf-Fix were optimized for current clinical workflows for facile transition from bench to patient. METHODS: Custom pouches that fit luer-lock syringes were filled with lyophilized Perf-Fix reagents for intuitive reconstitution with saline. Uncured Perf-Fix was applied to animal and surrogate TMs with a curette, then cured with blue light from a custom curing light. Perf-Fix delivery system designs were refined through user feedback and anatomical simulation. Safety and efficacy were evaluated through ISO 10993 biocompatibility studies. Shelf-life and sterility were evaluated with rheometry, aging and bioburden studies. RESULTS: Cured Perf-Fix formed a semi-interpenetrating network of hyaluronic acid and modified chitosan, and demonstrated no cytotoxicity after curing, amenable storage (2.5-5.0 kPa) and loss (0.2-0.4 kPa) moduli, and superior curing properties with human anatomical simulation testing. User-driven modifications of Perf-Fix, curing light, and delivery system resulted in positive clinician feedback and 90% reduction in procedure time. A sterility assurance level of 10-6 and shelf-life of 1 year by accelerated aging was achieved. CONCLUSIONS: Clinical translation requires constant user input with clear regulatory and implementation strategies from ideation. The adaptation of Perf-Fix to seamlessly fit clinical workflow may significantly improve tympanoplasty by eliminating the surgical aspect of TM repair and improve treatment outcomes.

Osteoarthritis (OA) is a degenerative joint disease that affects 1 in 3 people over 65 years old (1). OA established treatments often lead to complications and fail to deliver long-lasting satisfactory results. Therefore, tissue-engineering approaches aim to obtain de novo tissues to aid in the treatment of this disease (2). 3D bioprinting holds great promise in the generation of osteochondral constructs because it allows to deposit living cells combined with biomaterials in a layer-by-layer fashion (3). When combined with spheroids in a bottom-up approach, this technology has the potential to produce joint implants with the inbuilt biological information to produce osteochondral tissue in a process that mimics the endochondral ossification route.

In our work, we investigated hyaluronic acid as a biomaterial ink to form a spheroid-based bioink for bioprinting of osteochondral constructs. For this, hyaluronic acid was successfully methacrylated (HAMA), combined with Lithium phenyl-2,4,6-trimethyl-benzoylphosphinate (LAP) and photocrosslinked. Human mesenchymal stem/stromal cell spheroids (hMSC) were encapsulated in the synthesized biomaterial. Cell viability and distribution were assessed after one and seven days in culture, showing good cell viability and spheroid-to-spheroid fusion capacity within the biomaterial. Biomaterial inks were used to produce bioprinted scaffolds, and structural stability and resolution were optimized investigating the processing parameters. Ongoing and future experiments include osteochondrogenic differentiation analysis of encapsulated and bioprinted constructs. Furthermore the optimization of bioink formulations will take into account bioprintability, spheroid fusion allowance and degradation capacity. Finally, human periosteum derived cells will be studied as an alternative cell source for osteochondral implant manufacturing.

Background: Guided Bone Regeneration (GBR) is a regenerative therapeutic procedure that has been widely studied for its effective role in treating periodontal disease. Different membranes are currently used for GBR, however, none of them are completely fit for purpose(1). Researchers at Sheffield have partnered with Floreon Ltd. to test the biomedical potential of using a new polyester blend to manufacture an innovative GBR membrane.

Objective: The aim of this study was to fabricate a bilayer membrane made of ceramic-modified Floreon and to evaluate its mechanical and physicochemical performance.

Methods: A bi-layered membrane was fabricated which consisted of(i) porous bottom layer using electrospinning and Floreon reinforced with 10% of ceramic components; we hypothesise this membrane would preserve the bone socket; (ii) smooth layer of pure Floreon on top (physical barrier) obtained by spin-coating technique. PLA membranes were also produced as controls. Characterisation was performed for biophysical and mechanical properties through SEM, AFM, (DSC), porosity, wettability, tensile testing. The degradation was also monitored.

Results: The bilayer nanofibrous membranes exhibited excellent mechanical properties initially as well as after one month in PBS; Moreover, the electrospun Floreon membranes reinforced with ceramics exhibited an increase in pore diameter and fibre size which satisfies the ideal properties needed for GBR membranes.

Conclusion: Our combination of manufacturing techniques has proven to be a promising method for the development of new GBR membranes. This work demonstrates the potential of using Floreon and ceramic-modified Floreon for dental applications, and the advantages of modifying these blends with a Bio-ceramic components.

INTRODUCTION: Regeneration of osteochondral tissue presents a clinical challenge as its layered structure has depth varying mechanical properties and composition. Our lab has developed collagen scaffolds that can regenerate osteochondral tissue but their mechanical properties restrict their use to small joint defects [1,2]. To overcome this limitation, the aim of this study was to develop a biomimetic scaffold with mechanical properties suitable to restore function in large joint defects. METHODS: 3D-printed polycaprolactone scaffolds mimicking the mechanical properties of the of native tissue was combined with a tri-layered collagen type I based matrix with a chondral layer with an addition of collagen type II and hyaluronic acid (HyA), an intermediate layer with addition of HyA, and a osteo layer with an addition of nano-hydroxyapatite. RESULTS: The scaffolds' compressive modulus increased from 0.5MPa in the chondral layer to 16.5MPa in the osteo layer, and had high fixation (47.4kPa) and shear (0.93MPa) strengths to ensure that it can withstand the forces in an articulating joint. The scaffolds supported layer-specific stem cell differentiation, with cartilage matrix formation in the chondral layer and mineralization in the osteo layer. Mechanical properties of the scaffolds increased with culture time, proving that functional osteochondral restoration is possible with this scaffold. SIGNIFICANCE: This novel tri-layered scaffold was shown to support layer-specific stem cell differentiation in vitro, with mechanical properties suitable for load bearing joints to regenerate large defects to alleviate the need for joint replacement surgeries. In vivo assessment in an osteochondral defect model in goats is currently ongoing.

Damage or degeneration of any (biological) membrane is often as a consequence of disease and/or traumatic injury and current therapeutic treatments suffer from a number of limitations. The chicken eggshell membrane (ESM) is a unique material: not only does its innate physical and mechanical profile confer optimal barrier properties, it also demonstrates inherent biocompatibility/biodegradability characteristics. Moreover, to further enhance its therapeutic potential, the ESM may be further modified with the thermo-responsive polymer, poly(N-isopropylacrylamide) (PNIPAAm) as well as the incorporation of (drug-loaded) nanoparticles (NP): essentially, by changing the temperature, the release and delivery of NP can be targeted and controlled.

ESM samples were isolated using an optimised acid decellularization protocol and the physical and mechanical characteristics assessed using DMA, SEM, WCA, FT-IR and TGA/DSC. In vitro biocompatibility and cytotoxicity were performed using fibroblast cell lines (i.e. Malme-3, Malme-3M and 3T3) and standard cell culture assays. Optimisation of PNIPAAm hydrogel and NP formulations were identified before being combined with the ESM. Thereafter, additional mechanical and physical characterisation including drug loading, release and diffusion were performed on this construct.

ESM samples were successfully prepared and fully characterized. Fibroblasts cultured on both the extracted ESM samples and ESM-gel demonstrated high biocompatibility in terms of high cell attachment, spreading, viability and proliferation rates. NP were successfully loaded into construct and demonstrated a desirable release profile depending on the specific formulation (days to weeks). As such, this work summarizes the development of an ESM-based construct that may have significant impact in regenerative medical applications.

Drug discovery and development process comprise of preclinical and clinical phases that are very intensive, long, and expensive research phases. However, drug candidates can fail in clinical trials. Toxicity is the major reason that leads to about 30% of drug development failures. Recently, the withdrawal rate of drugs from the market was increased to 33.3% from 5.1% due to cardiotoxicity. When the drug fails at phase I, the reasons are probably related to 2-dimensional (2D) cell culture studies that do not represent the real tissue physiology; therefore, they provide misdirected data about the efficacy and toxicity of drug. On the other hand, cells in 3D cell culture give responses more alike cells in vivo conditions in terms of cell morphology, growth, proliferation, migration, and drug sensitivity [1]. For that reason, 3D cell culture is a promising approach to overcome problems of conventional methods at the preclinical phase. To create 3D cell culture models, cell manipulation techniques have been used for various tissue-engineering applications. Contactless magnetic manipulation techniques provide rapid, simple, and cost-effective 3D cell culture model formation where either paramagnetic agent [2-5] or magnetic materials [6] were utilized. We have developed 3D cardiac model based on a contactless magnetic manipulation approach to investigate doxorubicin-induced cardiotoxicity. This technique provides an easy and efficient way to fabricate 3D cardiac cellular structures for drug screening studies compared to conventional methodologies.

Keywords

contactless magnetic manipulation; cardiac tissue engineering; drug screening

Introduction

Loss and dysfunction of trabecular meshwork (TM) cells occurs with increasing age and is accelerated in primary open-angle glaucoma (POAG). TM progenitor cells (TMPCs) have the potential to repopulate the TM and could be used as a cellular therapy to restore the glaucomatous TM function. The biological properties and specific markers of TMPCs are still elusive. Understanding the transcriptome of TMPCs will identify specific markers and biological properties to facilitate the development of cell-based therapies to restore TM function in POAG.

Methods

Genome-wide transcriptome profiling was performed using RNA-seq of human primary TM cells (PTM), TMPCs and their differentiated cells (DTM) and analysed by using bioinformatics analyses. The differentially expressed genes (DEGs) of the three cell types were confirmed by NanoString.

Results

TMPCs proliferated, formed spheres, and could differentiate to TM cells in vitro. NanoString confirmed the RNA-Seq data and PLTP, PROS1, TIMP1 and MMP14 mRNA expression were increased in TMPCs compared with PTM cells. The IPA results identified that KDR, IGF1, FOS and MMP9 genes were nodal genes in the development of TMPCs. The activated pathways in the TMPCs which were related to the neuronal cell development.

Conclusion

TMPCs can be harvested and differentiated into the TM cells from human explant cultures in vitro. PLTP, PROS1, TIMP1 and MMP14 genes represent cellular markers for TMPCs. The pathways activated in TMPCs were consistent with the development of neuronal and endothelial cells. Understanding the key genes and pathways controlling TMPC biology are key to developing cell-based therapies for glaucoma.

BACKGROUND & AIMS:

Osteoporosis is a major health burden. Current therapeutic treatments have disadvantages such as systemic side effect and low bioavailability. Bone-targeting drug delivery system are designed to improve the therapeutic effect of drugs and minimize the potential toxic side effects. We fabricated a novel drug nanocarrier for bone-targeting alendronate delivery using glycol chitosan (GC)-poly(lactide-co-glycolide) (PLGA) and PLGA-alendronate conjugates.

MATERIALS & METHODS:

Chitosan-based nanoparticles were prepared with GC-PLGA and PLGA-alendronate conjugate by nanoprecipitation. Alendronate sodium, a commonly used bisphosphonate drug for osteoporosis therapy, serves as both a bone-targeting ligand and a loading drug. The size of the nanoparticles was determined by dynamic light scattering (DLS) measurement. The morphology of the GC-PLGA/PLGA-alendronate nanoparticles was examined by scanning electron microscopy (SEM). Drug release profile, cytotoxicity and cellular uptake were evaluated in vitro. Bone-targeting potential was assessed by hydroxyapatite binding assay and an ex vivo porcine bone model.

RESULTS:

The conjugation of GC-PLGA and PLGA-alendronate was confirmed by Fourier-transform Infrared Spectroscopy (FTIR) and nuclear magnetic resonance (NMR) analysis. The prepared nanoparticles are highly aqueous dispersible with an average size range from 90 to 130 nm based on various polymer ratio. Morphological characterization (SEM) revealed that the nanoparticles are spherical in shape. In vitro tests demonstrated sustained drug release of alendronate, good biocompatibility and intracellular uptake of nanoparticles. Hydroxyapatite affinity test and ex vivo porcine bone model confirmed the bone-targeting potential.

CONCLUSION:

The bone-targeting GC-PLGA nanoparticles may be a drug delivery system for the treatment of osteoporosis. Further study of biodistribution is warranted.

Abstract **#1893**

TOWARDS THE DEVELOPMENT OF A BIOARTIFICIAL KIDNEY USING POLYHYDROXYALKANOATES

Syed Mohammad Daniel Syed Mohamed$_P$[1], Gavin Welsh[2], Ipsita Roy[1]

[1] *Department of Materials Science and Engineering, Faculty of Engineering, University of Sheffield, Sheffield, UK*

Corresponding author's email: smdsyedmohamed1@sheffield.ac.uk

Acute kidney injury (AKI) and chronic kidney disease (CKD) are two common kidney problems where the kidney loses its blood filtration ability resulting from the deterioration of glomerulus.[1] Current approaches used to address these conditions include haemodialysis, stem cell therapy[2] and kidney transplantation. However new approaches and therapies are urgently required to diminish morbidity and mortality in patients with these diseases. Recent advances in tissue engineering technologies have led to the opportunity to develop a bioartificial kidney utilising human kidney cells to restore both filtration functionality and innate physiological activities.

This work involves the development of a potential bioartificial kidney using 3D printing (Fused Deposition Modelling). Polyhydroxyalkanoates (PHA), a family of bacteria-derived polymers, have been chosen as the main structural biomaterial. PHAs are highly biocompatible, have versatile mechanical properties, and are bioresorbable in the human body.[3] There are two types of PHAs, short-chain length PHAs, scl-PHA (monomer chain length C4-C5) and medium-chain length PHAs, mcl-PHAs (monomer chain length C6-C16). A specific type of elastomeric PHA, Poly(3-hydroxyoctanoate-co-3-hydroxydecanoate) has been chosen due to its mechanical properties being similar to that of kidney tissue, biocompatibility, and printability. Human conditionally immortalised podocytes (CIHP) have been initially used as the cell type.[4] A biomimetic construct has been developed as a first step forward towards the development of a mature bioartificial kidney. This construct is designed to mimic the glomerulus in the kidney. Ultimately, we aim to create a wearable kidney that will be able to replace an impaired kidney, maintaining the original physiological potency.

OSTEOCHONDRAL SCAFFOLD INNOVATION FOR EARLY INTERVENTION OF CARTILAGE DEFECT: FROM BENCH TO CLINIC

Chaozong Liu[P][1]

[1] *University College London*

Corresponding author's email: chaozong.liu@ucl.ac.uk

OA is a whole joint disease and affects both cartilage and the underlying subchondral bone. However, the spatial relationships between cartilage lesion severity and microstructural changes in the subchondral plate and trabecular bone remain elusive.

Femoral heads from hip arthroplasty for primary osteoarthritis and femoral neck fracture cases were used in this study. Scans of each femoral head were divided into 4 quadrants followed by morphometric analysis of subchondral plate and trabecular bone in each quadrant. Principal component analysis (PCA) was employed to assess differences between OA and non-OA samples, and the spatial relationship between CLS and subchondral bone changes.

Mapping of the trabecular bone microstructure in OA patients with low CLS revealed trabecular organisation resembling non-OA patients, whereas clear differences were identifiable in subchondral plate architecture. The OA-related changes in subchondral plate architecture were summarised in the first principle component (PC1) which correlated with cartilage lesion severity in all quadrants, whilst by comparison such associations in trabecular bone were most prominent in the higher weight-bearing regions of the femoral head. Greater articular cartilage deterioration in OA was regionally-linked with lower BV/TV, TMD and thickness, and greater BS/BV and porosity in the subchondral plate; and with thinner, less separated trabeculae with greater BMD and BS/BV in the trabecular bone.

Our findings suggest that impairment of subchondral bone microstructure in early OA is more readily discernible in the cortical plate and that morphological characterisation of the femoral head bone microstructure may allow for earlier OA diagnosis and monitoring of progression.

IONICALLY ANNEALED ZWITTERIONIC MICROGELS FOR BIOPRINTING OF POROUS STRUCTURES

3D bioprinting of clinically-relevant tissues requires a sufficient supply of nutrients to ensure cell survival, which is still a significant challenge.[1] Conventional hydrogels used in tissue engineering have two major limitations. Firstly, precursor solutions form a nanoporous hydrogel upon gelation, which greatly limits diffusion of nutrients, leading to reduced cell viability in the center of large grafts. Secondly, upon in vivo implantation, biomaterials are often encapsulated within a fibrous collagenous capsule.[2,3] To address both these limitations, microgel materials made of zwitterionic hydrogels were used to both provide a more permissive macroporous environment for cells and to evade foreign body reactions.[4,5] Here, we present a novel approach to bioprint zwitterionic microgels designed from the low molecular weight carboxybetaine acrylamide (CBAA). CBAA was photopolymerized using alginate methacrylate as a bifunctional crosslinker to produce a bulk hydrogel. Microgels were then mechanically fragmented using progressively fine steel meshes (500 µm to 35 µm pore sizes). Rheology revealed that swollen poly(CBAA) microgel bioinks showed both shear-thinning and shear-recovery properties optimal for extrusion bioprinting. Bioprinted structures were rapidly annealed in the presence of calcium at mild and cytocompatible conditions and showed excellent mechanical stability in cell culture medium. Human chondrocytes encapsulated in the granular material showed highly viable (>90%) during in vivo culture, suggesting that hydrogels were biocompatible. These macroporous and non-immunogenic bioinks show great promise for in vivo applications of bioprinted tissues and organs.

Extracellular vesicles (EVs), including exosomes, convey protein and biologic cargo to target cells through receptor mediated interactions and while not well understood, have shown to increase tenocyte proliferation, localization, and downregulate inflammation. Our hypothesis is that tendon derived EVs will also increase wound closure rates. EVs were purified via size exclusion chromatography from primary tenocyte enriched media from ovine infraspinatus tendons harvested 1-2 hours post-mortem and proliferated over 1-3 passages. Similarly, prepared cell lines were used to culture a mono-layer of tenocytes in a 96-well plate. A uniform scratch in the monolayer of each well was formed using the WoundMaker Tool (Incucyte®) and wells were washed with PBS and filled with culture media alone (negative-control), fetal bovine serum (FBS, positive-control) or purified EVs. Images were taken every 6 hours until earliest wound closure to determine the rate of closure via morphometric assessments. There was a significant increase in rate of wound closure when tenocytes received tenocyte-derived EVs up to 53% of the positive- as compared to the negative-control. These data demonstrated that tenocyte derived EVs have the potential to significantly increase tenocyte proliferation and localization leading to increase wound closure in an in vitro model of tendon damage. With the potential for tendon derived EVs to both increase tenocyte bioactivity and to downregulate macrophage pro-inflammatory signaling, these intercellular communicatory packages may contain a balanced means of directing tendon healing. Future investigation into the content of these EVs, their dose relation to effect and in vivo potential is warranted.

Total Hip replacement is an effective and successful treatment for osteoarthritis. Currently there are over a million patients which undergo this treatment and the number is expected to double in the next two decades [1]. Patients often undergo revision surgery to replace their hip implant due to either peri-prosthetic fracture or aseptic loosening. Stress-shielding is a mechanical phenomenon that refers to the reduction of bone density as a result of altered stresses acting on the host bone. Current orthopaedic prostheses undergo too much bone resorption secondary to stress shielding due to their solid metallic nature, which are much stiffer than the surrounding bone. With the use of 3D printing technology such as selective laser melting (SLM), it is now possible to produce porous graded microstructure hip stems to mimics the surrounding bone tissue properties [2].

Currently there have been several studies on developing fully porous hip implant, which used different porous structures to reduce stress shielding to some extent (45-50%). This includes structure such as Tetrahedron, Octet and Face and body centered cubic with vertical struts (FBCCZ) [2,3]. However, till now, no study has been performed on the two well known triply periodic minimal surface (TPMS) gyroid and diamond structures. These two TPMS structure have mechanical properties which are very close to cortical bone and are suitable for hip implant application. By using a validated FE model, this research has shown that stress-shielding can be reduced by more than 50% by using graded gyroid structure.

Bio-printing is emerging as a novel method to create bespoke items in medicine. Traditionally, bone implants are manufactured using metals, such as titanium and cobalt-chromium alloys.[1] However, the limitations of some of these metals include rapid wear rates and metal ion deposition in the body.[2] To overcome these limitations, a long-term solution is required to promote direct contact between bone and the implant surface and to reduce inflammation. Here, we investigate the ability to 3D-bioprint nanodiamonds (NDs) in a hydrogel matrix to enhance bone growth. Nanodiamond is an ideal candidate for use in biomedicine, due to its excellent biocompatibility.[3] The hydrogel is programmed for passive controlled release of the NDs, meaning that the properties of the NDs can be utilised in a localised setting. The fabricated material complements the natural processes in the body, especially to restore the essential cellular functions of bone. This uniquely 3D-bioprinted material will have a significant impact on the success of spinal implant surgery.

Human pluripotent stem cells (hPSCs) have great potential for tissue engineering and regenerative medicine owing to their unique abilities for self-renewal and differentiation. However, they are cultured on poorly defined, animal-derived extracellular matrix (ECM), not suitable for human use, with batch-to-batch variations. In this study, self-assembled peptide hydrogels which have a capping group that promotes the formation of fibrillar macromolecular complexes, have been developed for culturing HES3 human embryonic stem cells line. These hydrogels mimic the peptide motifs in extracellular matrix proteins that interact with cellular integrin receptors, promoting cell growth and survival. Herein, peptide-gelator-mimics of laminin (Fmoc-YIGSR), collagen (Fmoc-GFFGER), and fibronectin (Fmoc-GFFRGD) were screened for their ability to support the maintenance and growth of human embryonic stem cells and their differentiated progeny. Adhesion, proliferation, migration, colony formation, morphology, and pluripotency were analyzed for single and blended peptide-gelators. The blend Fmoc-GFFRGD + Fmoc-YIGSR (1:1) supported the maintenance and growth of hESCs more compared to other gelators. It is concluded that self-assembled, peptide-hydrogels provide a versatile platform to dissect the role of adhesive motifs for human pluripotent stem cell culture.

While strategies to transplant photoreceptors to the diseased retina have shown to be a promising approach to treat blindness, cell therapy remains far from clinical translation. It was previously believed that donor cells in the subretinal space integrate and synapse with the host retina to restore vision; however, recent studies have demonstrated that donor photoreceptors rarely integrate and instead transfer cytosolic proteins, including GFP, to host photoreceptors(1,2,3) in a process termed material exchange (ME). This observation suggests that rod-mediated vision rescue is through a mechanism distinct from cell replacement. To exploit ME for therapeutic applications and bridge the gap to clinical translation, it is imperative to investigate the mechanism of ME and identify modulators. Using a flow cytometry-based assay to quantify the transfer of mitochondria, we demonstrate that a hyaluronan and methylcellulose (HAMC) hydrogel(4) reduces the efficiency of photoreceptor ME in vitro. Dissociated retinas from post-natal day 4 mice were stained with MitoTracker Green (MTG) or MitoTracker Red (MTR) and co-cultured in HAMC or standard conditions for 2 days in vitro. There was significant reduction in the proportion of double positive cells (MTR+/MTG+) when retinal dissociates were cultured in the HAMC hydrogel compared to standard 2D culture conditions. This observation is also corroborated in vivo, where we observed a reduction in the efficiency of GFP transfer when donor cells encapsulated in HAMC were transplanted to the recipient retina. The HAMC hydrogel provides a tunable vehicle to add inhibitors or agonists of ME to benefit cell transplantation and future regenerative therapies.

Burns are hard-to-heal wounds due to the extensive water loss. Hydrogel-based dressings are ideal to provide moist environment and accelerate wound healing. In this research, different bioink formulations based on gelatin and alginate are prepared and evaluated in vitro. After printing the hydrogel mixtures, the printed constructs underwent chemical crosslinking using CaCl2 solution. In order to investigate the structural integrity of the printed constructs, the rheological behavior, tensile strength, and shape fidelity were measured. 3T3 fibroblasts and HaCaT keratinocytes were used to investigate the effect of hydrogel formulation and printing technology on cytotoxicity, and cell adhesion, and dermal/epidermal bilayer formation. Live/dead assay were used to study cell attachment and viability. Lack of amino acids in alginate results in increase in the number of RGD anchors for cell attachment in samples with lower alginate content, while the higher alginate concentration increased the mechanical integrity and printability. To evaluate the in vivo wound healing, animal test was performed on full-thickness burn in rat model with the best sample. After 4 weeks the wound contracture was measured along with further histological analysis using H&E staining. The results of this research highlight the potential of 3D printed hydrogels to induce skin regeneration in full-thickness wounds.

Ischemic stroke affects over 15 million people worldwide every year, and despite significant research patients are faced with limited treatment options. This is due, in part, to the blood brain barrier (BBB). It poses a significant challenge when delivering therapeutics to stroke injured tissue. To address this, our group has developed a non-invasive, localized drug delivery system that circumvents the BBB. The delivery vehicle is comprised of poly(lactic co-glycolic acid) nanoparticles (PLGA NPs) dispersed in a shear-thinning and biodegradable hyaluronan/methylcellulose hydrogel. We have previously shown that proteins can be electrostatically adsorbed to the surface of blank PLGA NPs and can exhibit similar release profiles to conventional encapsulation processes while preserving activity. We hypothesized that this system could be further implemented for the delivery of therapeutic peptides. Release of pituitary adenylate cyclase activating polypeptide (PACAP), a neuroprotective compound that is easily degraded in circulation, was assessed from our vehicle in vitro. Notably, as the zeta potential of the PLGA NPs became more negative and degradation was attenuated, release of PACAP was extended, achieving a burst-free release that was maintained for 14 days. We also demonstrated the bioactivity of released PACAP in the survival of neural cells, and the negligible inflammatory response to the vehicle in cultured astrocytes and microglia. Therefore, we present this drug delivery system as a useful technology for the controlled release of therapeutic peptides for chronic stroke therapy. Future work will investigate the effects of PACAP delivery on neuronal survival and functional recovery in stroke-injured mice.

ENZYMATICALLY CROSSLINKED COLLAGEN BIO-INK FOR RAPID AND SUPPORT-FREE HIGH-RESOLUTION BIOPRINTING OF COMPLEX MULTISCALE ORGANS

Dominic RütscheP[1,2]

Collagen is the most abundant structural protein in the human body and constitutes the primary component of the extracellular matrix [1]. Past attempts at bio-printing cellular constructs based on collagen were severely hampered by the slow gelation of the material, resulting in low printing fidelity and resolution. Recent technical advances, such as freeform reversible embedding of suspended hydrogels (FRESH), enabled the printing of more complex architectures. However, the method is still restricted by lengthy pH-driven thermal gelation and the requirement of a support bath[2].

Our group has developed a simple method to modify soluble collagen with an adaptable azide linker, making it susceptible to click-chemistry based bioconjugations. Coupling of this precursor with alkyne terminated enzyme recognition sequences allows for the printing of multidimensional networks due to rapid, bio-orthogonal enzyme-mediated crosslinking (factor XIII, sortase A, HRP) of the extruded bio-ink.

We have demonstrated the multi-scale production of cell-laden human organ scaffolds containing both blood and lymphatic vasculatures. These scaffolds were fabricated using extrusion 3D printing and could be tuned with respect to size and mechanical characteristics. Fast crosslinking kinetics resulted in high printing fidelity even at very low polymer concentrations (<1%). The bio-ink exhibited optimal shear-thinning characteristics and enabled printing of complex hierarchies without supporting materials. The porous microstructure of crosslinked collagen promoted cellular infiltration and the establishment of a microvascular network with different hierarchies necessary to support high cell viability. This novel bio-ink shows great promise as a highly versatile platform material for the bio-printing of large-scale tissues and organs.

The optimization of defined differentiation conditions is necessary for the development of the clinical application of human pluripotent stem cell derived cardiomyocytes (hPSC-DCM). Current research has focused on developing defined media formulations for the staged differentiation of hPSC-DCM with little attention to the establishment of defined substrates for hPSC-DCM differentiation and maturation. To address the comprehensive complement of factors that may help regulate hPSC-DCM proliferation, differentiation, and maturation, we report a systematic screening of extracellular matrix proteins (ECMPs) to developed and characterized a defined culture system for the improved differentiation efficiency, sarcomere organization, and calcium handling compared to commercial substrates. Using live-cell calcium imaging to observe the onset of calcium handling in the differentiation process, provides insight into how ECMP substrates can aid and precede the initiation of the first contractions. Observations of sarcomere assembly, alignment, and size also provides evidence of improved maturation on a defined ECMP substrate. In the future, the combination of ECM array techniques with other differentiation stimuli could lay the foundation for a new perspective in the further development of differentiation efficiency and maturation of human pluripotent stem cell derived cardiomyocytes and stem cell research.

Transplantation of hematopoietic stem cells (HSCs), progenitors for all types of blood components, is often the last option for patients with certain conditions, e.g. repeated chemotherapy, leukemia, lymphoma, bone marrow disorders. Protocols for isolation, characterization and transplantation have been well established, however, availability of human leucocyte antigens (HLA)-matched donor and scarcity of HSCs are still major challenges for allogeneic transplantation. In the current study, we developed a double-layered microcapsule for delivering paracrine factors from allogeneic HSCs. The umbilical cord blood (UCB) derived-HSCs were entrapped in alginate polymer and double protected by glutaraldehyde cross-linked chitosan coating. A mitochondrial activity assay revealed a restricted cell growth in encapsulated cells. Co-cultures between microencapsulated HSCs with bare HSCs showed significant increases of cell numbers and preserved CD34+ population than monoculture HSCs. This study is the first to report the potency of microencapsulated HSCs to deliver paracrine factors for improving proliferation and HSC maintenance.

DEVELOPMENT OF 3D PRINTED GRAFTS BASED ON BONE EXTRACELLULAR MATRIX (ECM) FOR BONE REGENERATION

Rotem Hayam$_P$[1], Marcelle Machluf[1]

[1] *Technion- Biotechnology and Food Engineering*

Corresponding author's email: rhayam@campus.technion.ac.il

Bone is a dynamic tissue with the ability to heal and repair without scaring. Nevertheless, in cases of delayed recovery or large non-healing bone defects resulting from trauma, tumor, or infection, bone grafting is required. The extracellular matrix (ECM) naturally provides cells with a supportive framework of structural as well as functional proteins, carbohydrates, and signaling molecules. Furthermore, the ECM was proved to have an important role in successful bone healing, as it increases the interactions among osteoprogenitor cells and growth factors.

The overall goal of the proposed research was, therefore, to reveal the potential of bone ECM (bECM) as a bioactive material for the bioengineering of advanced bone grafts. To this end, ECM was isolated from porcine and human bones, and their distinctive properties were studied, revealing high similarities between the human and the porcine bECM, and indicating the high potential of porcine bECM for bone grafting. Furthermore, in vitro biocompatibility studies showed no indication for an immunological response.

To address the technological aspects of graft additive manufacturing, we first developed a reproducible ECM bio-ink that can be thermally gelled and further crosslinked using natural crosslinkers. Next, we investigated the technological feasibility of 3D-bioprinting complex pbECM scaffolds by addressing the effect of different biomaterial properties and system parameters on the process and its outcomes.

To conclude, we have established the scientific as well as the technological basis for the development of novel 3D-printed pbECM-bone grafts and demonstrated their great potential use for bone regeneration.

Vascularization of tissue constructs by incorporating complex vascular networks into three-dimensional (3D) bioengineered constructs to achieve proper oxygenation, nutrient delivery, and waste removal after implantation remains a challenge in tissue engineering. To develop a 3D hybrid vascular system, we embedded tubular tropoelastin and silk fibroin composites (TCs) within enzymatically crosslinked gelatin hydrogel to mimic tissue constructs in customized pulsatile flow-induced bioreactors. The system utilizes alternative protein-based systems. Tropoelastin is highly elastic and cell interactive, promotes endothelial cell attachment and angiogenesis, while silk fibroin confers mechanical strength to the vascular system and bestows the ability to withstand sutures and cope with higher blood pressures. The TCs were fabricated by dip coating on sacrificial ice mold then stabilized. They were subjected to analysis and quality control using techniques including scanning election microscopy, immersed in cell-encapsulated hydrogel which was then cast around the TC to form a hybrid system. Human umbilical vein and other endothelial cells were seeded into the TC statically and dynamically. Concurrently, human cells including dermal fibroblasts were cultured in the hydrogel. Cells in the surrounding matrix, in the vicinity of vessels, were maintained as the porous TC provided proper nutrient diffusion. The 3D vasculature system was tested in a pulsatile bioreactor, which mimicked the native tissue microenvironment and delivered the further benefit of replicating tissue performance. We conclude that this simple and versatile 3D tissue construct system allows for the growth of complex vascularized tissue models in 3D and has great potential for vascularization, for biological and pharmacological uses.

HIGH STRENGTH AND HIGH PLASTICITY NITI-NB POROUS SCAFFOLD FABRICATED BY SELECTIVE LASER MELTING

Yintao Zhang$_P$[1]

[1] *State Key Laboratory of Metal Matrix Composites, School of Materials Science and Engineering, Shanghai Jiao Tong University*

Corresponding author's email: wang_liqiang@sjtu.edu.cn

For orthopedic implants, it is necessary to have high strength, low elastic modulus, high wear resistance, high corrosion resistance, and good biocompatibility. NiTi shape memory alloy has the above advantages, and the addition of Nb with good biocompatibility can improve its mechanical properties and shape memory effect. To avoid the stress shielding effect, it is necessary to produce a porous structure by additive manufacturing technology to reduce the overall elastic modulus. In this work, gradient porous NiTi-Nb scaffolds were fabricated by SLM, and their mechanical properties and shape memory effect were studied. Firstly, we explored the effect of heat treatment (annealing at different temperatures) on SLMed NiTi-Nb scaffolds' properties and carried out uniaxial compression experiments. It was found that the annealed samples showed high compressive strength, high plasticity, and low elastic modulus. The influence of pore size, gradient interface, and other structural factors on the scaffold's performance was also explored. DSC investigated the samples' shape memory effect, and the microstructure and deformation mechanism was investigated by optical microscope, SEM, and TEM. This work shows that the heat-treated SLMed NiTi-Nb scaffold shows excellent properties of high strength, high plasticity, and low modulus, which has great potential in the application of orthopedic implants.

Nowadays, the main approach to tailor mechanical properties of photo-crosslinked gelatin methacrylate (GelMA) is to control the light exposure time to activate free radicals in chain polymerization reaction. The number of activated free radicals increases linearly with light exposure time. Generally, to twice the stiffness of GelMA hydrogel, the exposure time of hydrogel needs to be extended to 3-5 times longer to activate more free radicals.1 However, the more activated radicals, more oxidative stress, and more damage to cells. Here, we developed a new method with less free radicals through executing extra reaction-time right after light exposure instead of stopping the reaction right away to precisely control photo-crosslinking degrees of hydrogel with required storage modulus. Human white adipose tissue derived mesenchymal stem cells (MSCs) and umbilical vein endothelial cells (HUVECs) were encapsulated and patterned into hexagonal three-dimensional (3D) structures to create functional vascular networks in vivo by this method. Our results demonstrated the cell-laden hexagonal structures can guide vasculogenesis and accelerate angiogenesis to form uniformly distributed vascular networks in the thick hydrogel (> 2 mm) within 7 days in diabetic mice with high repeatability and reproducibility. Lastly, the reproducible large-size microvascular networks significantly increase viability and function of transplanted islets in diabetic mice. This developed technique to engineer the large-scale and thick functional vascularized islet tissues will be expected to become the most effective method for clinical use in the near future.

The host immune response, specifically macrophage function, is a critical determinant of biomaterial success or failure post-implantation. Extracellular matrix (ECM) derived scaffolds have been shown to promote a pro-regenerative macrophage phenotype and a more constructive remodelling outcome. Here we demonstrate that macrophages adopt distinct phenotypes when exposed to articular cartilage (AC), ligament (LIG) and growth plate (GP)-derived ECM scaffolds. Macrophages were unresponsive to LIG-derived ECM, adopted an M2-like phenotype when exposed to AC-derived ECM, and a hybrid M1-M2 phenotype when exposed to GP-ECM. Furthermore, macrophages expressed higher levels of pro-chondrogenic factors (FGF2), when exposed to AC-ECM, and higher levels of angiogenic and pro-osteogenic factors (VEGF, IL-6 and TNF) when exposed to GP-ECM. In addition, these ECMs can differentially direct the differentiation of skeletal stems, whereby AC-ECM and GP-ECM promote chondrogenic and osteogenic differentiation respectively of multipotent stem/stromal cells (MSCs). In vivo characterization of immune cells following scaffold implantation into a large bone defect demonstrated that AC-ECM drives an M2 macrophage phenotype, while GP-ECM scaffolds promoted a hybrid M1-M2 phenotype and enhanced vascularization and vessel maturation. This distinct response to the implantation of GP-ECM containing scaffolds was associated with increased CD45+ leukocyte and CD3+ T cell infiltration, accompanied by elevated concentrations of IFN-γ and IL-17. Taken together this work demonstrates that the source tissue of ECM scaffolds plays a key role in regulating the phenotype of both macrophages and MSCs. Furthermore, these ECMs can direct the cellular differentiation and production of growth factors essential for the regeneration of their source tissue.

Immunomodulation has become an important strategy to advance biomaterials for bone regenerative purposes. Clinically applied therapeutic pathogen recognition receptor (PRR) ligands are known for their ability to skew the immune response in a specific direction. We investigated the effect of various PRR ligands on early inflammatory and bone cell responses. In vitro effects of these ligands on early osteogenic (Day 10) and osteoclast differentiation (Day 6) were assessed by measuring alkaline phosphatase activity in mesenchymal stem cells (n=7) and tartrate-resistant acid phosphate activity in human peripheral blood-derived monocytes (n=4), respectively. We measured TNF-α, IL-6, IL-8, and IL-10 expression in these cells by enzyme-linked immunosorbent assay as an indicator of the ligands' inflammatory properties. To further test their effects in vivo, a closed femoral fracture in osteoporotic rats was performed. The ligands were injected twice locally at the site of fracture. Cytokine production in fracture hematoma (Day 3,n=5) indicated the early inflammatory response. Mechanical testing (Week 4) along with weekly radiographs (n=7) to assess the callus morphometry were used as indicators of bone formation. In vitro, it was found that nucleic acid-based ligands Poly(I:C) and CpG ODN C enhanced early osteogenic differentiation by 4-fold, without inducing exaggerated immune reaction or interfering with osteoclast formation. In vivo, CpG ODN C and Poly(I:C)showed an altered cytokine expression in the hematoma. Qualitative analyses showed differences in calluses among groups. Thus, these findings show that nucleic acid-based ligands have broad osteo-immunomodulatory properties that can be harnessed as a strategy for bone- biomaterials based regeneration.

Oral squamous cell carcinomas (OSCC) are malignancies in the oropharynx and the oral cavity. These tumors are often associated with the alcohol and tobacco use as well as HPV infection. Since current treatments cause severe discomfort and significant side effects, the development of an alternative therapy is highly required. This project aims to develop a stem cell-based suicide gene therapy. Hence, human dental pulp stem cells (DPSC) are used as vehicles for gene-directed enzyme prodrug therapy.

Ganciclovir cytotoxicity could be demonstrated successfully in vitro in HSV1-TK expressing DPSC. For successful stem cell-based suicide gene therapy, gap junction formation in DPSC/OSCC co-cultures is essential. Immunocytochemistry indicated the presence of connexin-43 in DPSC/OSCC co-cultures. To assess gap junction functionality, cascade blue was micro-injected in one single cell and dye transfer to neighbouring cells was confirmed. These results suggest gap junctional communication between DPSC and OSCC in a co-culture system. Moreover, these gap junctions are likely to pass cytotoxic ganciclovir from DPSC to OSCC and consequently kill the tumor cells. This will be studied in future experiments.

In conclusion, based on the ganciclovir/HSV1-TK system, gap junction formation is key in the treatment of OSCC using DPSC as vehicles for suicide gene therapy.

Cystic fibrosis is one of the most common inherited lethal diseases, caused by mutations in the CFTR gene. Small-molecule therapies have revolutionised patient outcomes but are lifelong interventions and cannot correct all CFTR mutation variants.

We have demonstrated effective non-viral gene delivery to mice using peptide-nanocomplexes composed of plasmid (p)DNA and GET peptides. Glycosaminoglycan (GET) peptides bind and transduce cell membranes and we have generated mucus-penetrating formulations; allowing enhanced delivery and transgene expression to epithelium when aerosolised. Our formulations utilise endosomal-escaping strategies to deliver gene correction/augmentation strategies, presenting a 'genetic cure' which includes treatment of CF patients unaffected by current state-of-the-art therapies.

Our pDNA vector library (lacking CpG dinucleotides, reducing methylation silencing), modified with S/MAR sequences, allows for increases in long-term retention/expression viability. Additional 'integration sequences' have been included, enabling us to target stable integration into the 'safe harbour' AAVS1 locus. We have confirmed our system's efficacy with fluorescent-protein encoding ZsGreen1 and will confirm CF correction in patient-derived lung cells with CFTR transgene pDNAs.

Presently, we are comparing strategies: HDR (homology driven repair) and HITI (homology-independent targeted integration) via CRISPR. We are also exploring directed integration with Rep-mediated (exploiting viral mechanisms targeting P5IEE to the AAVS1 locus) systems and Sleeping beauty transposase.

Here we present the efficiencies and comparison of different systems. Repeat delivery/transfections using GET technology does not affect cell viability, so we can build integration. Ultimately, an aerosol-based strategy to progressively correct CF patients, converting transient gene expression into stable life-long genetic correction, may be viable.

Corneal vision impairment is affecting 4.9 million people, globally. Treatment options to repair damaged corneal tissue is limited to corneal transplantation and only a limited number of people can receive corneas while millions being in the waiting list due to the limited tissue availability. An artificial cornea would provide an alternative solution for transplantable tissue shortage. An ideal bioengineered corneal scaffold for vision recovery is expected to provide optically transparency, biocompatibility, triggering tissue healing, and cornea-like structure. Various biomaterials including decellularized scaffolds, natural polymers and peptide amphiphiles have been found promising for corneal applications due to their biocompatible, permeable and transparent nature.

Hydrogels with their high-water content are promising candidates for 3D cell culture for corneal stromal cells. Here, we aim to utilize self-assembling peptide hydrogels as stromal substitutes due to their ease of synthesis and gelation properties. Among self-assembling peptides, β-sheet forming peptides can easily be triggered to form hydrogel network by adjusting the ionic strength of the solution. In this study, MAX8, a 20-residue self-assembly peptide, was folded and formed a hydrogel within serum free corneal keratocyte cell culture media. MAX8 hydrogels were produced with three different biomarker peptides to provide cell adhesion and anti-angiogenic properties while preserving transmittance and mechanical stability to mimic the cornea structure. The hydrogels showed advanced biocompatibility to promote cell adhesion and proliferation for corneal keratocytes. ECM production of keratocytes within peptide hydrogels and tissue specific properties such as the optical transparency and mechanical strength of produced 3D tissue substitutes are being evaluated.

Cornea is the outermost layer of the eye that provides protection as well as the first line of light refraction for proper vision. Cornea is a transparent tissue composed of highly ordered collagen fibrils and providing pressure resistance. All three corneal cell types have unique properties to constitute this transparent, permeable and durable tissue. Corneal endothelial cells residing on Descement's membrane restrain fluid to the cornea. Corneal stromal cells, keratocytes, give the unique structure of the stroma play an important role in light transmission. Epithelial cells provide the protective barrier, light reflection, water, gas, and nutrient transport in and out of stroma. External chemical/mechanical damage, aging and diseases can directly affect these cells and thereby cause visual disturbances. Currently, the only effective treatment for corneal vision impairment is keratoplasty, namely corneal transplantation. However, there is a limited number of donor cornea. A bioengineered cornea as a tissue substitution holds the promise to overcome transplantable tissue shortage as well as drawbacks related to implant quality.

Here we aim to engineer a β-sheet peptide hydrogel supported with an elastomer layer for increased durability, controlled shape and surface topology. We, initially isolated primary human corneal cells. Epithelial and endothelial cells were cultured on elastomer membranes as mimics of Descemet's membrane and Bowman' layer of natural cornea. As a stromal layer mimic, keratocytes were cultured on 3D peptide hydrogels. Hydrogels and elastomer membranes were transparent and non-toxic for the cells. Proper ECM production, optical transparency and mechanical strength of tissue substitutes are under investigation.

INTRODUCTION: Drug delivery systems allow the therapeutic substances to be administered to a specific part of the body. For this purpose, biomaterial-based platforms have been designed that can release the drug active ingredient it contains. Herein, we develop a minimally invasive drug delivery system that is targeted only to ovarian cells and has the potential to eliminate inflammation in the operated area after any surgical intervention in the ovaries and reduce ovarian cell loss/damage.

METHOD: An anti-inflammatory drug curcumin was loaded with 95% efficiency into chitosan-coated sodium alginate nanoparticles and then functionalized with folic acid for providing targeting property to nanocarrier towards ovarian cells. After their characterization with FT-IR, UV-Vis spectrophotometer and TEM, they were incorporated into thermo-sensitive pNIPAm–based hydrogels as injectable drug delivery system. Rheological tests, swelling capacity, morphological analysis and evaluation of thermo-responsiveness of hydrogels were evaluated.

RESULTS: This polymeric scaffold design was demonstrated to form the hydrogel structure mixed with nanoparticles to gel in a very short time when injected into the tissue wound region at body temperature.

DISCUSSION AND CONCLUSION:
The obtained multifunctional scaffold was shown to liberate drug molecules 3 times slower compared to intact free nanoparticles, which might contribute to local administration of therapeutic agents during minimally invasive tumor resection based surgeries for both facilitating wound healing and sustained diminishing of chronic inflammatory immune system responses.

ACKNOWLEDGEMENTS:
This research has been supported by Acıbadem University Scientific Research Commission (ABAPKO Project No: 2019/04-04).

Type 1 diabetes is described as an autoimmune condition which, through pathological immune system action, enables destruction of the β-cells of the pancreatic islets of Langerhans, reducing insulin production capacity (1). A proposed biomaterial solution to this problem has been microcapsule immunoisolation, where the (often alginate) microspheres of islet containing membranes separate the immune system from implanted allogeneic and xenogeneic tissue (2), However, barriers to effective therapies remain, including hypoxia prior to revascularization and microbead mechanical degradation (3).

This work builds on previous research exploring the use of biodegradable, non-immunogenic Polyhydroxyalkanoate (PHA) polymers for the generation of a semi artificial pancreas (4). Pseudomonas Putida fermentation was used to produce a PHA which was purified and described as Poly(3-hydroxyoctanoate)co(3-hydroxydecanoate) (PHOHD). The viability and glucose dependent insulin secretion of BRINBD11 and INS-1 832/13 cells (a pancreatic cell line) grown on PHOHD was compared to cells grown on poly(Caprolactone) and poly(3-hydroxybutanoate) films. Following this, the islet cell lines were encapsulated in calcium/strontium-crosslinked alginate and bioprinted into sub mm wells within a novel 3D-printed PHOHD construct design. Islet cell lines were described in terms of viability, glucose responsiveness and insulin secretion. This work will act as a template for a construct encapsulating whole human islets and modifications to both the alginate and the PHOHD components to improve mechanical properties, glucose responsiveness, vascular tissue ingrowth, oxygen availability, non-immunogenicity, and antibacterial capacity.

INTRODUCTION: Today, 40% of the hospital infections are caused by the urinary tract infections and within this; 80% of them are due to the catheters. Especially in the cases which the catheter usage is obligatory more than one week, microorganisms can produce biofilm on the surface of the catheter [1,2]. Hence, the main goal is the obtain more efficient catheter than already existing catheters with antimicrobial properties through a surface modification with a higher binding efficiency using a single intermediate binding molecule.

METHOD: The thiolated antimicrobial peptides(C-AMPs) were designed in the scope of the project and chemically synthesized, purified and characterized with LC-MS/MS systems. Antimicrobial effect examined with in vitro cytotoxicity, minimal inhibitory concentration, and hemolytic assays. With a single intermediate molecule, antimicrobial peptides were immobilized to silicone catheter surface through thiol-ene chemistry. Chemical, physical characterizations of catheter surface were done, stability of the immobilization examined.

RESULTS: For the EDS point analysis carbon (C), oxygen (O), nitrogen (N), and sulfur (S) atoms were chosen and especially the presence of S indicates the presence of C-AMPs and their immobilization to the surface

DISCUSSION AND CONCLUSION:
This result indicates that C-AMPs could be immobilized to silicone surfaces via a single intermediate molecule rather using double linker similar in literature to allow us to generate antimicrobial medical implants.

ACKNOWLEDGEMENTS:
This research has been supported by The Scientific and Technological Research Council of Turkey (TÜBİTAK Project No: 118Z859).

High hydrostatic pressure (HHP) can be applied to large three-dimensional tissues for decellularization without the risk of residual reagent. However, high level of HHP denature extracellular matrix (ECM), whereas low level of HHP remove cells not-sufficiently. Supercooling is the liquid state below the freezing point, and does not cause physical damage. By preserving the tissue in a supercooled state without a cryoprotectant, it is considered that cells are damaged due to osmotic pressure between intracellular and extracellular fields whereas the structure of ECM is retained. In this research, the effect of combined application of supercooling and HHP on decellularization was investigated. Specifically, the device to enable supercooling preservation of cells and cell-containing constructs and the device that could apply HHP were developed. Human skin fibroblasts (NB1RGB) were preserved at 4, -4, or -8 ℃ in nonfreezing state for 12 h, then 100, 150, and 200 MPa of HHP were applied on the cells. After HHP application, cell morphology, cell viability, cell adhesion, and cell proliferation were evaluated. As a result, denaturation of cell membrane was increased with decrease in storage temperature. In addition, viability, adhesion, and proliferation of cells subjected to lower storage temperature decreased when the cells were treated with the same level of HHP. In conclusion, it was suggested that decellularization could be promoted at a lower level of HHP than that of previous approaches by combined effect of supercooling and HHP.

Fores play a crucial role in our bodies. The forces generated in the extracellular matrix can direct the release of growth factors to cells in the surrounding tissues, which catalyzes important bioactivities such as growth factor release or immobilization[1]. The extracellular matrix's biopolymers are evolved to support these complex functional dynamics. Therefore, the extracellular matrix is described as a complex hydrogel & natural mechanochemical model.

We have designed a force-responsive double-network hydrogel material to recapitulate the native extracellular matrix's force medicate molecule release. It releases tethered molecular cargo in response to tension and compression under physiological forces. The flex-activated force-sensitive mechanophore crosslinkers give the hydrogel network a dynamic nature and maintain the overall gel architecture without degradation during successive molecule release steps. The results showed that the gel with 5 wt% mechanophores releases 10%, 15%, 20%, and 7% of molecules under compression of 0.1 MPa, 0.5 MPa, 1 MPa, and 2 MPa, respectively. This work may pave the way to develop force activated biomaterial such as implant coatings, "smart" bandages, contact lenses, and soft robotics for advanced tissue engineering applications.

THERE'S MORE TO FAT THAN STEM CELLS, CHARACTERISING FAT GRAFT MATERIALS TO UNDERSTAND THE REGENERATIVE PROPERTIES OF ADIPOSE TISSUES

The discovery of adipose derived stromal cells (ADSCs) in 2001 led to an explosion of studies investigating their potential in a range of clinical applications. In parallel, plastic surgeons developed novel techniques following observations that fat grafting can not only restore volume but can also improve tissue repair and regeneration (1.). At present we have limited understanding of how adipose tissue processing affects biological function of injected tissues, which is urgently needed to optimise clinical fat grafting techniques. This study aimed to fully characterise lipoaspirate and formulations of adipose tissues (FAT); bridging the gap between in vitro ADSC studies and clinical fat grafting results.

Adipose tissue collected from consenting patients (NHS ethics 15/YH/0177) was processed to produce four different FAT, namely: lipoaspirate, emulsified fat (or "nanofat"), lipocondensate (condensed SVF, with lipid removed) and cultured ADSCs. We observed lipoaspirate, emulsified fat and lipocondensate all retained some of the microstructure of adipose tissues with intact adipocytes and evidence of blood vessels. Via cytokine array analysis, adipose tissues secreted more chemokine signals compared to ADSCs while all samples secreted factors involved in extracellular matrix regulation. Functional assays demonstrated conditioned medium from adipose tissue but not cultured ADSCs were able to inhibit myofibroblast differentiation.

This study provides important data on the composition and secretory phenotype of FAT and highlights important differences between cultured ADSCs and whole tissue. It is evident the regenerative effects observed from fat grafting arise from heterogeneous tissues rather than ADSCs alone, with work ongoing to understand the mode of action.

ON-CHIP 3D CELL CULTURE PLATFORM FOR TUMOR MODELING AND DRUG SCREENING

Özüm Yıldırım[P][1], Ahu Arslan Yıldız[1]

[1] *İzmir Institute of Technology, Faculty of Engineering, Department of Bioengineering, İzmir, Turkey*

Three-dimensional (3D) cell culture allows cell-cell and cell-matrix interactions and provides more in vivo like models rather than 2D cell culture which cannot fully mimic native tissue. 3D cell culture on microfluidics allows formation of 3D structures that mimic the physiological and chemical microenvironment for cells[1]. These microfluidic platforms also downsize bench-top laboratory to a microchip, require miniaturized reagent, and are convenient for dynamic drug screening[2]. In this study, a microfluidic platform was designed which is housing a PLLCL scaffold fabricated by electrospinning methodology. The electrospun material resembles fibrillar structure of the extracellular matrix while favoring cell adhesion and proliferation with the help of micro-to nano-meter range fibers[3]. By combining these advantages of electrospinning technique with microfluidic system, here it was aimed to develop scaffold-based 3D tumor models and to provide a platform where drug-screening applications can be carried out easily and in a controlled manner. Developed platform has a reservoir, which allows the fabrication of free-standing electrospun PLLCL scaffold directly on top of the microfluidic chip, a channel for transporting of cell, media, and drugs, an inlet and outlet to be applicable for both static and dynamic culture. Following characterization of scaffold and microchip, 3D tumor formation was achieved on this platform by using HeLa cells, which results in high cell viability and proliferation rate. Drug screening analysis provided more in-vivo like results. These results demonstrate that this developed platform is convenient for formation of various 3D tumor models and a potential candidate for drug screening and toxicity analysis.

Human mesenchymal stromal cells (hMSCs) have long been identified for their beneficial anti-inflammatory and immunomodulatory properties making them a promising cellular therapy candidate for a wide variety of disease indications. Despite almost three decades of clinical development, few hMSC products have had success making it to market.[1] While early phase hMSC clinical research progressed rapidly with promising early results, significant setbacks were faced at advanced clinical phases as clinical endpoints failed to be met.[2–6] These late stage set backs are largely attributed to the inability to accurately assess cell potency through scale up processes and across variable donor populations.[6] To address these challenges, we have engineered a perfusable microfluidic platform as a tissue-on-a-chip to predict hMSC functional performance. The system we have engineered encapsulates hMSCs in 4-arm poly(ethylene glycol)-maleimide (PEG-4MAL) hydrogel environments within a perfusable microfluidic device. We have previously demonstrated that the immunomodulatory secretion profile of hMSCs is significantly influenced by their microenvironment.[7] We have found a loss of functional utility of established potency markers IDO and PD-L1 of hMSC cultured in our microfluidic system compared to traditional 2-dimentional static culture, as well as differential protein regulation between the two platforms. Furthermore, when compared to an in vivo model, we found that the protein correlations of specific immune-relevant pathways are conserved in our microfluidic system but not 2D cultures. From these findings, we will establish a more predictive and robust hMSC potency metric.

Decellularized extracellular matrix (ECM) is an attractive and natural biomaterial for tissue engineering applications due to the native biochemical cues and composition. Vasculature is the key to viable tissues, which is still the greatest challenge in the field of regenerative medicine for building larger tissues and organs. Manufacturing ECM derived biomaterials from native vessels could be a possible solution to generate artificial vasculature.

We therefore developed a simple but efficient composition preserving decellularization method for sheep vein tissue to produce vascular extracellular matrix hydrogels for tissue engineering applications such as 3D bioprinting. The sheep veins for the study were harvested from local university farm, and frozen to -80 °C as first step of the decellularization, followed by CHAPS detergent and Benzonase nuclease washes. The PicoGreen assay was used to measure the DNA content, and collagen and glycosaminoglycan (GAG) contents were detected by hydroxyproline and Blyscan assays. The vein tissue proteome was assessed by liquid chromatography mass spectrometry (LC/MS).

The decellularized veins had less than 1 ng mg-1 total DNA per dry weight (mean 99,6 % reduction, n=6) while total collagen and GAGs were highly preserved compared to untreated native control. These results and absence of nuclei were also confirmed by histological analysis. The proteomic profiling showed overall well-preserved ECM, suitable for biocompatibility determination of the material for further tissue engineering applications.

These preliminary results are strong for further biomaterial development and aimed to be translated to human material from cardiac bypass surplus tissues for allogeneic option for vascular tissue engineering.

For decades in vitro 2D cell culture techniques have been employed in research, but they fail to recapitulate the complexity of natural tissues. 3D Bioprinting could potentially overcome this drawback due to the possibility to control the geometry and the 3D disposition of living cells within the scaffold.

This study describes a procedure to design and characterize a novel bioink for extrusion-bioprinting, analysing different blend formulations of alginate, gelatin and methylcellulose, suitable to bioprint and study lymphoid cells, in particular Chronic Lymphocytic Leukemia (CLL) cells. Rheological properties, the printability and the sol-gel transition temperature of the formulations were investigated to define the optimal printing parameters. Stability under culture conditions of printed scaffolds was investigated and compression tests were performed on bioprinted scaffolds to compare their mechanical properties to a fresh lymphoid tissue's ones. Finally, MEC1, a CLL cell line, was bioprinted to analyse cell viability, cell density and cell tendency to leave the scaffold over time.

Results showed that, for the selected blends, good shape fidelity and printing accuracy are achieved with a limitation on the scaffold height. Scaffolds have withstood to culture conditions showing stability up to three weeks and their mechanical properties were similar to the ones of tonsillar tissue and to the ones reported in literature [1]. High cell viability after 21 days was observed also bioprinting MEC1 and lymphoid stromal cells, suggesting the possibility to use this material to mimic CLL cells microenvironment.

The 3R guidelines impose the replacement of animal testing with alternative models. Liver-on-chip represents a promising alternative for drug screening and toxicological assays. However, optimisation is required in order to mimic in a trustworthy way the functionalities and the microsomal environment of liver cells. In this work, we developed a new liver-on-chip model including a relevant 3D matrix to support hepatic cell growth and function. This 3D matrix (BIOMIMESYS® Liver hydroscaffold) is a porous hydrogel composed of liver ECM components. The HepG2/C3a cell line was cultured in the gel, either on-chip under flow for 20 days or in static condition in 96-well plates. In contact with the hydrogel, cells tend to assemble and form spheroids while attaching to the adhesion sites of the hydroscaffold. First of all, flow rate measurements indicate that an optimal flow is preserved with and without the gel. An increase of pressure in the biochip has been noted due to cell growth which caused an increase of the hydraulic resistance. Cell viability, physiology and spheroid integrity were studied by immunostaining of the tight junctions and the development of the actin network, in addition to the albumin production and compared in the two conditions. Dynamic conditions were associated with a significant increase in albumin production, a higher viability and a conservation of the integrity of the spheroids compared to static conditions. These results highlight the tremendous role of the liver-on-chip model coupled with ECM matrix in a dynamic condition in the enhancement of cell functions and physiology.

Osteochondral regeneration remains a vital problem in osteoarthritis due to the cartilage defect site's low healing mechanism. Articular defects are challenging to treat because they extend deep to the subchondral bone range, and those two tissues are dissimilar. Surgical therapies have been advocated to treat diseased site likely micro fracturing, autologous chondrocyte implantation and autograft. These treatment methods have limitations such as fibrocartilage formation, donor site morbidity, the mismatch between tissue repaired site and lack of tissue integration. To improve the tissue repair biomaterials widely used but still could not mimic the naïve tissue structure. 3D printing gained attention for developing 3D scaffolds that can provide mechanical strength and allows tissue regeneration. In this context, using calcium-deficient apatite (CaP) with Mn for the osteochondral repair has been shown to improve the tissue regeneration. The influence of Manganese (Mn) with CaP on cell behaviour will tend to evoke human mesenchymal stem cell (hUMSCs) differentiation. The 3D printed Mn-doped CaP scaffolds were studied for in vitro cell proliferation and differentiation of human mesenchymal stem cells (UMSCs). The structure morphology, and extruded line width has been checked using scanning micrographs. Increasing Mn concentration led to increased cell attachment on the 3D printed scaffolds. The fabricated constructs analyzed for bone-specific alkaline phosphatase (ALP) marker using ALP staining and assay. All the group shows the positive expression of ALP on day 14. The Mn-CaP composition revealed the best set of bioactivity properties, potentially a good candidate for future applications of CaP materials in osteochondral regeneration.

MAKING IT STICK: A NOVEL APPROACH TO BIND AND PRESENT PHYSIOLOGICAL AMOUNTS OF BMP-2 VIA COLLAGEN-BASED SUBSTRATES

Stylianos Sarrigiannidis[P][1], Oana Dobre[1], Matthew Dalby[1], Manuel Salmeron-Sanchez[1]

Corresponding author's email: s.sarrigiannidis.1@research.gla.ac.uk

Introduction: Collagen type I, often used in tissue engineering, does not have a high affinity to GFs such as BMP-2. Absorbable collagen sponges loaded with BMP-2, even the medically approved systems such as Infuse®, use high concentrations of BMP-2 [1] to compensate for the swift BMP-2 leakage out of the material. High concentrations of BMP-2 can have adverse side effects e.g. ectopic bone formation [2]. The aim of this study is to use a new peptide to bind low amounts of BMP-2 onto collagen substrates. This allows controlled, local BMP-2 presentation to the biological environment to promote osteogenesis.

Methods: A protein fragment linking the fibronectin collagen binding and GF binding domains was expressed in E. Coli and incorporated into collagen substrates in 2D, 2.5D and 3D. The BMP-2 release from collagen combined with the peptide was assessed. Human mesenchymal stem cells (hMSCs) were seeded on the material to conduct viability, attachment and osteogenic differentiation.

Results: The new fragment successfully binds to collagen substrates and allows for the sustained release of BMP-2. Osteogenic differentiation experiments show that the collagen substrates treated with the peptide and BMP-2 show upregulation of osteopontin (OPN) - 21 days as well as calcium deposition after 24 days.

Conclusion: This system is an innovative method of absorbing and retaining physiological amounts of BMP-2 to promote osteogenic differentiation of hMSCs. It has the potential to improve already medically approved collagen-BMP-2 materials and can be expanded to other GFs in the future for tissue regeneration.

Vascular tissue engineering requires the implants which avert the restenosis, thrombosis and immunological reactions and must withstand physiological pressures without any leakage. In the clinic, synthetic polymer vascular grafts such as PTFE (Teflon) and PET (Dacron) have improved the diseased vessel function. Even though synthetic grafts provide good mechanical properties, it could not mimic the native blood vessel. Hydrogels gained attention to fabricate the 3-dimensional (3D) scaffolds. The existing casting, salt leaching methods have limitations in developing a biological scaffold. To improve the fabricating methods 3D printing procured attention for fabricating cells encapsulated scaffolds by layer-by-layer deposition in a controlled architecture. In order to use hydrogel for 3D bioprinting, we opted for photo-cross-linkable gelatin methacrylate (GelMA) due to its better biocompatibility and printability. We have performed a pilot study on the 3D bioprinted scaffolds with human mesenchymal stem cells (MSCs) and endothelial cells (ECs), namely cell viability by live/dead staining and cell proliferation using Alamar blue assay. From the staining results, we could observe that cells were attached and have actin filament spreading when compared with other cells encapsulated scaffolds (Alginate-gelatin). Additionally, we aimed to mimic a blood vessel's physiological conditioning using bioreactor (dynamic culture condition). The flow-induced physiologic system plays a pivotal role in cell alignment and vessels maturation. This study explores mechanical stimulation's influence on the 3D bioprinted scaffolds by a bioreactor system that could contribute to cell alignment for vessel maturation.

Advances in 3D bioprinting technology enabled fabrication of thick in vitro tissue models, further pushing the need for a supporting vascular network [1, 2], ideally built with simple and versatile approaches to create user-tunable structures. Our strategy involved the combined use of Gelatin Methacrylate (GelMA) and Pluronic F127 (PLU) hydrogels. GelMA is known for its many applications in tissue engineering [3], and to optimize its performance as a cell-laden hydrogel we blended it with PLU (0.1 to 1%). The addition of PLU, which is washed away after GelMA crosslinking, led to an increased porosity with a bimodal distribution of radiuses (10-20 µm and 50-100 µm) without affecting the bioink printability. Our second hydrogel is a high-concentration Pluronic F127 (PLU) solution that can be printed in pillars and short bridges without collapsing, enabling printing both 2D and 3D freestanding filament networks. The stepwise 3D printing protocol is as follows: it started with the deposition and partial crosslinking of a thin layer of a cell-laden photocurable GelMA-PLU blend, followed by the construction of the PLU channel networks on top of it; these networks were then surrounded by more cell-laden hydrogel, finally photo-crosslinked to yield the final construct. After washing away the sacrificial PLU, we seeded the hollow channels with HUVECs to cover the internal vasculature surface with an endothelial monolayer. When using Mesenchymal Stem Cells (MSCs) in the hydrogel bulk, the final structure and porosity of the material not only enhanced cell adhesion and viability, but also increased MSCs osteogenic potential.

Adipose tissue is a highly specialized tissue which plays a number of functions in the organism. This tissue is also a perfect source of Adipose Derived Mesenchymal Stem/Stromal Cells (AD-MSCs). Main advantages of adipose tissue as a source of stem cells are high accessibility and abundance. AD-MSCs may be found either in subcutaneous or visceral adipose tissue. The aim of the study was a comparison of different anatomical adipose tissue harvesting sites on the mesenchymal stem/stromal isolation yield.

The adipose tissue was obtained from 14 male domestic pigs from three anatomically different harvesting sites: the subcutaneous layer of the neck, the subcutaneous inguinal layer and the preperitoneal layer. The cells were isolated through digesting the adipose tissue with collagenase P. The number and viability of isolated cells were evaluated. The success rate of establishing a primary culture of AD-MSCs, immunophenotyping and proliferation kinetics were assessed.

The overage numbers of isolated cells from the neck subcutaneous adipose tissue, inguinal subcutaneous adipose tissue, visceral adipose tissue were 579,179 (± 156,820), 2,232,339 (± 799,050) and 313,787 (± 179,968) cells respectively. All the AD-MSCs populations showed high expression of CD29, CD31, CD90 markers; and very low expression of CD11b, CD31 and CD45 markers.

The subcutaneous inguinal adipose tissue seems to be a better source of mesenchymal stem cells in a porcine model compared to other examined sources: the neck subcutaneous adipose tissue and visceral adipose tissue.

Engineered natural biomaterials able to perform the sol-gel transition under specific external stimuli, also in the presence of cells, have gained great attention in the field of tissue engineering and regenerative medicine [1]. Despite of this, the encapsulation of neurons for the development of 3D neuronal networks, is still limited. In order to study neuronal (dys)functions and particularly neuronal connectivity, in vitro human brain models need to include not only a chemically and physically relevant microenvironment, but also structural network complexity [2]. To mimic the brain ECM environment, a porous and soft structure is preferred in the design of an artificial neural network. The goal of this study was to demonstrate the versatility of thermosensitive chitosan-based scaffold as an artificial matrix for 3D neuronal networks for in vitro studies and as an injectable-hydrogel for the in-vivo applications or innovative ink for 3D bioprinter. Chitosan is a widely used biomaterial, well known for its biocompatibility, biodegradability, muco-adhesiveness as well as its antibacterial activity [3]. It is already demonstrated that chitosan is able to sustain the development of 3D scaffold for neuronal networks [4]. In this work, chitosan thermogels were fabricated and characterized by different techniques. Primary rat neurons and human-induced neurons were mixed within chitosan thermogelling solution prior the scaffold gelation. The 3D neuronal cultures were morphological characterized by immunofluorescence techniques and a preliminary electrophysiological characterization of spontaneous activity by Micro-Electrode Arrays, was carried out

Mesenchymal stem cells (MSCs) have been used in cell transplantation and tissue engineering for their self-renewal and multipotency capabilities. The conventional stem cell expansion normally performed on a two-dimension surfaces such as culture flasks which take up large number of spaces. In this study, different supplements were used to identify a scalable xeno-free culture environment for MSCs proliferation. The cell yield, cell surface markers, cell plasticity, and immunomodulation have been compared against those cultured in standard fetal bovine serum supplemented medium. The MSCs cultured in human platelet lysate supplemented medium exhibit highest cell yield with comparable cell characteristic aforementioned to the control. In spinner flask culture, suitable culture parameter has been optimised to maximise the yield of MSCs. MSCs were cultured on three different microcarriers (Cytodex 1 (C1), Cytodex 3 (C3), Corning collagen coated microcarrier (CCM)) for cell expansion. At initial seeding process, visible aggregates were observed in C3 and CCM, whereas MSCs cultured on C1 formed minimal aggregation throughout the culture period. The results of current study demonstrate the feasibility of scale-up production of MSCs in spinner flask under xeno-free environment. It also highlights the potential of bioreactor in future MSCs up-scaling production for tissue engineering application.

Because the incidence of skin wounds requiring clinical treatment represents a public health problem worldwide, the present work aims to develop a bilayer scaffold of PLGA/fibrin electrospun membrane and fibrin hydrogel layer to be tested in vivo as skin substitutes. Primary cultures of fibroblasts and keratinocytes were isolated from isogenic Wistar Kyoto rats (WKY). Fibroblasts were cultivated in the fibrin hydrogel and keratinocytes on the electrospun membrane to generate a skin substitute using an air/liquid system. The scaffolds were tested in a full-thickness wound model in WKY rats of 3 months. Three groups were analyzed macroscopically: 1 (bilayer scaffold without cells), 2 (heterotypic skin substitutes), 3 (negative control). Results showed scab formation at day 14 in all animals from groups 1, 2, and 3. No signs of wound infection were presented. Regarding hair growth, 71% of the lesions in group 2 presented hair growth at day 14, while no hair growth was seen in groups 1 and 3. Additionally, distant suture points were seen in groups 1 and 2, which suggest skin regeneration and little wound contraction on both days 14 and 21. On day 21 all the wounds were re-epithelialized and presented hair. It could be concluded that the bilayer scaffold is thus a promising matrix for use as a skin substitute. However, it will be necessary to complete the sample size for each group and realize histological and immunoenzymatic assays to confirm the regeneration of the tissue. Purpose: Microtia is a congenital disorder manifested by an external ear malformation or a lack of the entire external ear auricle (anotia) [1]. The aesthetic reconstruction of the auricle remains a significant clinical problem. Children suffering from microtia often require repeated reconstructive follow-up operations [2, 3]. Therefore, we developed a novel tissue-engineered based reconstruction approach for microtia treatment.

Methods: Human auricular chondrocytes were bioprinted within a hyaluronan transglutaminase (HATG) bioink and combined with a bio-engineered human pigmented and prevascularized dermo-epidermal skin substitute [4, 5, 6]. Human fibroblasts and endothelial cells were used to develop a collagen type I-based dermal component with keratinocytes and melanocytes seeded on the surface. The cartilage constructs were transplanted onto immune-incompetent rats with pre-vascularized, pigmented skin substitutes on top. After short (1 week) and long-term (5 weeks) studies, the grafts were excised and used for histological and immunofluorescence analysis.

Results: Short-term in vivo tests have confirmed the anastomoses of the engineered blood capillaries with the recipient's vasculature enabling a rapid perfusion. Long-term in vivo tests have demonstrated that bioprinted material creates mechanically stable cartilage. Histological staining of the cartilage implant demonstrated extracellular matrix with glycosaminoglycans and collagen type II. In addition, bio-engineered skin displayed a stratified epidermis containing keratinocytes and melanocytes distributed throughout the basal layer that efficiently restored the donor native skin color.

Conclusions: Bioprinted auricular cartilage combined with a bio-engineered human pigmented and prevascularized dermo-epidermal skin substitute represents a novel and promising treatment option for children born with microtia.

Introduction

Retinitis pigmentosa (RP), the leading cause of hereditary blindness, is characterized by the degeneration of rod photoreceptors and subsequent loss of cone photoreceptors. Rod-derived cone viability factor (RdCVF) is a protein paracrine factor which maintains the structure and function of cone photoreceptors (1). RP patients may benefit from exogenous application of RdCVF; however, effective administration of protein therapeutics to the retina remains challenging. Topical applications are limited by bioavailability and bolus injection by risk of infection. To address these challenges, we developed an injectable hydrogel composed of hyaluronan and methylcellulose (HAMC) (2,3) modified with peptide binding partners of the Src homology 3 (SH3) domain and expressed a fusion protein of SH3-RdCVF, enabling its controlled release.

Methods

SH3-RdCVF was dispersed into a HAMC hydrogel modified with SH3 binding peptides immobilized by Michael addition between the maleimide-functionalized peptides and thiolated methylcellulose polymer chains. Sustained release was investigated in vitro for 7 days, quantified using a custom ELISA, and its bioactivity tested with chick retinal dissociates (E6).

Results

The sustained release of SH3-RdCVF was achieved by modulating the affinity between SH3 and its binding peptides for at least 7 days. Moreover, released SH3-RdCVF was bioactive as demonstrated with a significant increase in the viability of cone-photoreceptor cells in vitro.

Conclusions

For the first time, RdCVF was incorporated into a hydrogel from which its controlled, bioactive release was demonstrated, thereby laying the foundation for its use in vivo. Our affinity-based system constitutes a versatile delivery platform for the treatment of retinal degenerative diseases.

Osteoarthritis (OA) is a leading cause of disability around the world. With an aging population and increased incidence of obesity the burden of OA is set to rise, paving way for intra-articular mesenchymal stem cell (MSC) therapy.A PRISMA systematic review and meta-analysis was conducted employing four databases (MEDLINE, EMBASE, Cochrane, Web of Science) to identify all clinical studies which utilised adipose tissue derived MSCs or SVF (stromal vascular fraction) for the treatment of knee OA. In particular, the Western Ontario and McMaster Universities Osteoarthritis Index (WOMAC) was analysed for quantifiable outcomes.Eighteen studies were found which met the inclusion criteria. Eleven studies investigated the effects of adipose tissue derived MSC treatments on knee osteoarthritis, while eight studies examined SVF. All studies found that both therapies are effective in reducing pain and improving knee function in patients with knee OA. When stratifying studies by the change in WOMAC across time, the studies reported a 17.3%[CI 2.4-32.1%] decrease at ≤1 month, 39.6%[CI 29.0-50.2%] decrease at 2 months, 36.6% [CI 21.4-51.7%] at 3 months, 41.3% [CI 29.9-52.6] at 6 months, 35.9%[CI 11.8-60.0%] at 12 months, 65.7%[CI 51.3-80.1%] at 18 months, and 62.1%[51.5-72.7%] at 24 months. These results suggest MSC treatments on knee OA provide long-term pain relief and improved joint function, with a dose-dependent effect.The studies in this systematic review have established the safety and efficacy of both adipose tissue derived MSC and SVF therapy for knee OA in humans.

Electrospraying (ES) technique is widely used in the development of nanocapsules (NC) for use in tissue engineering (TE), allowing for encapsulation of biomolecules. In this work, NC containing the anticoagulant heparin (Hep) were developed by ES, with the aim of their future association with vascular TE grafts. NC were developed using an emulsion of poly (lactic-co-glycolic acid) (PLGA) by the ES technique, with 0 (Control/NC) or 1000 IU of Hep (Hep/NC). The size, polidispersion (PdI) and zeta potential of the NC were analyzed by ZetaSizer, and their morphology, by scanning electron microscopy. The efficiency of encapsulation (EE) and release of Hep were determined by the turbidimetric method. The functionality of Hep/NC was analyzed by activated partial thromboplastin time (aPTT). The Control/NC and Hep/NC showed round and homogeneous morphology. The control/NC showed of mean diameter of 178.8±3.7 nm, 0.326±0.04 of PdI and -23.4±1.5 mV of zeta potential. The Hep/NC showed 262.6±14.6 nm of diameter, 0.291±0.01 of PdI and -28±2.5 mV of zeta potential. The EE was 98.9%. In the release test, most of the Hep was released in the first hour. However, after this, the release was gradual and controlled. In the functionality test, the blood incubated with Hep/NC did not coagulate. The NC were successfully produced by the ES technique, with a high EE rate. However, this process did not alter the activity of the Hep. Electrosprayed NCs can be easily associated with TE biomaterials, increasing their success in their application as vascular grafts.

Introduction

Hypospadias is a common birth defect requiring surgical repair and associated with long-term complications. Cross-linked or non-cross-linked decellularised tissue matrices were hypothesised to provide natural substrates to augment the tissue bed in surgical situations where the native tissue bed is insufficient to support an enduring repair.

Methods

Single patches of acellular, non-cross-linked biomaterial developed from full-thickness porcine urinary bladders (Porcine Acellular Bladder Matrix; PABM) or commercial cross-linked acellular matrix derived from porcine dermis (Permacol™) were implanted in a peri-urethral position in male pigs. After three months, macroscopic and microscopic evaluations including a novel objective quantitative analysis of immunohistochemically-labelled tissue sections were performed to assess tissue integration outcomes.

Results

All pigs survived the post-operative period with no complications. Macroscopic evaluation revealed no evidence of residual PABM, but Permacol™ remained evident. Microscopically, there was no sign of any adverse or inflammatory tissue reaction. Permacol™ grafts showed evidence of partial encapsulation and very sparse cell infiltration. By contrast, PABM implants showed uniform cellularisation, including neovascularisation, throughout the implanted biomaterial. Total cell counts, as well as the densities of infiltrating cells, resulted significantly higher in PABM than in Permacol implanted grafts.

Discussion

The strong, compliant structural and integrative properties of PABM support its use in surgical situations where there is an insufficient tissue bed to withstand repair. In particular, we propose an application in primary complex hypospadias repair, where rapid integration as a supportive layer is predicted to reduce complications and the need for revision surgery.

Meniscus tears are frequently encountered in clinical. As a load-bearing tissue, the dynamics of meniscus repair in vivo are governed by both biological and biomechanical cues. Biocompatible hydrogel and tissue specific stem/progenitor cells are the most physiological mimetic elements that have been used in meniscus tissue engineering1. In this study, we have established a homemade GELMA hydrogel-based bioreactor, which can provide repetitive mechanical loading to 3-dimensional (3D) cultured human meniscus progenitor cells (hMeSPCs)2, mimicking the mechanical microenvironment of meniscus tissue in vitro. hMeSPCs (n=9, from hospital with ethical approval) were isolated by multiple colony selection, and expanded in vitro. The cells showed 12.5% of CFU, and were characterized by flowcytometry for stem cell surface markers (CD90/73/105/44/45/34). Controlled tensile strain (10% hydrogel deformation, 0.5 Hz, 1 h/day, loading group)3 was applied to the Gelatin Methacryloyl (GelMA) hydrogel-encapsulated cells through the bioreactor, which enabled the 3D-cell culture of hMeSPCs for more than 15 days with 94% of the cell survival rate, examined by PI staining, flowcytometry. The loading enhanced the differentiation of encapsulated hMeSPCs, and increased the extracellular matrix (ECM) deposition, compared with the static group (n=9, pooled cells into 3 batches, $p<0.05$). Furthermore, we evaluated the gene expression levels of 3D static and loading groups by RNA-seq (n=6, 2 batches), and 198 genes were identified that are regulated by the dynamic mechanical loading. Together, we here report a functional physiological 3D dynamic mechanical loading platform for meniscus tissue engineering. (Supported by National Key R&D Program of China, 2019YFA0111900).

Allogeneic Islet transplantation holds appreciable recovery towards the normoglycaemia in T1D patients; but the greatest challenge is to have an ideal encapsulation device. An effective device, firstly never eliciting a foreign body response, ensures the encapsulated cells viable, transducing the signals; yet protecting from the host immune responses [1]. To overcome the challenges, we tuned the physical features of the Cellulose acetate (CA) and Polyethersulfone (PES) through electrospinning technique, assessed in vitro and in vivo. Fabricated nano-porous membrane devices expressed the ability of selective immune-isolation property, insulin secretion to glucose levels and ensured the encapsulated cells functionality. Electrospinning resulted a modified surface wettability converting the hydrophilic CA (136°) and PES (126°) to hydrophobic [2]. Enhanced hydrophobicity helped in maintenance of the 3D morphology of the L929 cells and Min6 Spheroids. SEM evidenced the nano-topographical features effectively stopped the monocyte to macrophage conversion even after 96 hours; complimenting the mRNA levels. All nano-fibrous membranes ceased the migration of Thp-1 Monocytes in a trans-well migration assay mimicking a xenogeneic model. Further GSIR studies revealed the efficient insulin release upon glucose stimulation in vitro with Min6 and rat islets. In vivo implantation of CA and PES devices in allogeneic rat models encapsulated with rat islets found to be insulin independent even after 4 weeks, successful engraftment with visible vasculatures around the devices makes them promising for encapsulation technology. Thus exploiting topography and physical features can envisage us to have an ideal encapsulation device for immune-isolation therapies.

REPAIR OF INTRAUTERINE ADHESIONS BY USING ENZYMATICALLY CROSSLINKED GELATIN HYDROGEL LOADED WITH HUMAN MENSTRUAL BLOOD-DERIVED STROMAL CELLS

Fengyu Wang[P][1]

[1] *School of Medicine, South China University of Technology, Guangzhou, China*

Corresponding author's email: mswangfengyu@mail.scut.edu.cn

Approximately 25-30% of infertility is caused by intrauterine adhesions (IUA; also known as Asherman syndrome) [1]. A traditional treatment for IUA is resection of adhesion by hysteroscopy. However, it fails to prevent IUA recurrence and endometrial scarring formation. In present study, we aim to investigate the therapeutic effects of transplanting of human menstrual blood-derived stromal cells (MenSC) combined with enzymatically crosslinked gelatin hydrogel (enGel) in rat IUA models and the possible mechanisms in the treatment of endometrium regeneration. Particularly, we record endometrial morphology and pathology, tissue proliferation, inflammation, pregnancy outcomes etc. Our results suggest that enGel could partially repair IUA caused by mechanical injury, more interestingly, MenSC/enGel complex transplantation has notable dual repair effects: a reliable antiadhesion property and the remarkable promotion of endometrial regeneration.

The physical environment sensed by cells is central to defining their behaviour. To understand how local environmental features may influence cellular responses such as attachment, adhesion, proliferation, migration and differentiation, we have implemented a method by which surface characteristics are parameterised through particle synthesis and controlled assembly. We show that such particle-decorated surfaces are not only cell-relevant, but can act as instructive interfaces. Negatively charged silica particles adsorbed to a poly(L-lysine) treated surface are removable by A549 lung adenocarcinoma cells only when the particle size is greater than 480 nm, while human monocyte-derived macrophages are able to remove particles as small as 180 nm. Additionally, stiffness-dependent effects are manifest with preferential interactions supported by more rigid particles when presented with differentially crosslinked poly(N-isopropylacrylamide) particles. Confocal microscopy has indicated that in response to these particle surfaces, alterations to adhesion complex formation are apparent. Localisation of paxillin and vinculin to the particles highlights how topographical cues are sensed by the cells and guide their response. To highlight how such particle surfaces might guide behaviour, we use surface particle removal as a novel method for the introduction of functional molecules into adherent cells. Using these insights, we show how different cell instructive interfaces based on controlling particle properties and location can be developed and deployed.

DEVELOPMENT OF BIOACTIVE HYDROGELS FOR NERVE TISSUE REGENERATION

ozgul gokP[1], Ali Murad Özmen[2]
[1] *Assist. Prof. at Acibadem University*
[2] *Acibadem University*
Corresponding author's email: ozgul.gok@acibadem.edu.tr

INTRODUCTION: Hydrogels are promising polymeric scaffolds as they provide biocompatible and biodegradable network structures for the growth of cells together with necessary growth factors and desired cell adhesion peptides.1 In this study, different peptides were immobilized into biodegradable PEG-based hydrogels and in vitro studies were conducted to demonstrate their biological efficiency towards especially for nerve cell growth and proliferation.2

METHOD: PEG-based hydrogels were synthesized under UV light (365nm) using thiol-yne click chemistry. Hydrogels were added with PLA (5-10-20% by weight) and hyaluronic acid (10-20-30% by weight) for adjusting the stiffness of resultant scaffold to be suitable for neural tissue. Also two cell adhesion peptides were introduced into scaffold to enhance nerve cell growth and proliferation.

RESULTS:

Figure 1. SEM image of PEG-based hydrogel with 10%PLA and %0.1RGD peptide.

DISCUSSION AND CONCLUSION:
The obtained hydrogels were characterized by FT-IR for their functional groups and mechanical behavior was analyzed by reometer. SEM results indicated that all hydrogels have porous structure and they were shown to be non-toxic over L929 fibroblast cell line (>85% cell viability).

ACKNOWLEDGEMENTS:
This research has been supported by ACU Scientific Research Commission (ABAPKO Project No: 2018/01/07 and 2019/04-03).

Autografts, the gold standard for craniofacial repair but have limited source tissue and harvested site morbidity. Tissue-engineering has the potential to facilitate craniofacial bone regeneration but advanced materials that can address these limitations are warranted. Poly(glycerolsebacate) (PGS) has been investigated for soft tissue regeneration, but not been widely studied for bone. Its mechanical properties can easily be tailored whilst being biocompatible. Cell-derived extracellular matrix (ECM) has been shown to enhance osteoprogenitor cell proliferation, differentiation and mineralisation(1). However, it has limited mechanical properties and cannot be shaped to fill complex bone defects. Therefore, we aim to create 3D bone-like tissue for craniofacial repair using a combination of PGS and cell-derived ECM. PGS were synthesised using a porogen-leaching technique with different ratios (1:2.5- 1:4.5) of prepolymer to salt (w/w), porosity assessed using pycnometry and scanning electron microscopy (SEM). Y201 (mesenchymal stem cell (MSC) cell line) attachment and matrix deposition onto the scaffolds were investigated by resazurin reduction assay and Western blot over 21 days. It showed that the ratios used produced a range of pore densities, with a higher salt content producing higher porosity. While pore sizes are between 50-400 µm, suitable for cell attachment and growth(2). The scaffolds supported cell attachment (up to 65%), with slightly higher attachment on lower porosity scaffolds. Furthermore, western blotting confirmed that the scaffolds supported deposition of key bone proteins including collagen, fibronectin, bone-sialoprotein 2, and osteopontin. In summary, the scaffolds support MSC growth and bone matrix deposition and have potential applications in craniofacial bone regeneration.

Abstract:

Cellular transition to hypoxia following tissue injury, has been shown to improve angiogenesis and regeneration in multiple tissues. To take advantage of this, many hypoxia-mimicking scaffolds have been prepared, yet the oxygen access state of implanted artificial small-diameter vascular grafts (SDVGs) has not been investigated. Therefore, the oxygen access state of electrospun PCL grafts implanted into rat abdominal arteries was assessed. The regions proximal to the lumen and abluminal surfaces of the graft walls were normoxic and only the interior of the graft walls was hypoxic. In light of this differential oxygen access state of the implanted grafts and the critical role of vascular regeneration on SDVG implantation success, we investigated whether modification of SDVGs with HIF-1α stabilizer dimethyloxalylglycine (DMOG) could achieve hypoxia-mimicking responses resulting in improving vascular regeneration throughout the entirety of the graft wall. Therefore, DMOG-loaded PCL grafts were fabricated by electrospinning, to support the sustained release of DMOG over two weeks. In vitro experiments indicated that DMOG-loaded PCL mats had significant biological advantages, including: promotion of human umbilical vein endothelial cells (HUVECs) proliferation, migration and production of pro-angiogenic factors; and the stimulation of M2 macrophage polarization, which in-turn promoted macrophage regulation of HUVECs migration and smooth muscle cells (SMCs) contractile phenotype. These beneficial effects were downstream of HIF-1α stabilization in HUVECs and macrophages in normoxic conditions. Our results indicated that DMOG-loaded PCL grafts improved endothelialization, contractile SMCs regeneration, vascularization and modulated the inflammatory reaction of grafts in abdominal artery replacement models, thus promoting vascular regeneration.

Nucleic acids have gained much popularity due to their clinical potential for gene therapy and regenerative medicine. Plasmid DNA (pDNA) was the first nucleic acid to be pursued as a therapeutic molecule and remains the most used for cellular modification. Later on, several RNAs came into play as they offer several advantages: complete degradation, avoid transport across the nuclear membrane, and do not hold risks associated to genome integration. It is generally accepted that both mRNA and pDNA cellular internalization occurs via endosomal uptake and cytosolic release. pDNA needs nuclear entry. Nevertheless, their mechanistic process of cellular uptake remains poorly understood.

In this study, we investigated the transfection efficiency and protein expression kinetics of two nucleic acids, i.e. pDNA and chemically modified mRNA (cmRNA). The reporters Metridia Luciferase (MetLuc) and enhanced green fluorescent protein (eGFP) were used. pDNA and cmRNA were delivered using two lipid vectors in HEK293 and hMSCs. Protein expression and biocompatibility were evaluated spectrophotometrically at up to 3 days post-transfection. Mechanisms of cellular uptake were studied by endocytosis inhibition whereas cellular internalization was investigated by Correlative Light and Electron Microscopy. Results in HEK293 showed highest expression when pDNA lipoplexes (lipofectamine) was used. Interestingly, in primary cell, the best performance was observed with the vector 3DFect and cmRNA. Additionally, while mRNA-transfected cells showed an early peak of MetLuc activity (day 1), pDNA transfection resulted in a later onset of expression with peaks at day 2 and day 3 for HEK293 and hMSCs, respectively.

Bioprinting of functional tissue poses a major challenge as the process cannot reproduce the intricate complexity of native tissue and post-printing tissue maturation is required. We recently reported on a novel mechanism for enzymatically crosslinking bioinks,[1] where the outstanding chondrogenic properties of the hydrogel hyaluronan transglutaminase[2] was translated to cartilage bioprinting. However, while bioprinted constructs reached compressive moduli of up to 400 kPa and were stable in vivo for 6 months, the tissue displayed a tendency to develop towards fibrocartilage.

To steer tissue maturation towards elastic cartilage and to preserve the chondrogenic capacity of human auricular chondrocytes, we altered the bioink's composition to include a low percentage of alginate and explored the addition of various growth factors such as FGF-2 and TGF-β3. Matured constructs showed an abundance in glycosaminoglycans, collagen II and elastin without the presence of collagen I, as observed in human auricular cartilage. The mechanical properties of these constructs further reached up to 1 MPa, approximately two thirds of the compressive modulus of native human auricular cartilage, after 9 weeks in culture.

By replicating elastic cartilage, these results demonstrate a significant step towards the treatment of microtia patients. However, challenges remain in upscaling to larger constructs as nutrient availability limits tissue maturation. To overcome these limitations, we explore methods to incorporate nutrient channels which improve tissue maturation throughout the construct. Lastly, to reduce skin tension on the bioprinted auricle, we combine bioprinted cartilage with tissue engineered skin[3,4].

Low-Intensity Pulsed Ultrasound (LIPUS) is an intriguing tool that allows providing cells and tissues with mechanical energy in a non-invasive way, inducing beneficial bioeffects [1]. LIPUS demonstrated high potential in the regulation of inflammatory processes [2]. However, US set-ups for in vitro experiments are usually featured by considerable errors in the US dose delivered to cells [3]. Thus, the stimulation conditions in the state-of-the-art are not entirely comparable/reliable and the optimal ones are often unknown [4]. In this study we developed two controlled LIPUS systems able to guarantee precisely controlled US dose at the target cells modulating different parameters. We used to test this technology on a pro-monocytic, human cell line (U937) that was stimulated with 50 ng/mL of PMA for 48 h and induced to inflammatory conditions by treating it with 1 µg/mL LPS. Then, dose-controlled LIPUS stimuli were provided for 2 h, by varying US parameters. First, three different frequencies were screened (38 kHz, 1 MHz and 5 MHz). Then, the role of US intensity was evaluated, by varying it (25, 100, 250 and 450 mW/cm2). Finally, different duty cycles were applied (10%, 20%, 30%, 40%). Results showed that the optimal anti-inflammatory conditions, minimizing the release of inflammatory cytokines (IL-1β, IL-8 and TNF-α) with respect to the non-stimulated controls, were: 38 kHz, 250 mW/cm2 and a duty cycle of 20%. Future efforts will investigate the intracellular pathways activated by these stimuli. Furthermore, additional in vitro tests will be performed on other cell models of the immune system.

In Tissue-engineered vascular grafts (TEVGs) thrombogenicity is a common failure cause in small diameter applications. Herein, we aim to study the correlation between mechanical-hemodynamic-biochemical variables on protein adsorption processes responsible for thrombogenesis through computational simulations and in vitro models. Briefly, a two-way Fluid-Structure Interaction (two-way FSI) model in ANSYS Fluent-2019R3® and ANSYS Transient Structural® was linked to a kinetic model for albumin and fibrinogen adsorption on the TEVG surface implemented in COMSOL Multiphysics5.3®. Physiological pulsatile pressures were introduced as User Defined Functions (UDF). For the in vitro validation, we conducted fluorescent labeling of albumin and fibrinogen for further adsorption on a 1 mm diameter TEVG placed into a fluidic device under controlled physiological and pulsatile flow conditions where the proteins were circulated. The protein adsorption was allowed at different time spans. Surface protein concentration and distribution were evaluated by confocal microscopy. The two-way FSI model provided physiological-baseline velocity profiles and wall shear stresses. The kinetic model linked to the two-way FSI model showed time-spatial dependent protein concentration and saturation, thereby demonstrating the influence of wall properties and pulsatile flow. This was further confirmed by the collected confocal images. In both cases, fibrinogen saturation rates were faster than albumin. As fibrinogen is thrombogenic, our models provide a robust tool to conduct multiparametric studies of TEVGs and consequently improve their rational design.

Combining biodegradable polymers with inorganic sulfate-minerals have shown encouraging results for bone conductivity. Nevertheless, several challenges are yet to be solved including modulation of oxidative stress and improvement of angiogenic potential and mechanical properties. An avenue to overcome such issues is to include bioactive-fillers to attenuate the signaling of reactive-oxygen-species of osteoclasts during bone resorption, while enhancing mechanical performance in terms of tensile and compressive strength. Natural-fibers main constituents have been successfully tested for biomaterial reinforcement and functionalization. In fact, natural additives not only act as reinforcement, but also improve surface-bioactivity as has been reported for Cocoa Bean Shells. A byproduct-waste of chocolate production (60.535tons/year) rich in polysaccharides and antioxidants. Hence, this work presents the formulation and the preliminary in-vitro evaluation of poly(lactic-acid)/Hydroxyapatite/Cocoa-Bean-Shells-based (PLA/HA/CBS) composites fabricated by solvent-casting/particle-leaching method. Structural analysis (FTIR) confirms absence of covalent-bonding between materials. Tensile modulus of composites shows a stiffer material when HA/CBS content is increased, approaching that of cortical bone. Antioxidant activity as assayed by DPPH demonstrates a marked radical-scavenging activity attributed to CBS presence. Metabolic activity measurements via MTT indicate low cytotoxicity (below 10%), however, platelet aggregation increased up to 40%. In summary, the developed composites hold a significant promise for biomaterial-engineering as their tensile properties are tunable, exhibit strong antioxidant activity and might induce angiogenic factors release for the potential treatment of bone defects. Further studies of the possible role of CBS as bioactive-filler are therefore encouraged including immune-response in-vivo. Moreover, this is an eco-friendly alternative to take advantage of chocolate-industry byproducts.

MESENCHYMAL STROMAL CELL MODULATION OF THE SYNTHETIC BIOMATERIAL IMMUNE MICROENVIRONMENT

Karen Martin[P][1], Rebecca Schneider[1], Andrés García[1]

[1] *Georgia Institute of Technology*

Corresponding author's email: karen.martin@gatech.edu

The immune system plays a central role in orchestrating repair and regeneration of damaged tissue following disease or injury. Because of their immunomodulatory properties, mesenchymal stromal cells (MSCs) are an attractive cell source for use in diverse regenerative medicine applications. However, clinical translation is hampered by poor control over MSC survival, localization, and secretome upon transplantation in vivo. To overcome this, MSCs are often utilized in conjunction with biomaterial scaffolds (e.g. hydrogels), which are also known to dramatically alter the local immune landscape via host-biomaterial interactions. The combined impact of biomaterial and MSC delivery on the temporal recruitment and phenotypic shifts of immune cells within the local environment remains unclear.

We evaluated the effects of primary murine MSC co-delivery on the in vivo immune response to synthetic PEG-4MAL hydrogels in C57BL/6 immunocompetent mice by: (1) analyzing the local cytokine milieu via multiplex ELISA and (2) characterizing immune cell infiltration into the hydrogel over time via flow cytometry. Across all conditions, monocyte infiltration predominates at day 1, granulocytes peak around day 3, and macrophages are the predominate myeloid population by day 7. On day 3, two key chemokines, MCP-1, a potent monocyte chemoattractant, and MIP-2, a neutrophil chemoattractant, are present at significantly higher concentrations in IFNγ-stimulated MSC-laden hydrogels compared to acellular and unstimulated mMSC-laden hydrogels. A corresponding increase in the number of granulocytes and monocytes on day 1 and granulocytes and macrophages on day 3 was seen in the IFNγ-stimulated MSC-laden hydrogels compared to the other groups.

Vascularization of a scaffold or implant is one of the most fundamental challenges tissue engineering faces to successfully transplant engineered constructs. The blood vessels can provide the necessary nutrients and oxygen required for cell survival. Various strategies are being explored to enhance vascularization, including controlled release of growth factors. Modulating a scaffold's microarchitecture can also improve blood vessel formation because our native tissues are immensely organized at the microscale level. In the 1990s, Baxter Healthcare had already reported that biomaterial topography could influence blood vessel formation. In this work, we fabricate micro- patterned porous free-standing membranes by using photolithography and non- solvent-induced phase separation techniques. Random- pore membrane is taken as a control. SU-8 micropillars with 5µm and 40µm diameters are fabricated using photolithography. The fabricated micropillars are further used to produce patterned porous membranes via the phase separation method. Optical 3D profilometer and Scanning electron microscope (SEM) investigated the microarchitecture and surface topography of the membranes. The contact angle measurements reveal the hydrophilicity of the membranes, which will encourage cell attachment. The micropatterned membrane promotes endothelial cell proliferation in-vitro, a significant contributor to blood vessel formation. These findings validate the use of micro-patterned porous free-standing membranes to promote vascularization.

Immediately after a fracture occurs, a hematoma is formed. This hematoma plays an important role in fracture healing and, under healthy circumstances, aids in generating an environment in which a wide variety of cells orchestrate processes involved in fracture healing. MicroRNAs may influence these processes. The aim of this study was therefore to profile the expression of microRNAs in human fracture hematoma (fxH) samples.

fxH was harvested from 63 patients (mean age 51 ± 19; 32) during initial surgery. miRNAs were isolated, transcribed and pooled for qPCR array analysis. Qiagen fibrosis- and inflammation qPCR arrays were used based on an extensive literature study related to fracture healing and osteogenesis.

The array data revealed a tendency towards an anti-inflammatory miRNA signature in the fxH and showed a propensity for cytokine activity due to the downregulation of microRNAs which play a central role in cytokine metabolism and regulation. Pro-fibrotic microRNAs were strongly downregulated as compared to anti-fibrotic microRNAs, which showed relatively equal numbers of over- and under-expressed microRNAs. Angiogenic microRNAs were equally over- and under-expressed. Innate- and adaptive immunity microRNAs showed a minimal number of over- and under-expression.

This study reveals expression profiles of microRNAs in human fxH, linked to key processes in fracture healing. Further research will focus on more extensive analysis of these array data and validation of specific microRNA's in different subgroups of patients. Also targets of the miRNAs will be elucidated. These data will broaden our view on potential therapeutic implications of miRNAs in fracture healing.

DEXAMETHASONE REGULATES CIRCULAR RNA EXPRESSION DURING HUMAN BONE MARROW MESENCHYMAL STROMAL CELLS DIFFERENTIATION

Elena Della Della Bella[P][1], Ursula Menzel[1], Valentina Basoli[1], Céline Tourbier[1,2], Mauro Alini[1], Martin J. Stoddart[1,2]

[1] *AO Research Institute Davos, Switzerland*

[2] *Department of Oral and Maxillofacial Surgery, Medical Center - University of Freiburg, Faculty of Medicine, University of Freiburg, Germany*

Corresponding author's email: elena.dellabella@aofoundation.org

Understanding the molecular mechanisms underlying in vitro differentiation of human bone marrow mesenchymal stromal cells (MSCs) is of utmost importance for regenerative medicine. The role of circular RNAs (circRNA) in gene expression regulation was recently acknowledged, but their effect in stem cell differentiation is currently unclear. The aim of the present study was to identify the differential expression of circRNA in early differentiation of human MSCs. Osteogenic and chondrogenic differentiation were induced in monolayer and pellet cultures, respectively, for 7 days, then samples were collected for RNA isolation. RNA hybridization arrays were used to identify differential circRNA expression during differentiation, and results were validated by qPCR. Moreover, the effect of dexamethasone or the glucocorticoid receptor agonist (+)-ZK216348 on gene expression in monolayer or pellet cultures of undifferentiated cells was assessed. Bioinformatic analysis identified several differentially expressed circRNA during differentiation. Among others, four different circRNAs derived from FKBP5 gene were upregulated in both osteo- and chondrogenesis. Validation experiments showed that total and circular FKBP5 (of which the linear transcripts encode for a co-chaperone of glucocorticoid receptor) were consistently upregulated in both osteogenic and chondrogenic differentiation. Dexamethasone alone was shown to strongly influence the expression of total FKBP5 expression. This effect was mediated by a transactivation mechanism, since (+)-ZK216348, which preferentially induces transrepression, did not have the same influence on FKBP5 gene expression. The functional role of FKBP5-derived transcripts in differentiation should be explored in follow on studies, allowing to better understand the role of dexamethasone during in vitro differentiation.

HEPARINIZED ALGINATE BIOMATERIALS FOR THE TREATMENT OF ISCHEMIC INJURIES

Fabiola Munarin[P][1], Isobel Rountree[1], Collin Polucha[1], Kareen LK Coulombe[1]

[1] *Brown University*

Corresponding author's email: fabiola_munarin@brown.edu

In this work we propose an acellular approach to localize and control the release of angiogenic growth factors, for promoting angiogenesis in ischemic injuries. Heparin moieties are bound to alginate backbone (200 μg heparin/mg of alginate), to mimic the natural affinity of the extracellular matrix for heparin-binding growth factors, including bovine serum albumin (BSA), vascular endothelial growth factor (VEGF) and pleiotrophin (PTN). Release profiles of fluorescently-labeled BSA delivered from optimized heparin-alginate hydrogels show a controlled release of the protein over a period of 14 days in vitro and 7 days in vivo. Furthermore, VEGF or PTN loaded in heparinized alginate microspheres or bulk hydrogels enhance angiogenesis in vitro (Matrigel network formation assay performed with translational hiPSC-derived endothelial cells (hiPSC-EC)), ex vivo (aortic ring assay) and in vivo (Matrigel plug assay and subcutaneous implant of heparin-alginate hydrogels). Angiogenic metrics, including endothelial cell migration, number of networks and number of branches, increased to a varying extent comparing the growth-factors loaded heparin-alginate hydrogels with the unloaded and culture medium controls in hiPSC-EC cultures and in the aortic ring assay[1]. Histological assessment of heparin-alginate subcutaneous explants demonstrates a rapid migration of host endothelial cells and macrophages at 4 days after implantation, and the formation of structures resembling the healthy granulation tissue, as assessed by CD68 and CD31 staining (labeling the infiltrating macrophages and endothelial cells, respectively)[2]. Ongoing studies are further investigating this novel therapeutic for pursuing increased vascular density for efficient regeneration of ischemic tissues, including ischemic skin flap wounds and the infarcted myocardium.

Background and Aims: Autologous grafts, i.e. saphenous vein (SV), and internal mammary artery, are currently utilised in coronary bypass grafting (CABG). Unfortunately, these grafts are limited by the quality, size, and availability from the donor [1]. Bypasses commonly fail because of additional blockages from thrombosis and the irregular performance of vein grafts. Saphenous vein grafts have a 50% failure rate after 10 years [2]. We hypothesised that cells populating the SV are the contributing factor for its lower patency due to their different phenotypic expression. Therefore, this study aims to assess the suitability of decellularised human SV for arterial grafting via in vivo assessment using a porcine model of carotid artery replacement.

Methods: Human SV were decellularised and then implanted in female Landrace pigs (n=3), under strict clinical standards including anti-platelet therapy and anticoagulation with heparin. Pigs were recovered and maintained under optimal animal welfare conditions for 4 weeks. Implanted grafts were surgically exposed and evaluated after a month. Implants were excised, and formalin fixed, along with a section of the native carotid artery, and sectioned at 5 µm thickness. Sections were stained with H&E, Picrosirius Red, EVG and Alcian blue to analyse conduit lumen diameter, wall thickness, and extracellular matrix composition.

Results: In vivo xeno-transplantation confirmed excellent mechanical strength and biocompatibility without mechanical failure, and a 50% patency rate at 4-weeks.

Conclusions: Our preliminary findings support feasibility testing in pig, and the approach has great potential both as a pre-clinical graft testing model, and in the clinical setting.

Vascular endothelium is an important layer that serves as a permeable barrier and helps in the regulation of blood flow. Damage to the endothelial layer can result in the development of intimal hyperplasia (IH). Subsequent event following EC injury that leads to IH development are yet to be fully elucidated. An ex vivo model of intimal hyperplasia is of value to further understand reendothelialisation mechanism in order to combat IH. Healthy human umbilical arteries (hUAs) that are easily obtained will be utilised to set up an ex vivo IH model. In this study, we aim to create and optimise denudation method of hUA, to enable understanding of IH development and reendohelialisation. Here, we assessed the denudation of human umbilical artery (hUA) using Trypsin enzyme with different incubation times applied to the hUAs. The denuded hUAs were stained with Alcian Blue staining, Haematoxylin & Eosin staining and EC coverage and glycosaminoglycans (GAG) coverage were analysed. Results from the study shows that EC coverage in the denuded hUA is reduced as compared to native hUA. While several differences were recorded between denuded and native hUA on the lumen size and GAG distribution. In conclusion, incubation with Trypsin for 10 minutes managed to remove almost 50% of the ECs. Other parameters need to be adjusted to establish a protocol that can result in total hUA denudation. Understanding the potential reendothelialisation of denuded human umbilical artery using recipient's progenitor cells could have a significant impact on finding an alternative vessel graft for bypass surgery.

ALL CELLS ARE IMPORTANT: MSC AND HUVEC COMMUNICATION IN THE 2D CO-CULTURE MODEL

Irina Beloglazova[P][1], Ekaterina Zubkova[1], Konstantin Dergilev[1], Elizaveta Ratner[1], Yelena Parfyonova[1,2]

Corresponding author's email: irene.beloglazova@gmail.com

In this study we used a 2D model of human umbilical vein endothelial cells (HUVEC) contact co-culturing with human adipose stromal cells (MSC) without exogenous matrix addition. As a control we used non-contact co-culturing in Transwell. In the contact model HUVEC self-assembled into the capillary like network (CLN) within 48h in contrast to Transwell. By the first day of contact co-culture, MSC formed a fibronectin scaffold as a basis for extracellular matrix (EM) formation. By the second day both MSC and HUVEC upgraded EM by laminin, collagen 1 and 4. Notably, laminin (mainly laminin 411, according to qRT-PCR data) formed basal-like membrane in the area of contact between MSC and HUVEC and separated them.

We discovered that co-culturing of HUVEC with MSC led to the b3 integrin mRNA upregulation in both cell types and didn't influence mRNA expression of av, b1 and b5 integrins. Blocking antibodies to av integrin subunit not only prevented CLN formation in co-culture but also altered mRNA expression of VEGF receptors, Notch signaling and proteolytic system components in HUVEC.

We can conclude that both MSC and HUVEC are involved in the formation of the specific microenvironment that promotes the CLN formation. Integrin avb3 probably serves as a switch of VEGFRs, Notch and EM signals to control the CLN.

Our results may have important implications in the optimization of cell-based strategies to promote angiogenesis during tissue reparation.

INTRODUCTION: Treatment of large osteochondral defects presents an unmet clinical need in orthopaedics. This study investigated the efficacy of a multi-layered osteochondral scaffold for repair of large defects in vivo using sheep condyle model. In addition, the effect of bone marrow concentrate (BMC) as a source of growth factors and stem cells1 was evaluated in conjunction with the osteochondral scaffold. METHODS: The multi-layered scaffold was fabricated using additive manufacturing techniques. A collagen/hydroxyapatite scaffold was used as control. 24 sheep were randomly assigned to one of the four treatment groups: scaffold ± BMC and control ± BMC. The tissue was retrieved 6 months post-operation. Bone regeneration was evaluated using µCT, while cartilage regeneration and quality were examined macroscopically (modified ICRS) and by histology and gene expression. Gait was examined pre-operation and before termination.RESULTS: Gross evaluations of the joint showed minimal to slight reactions for all groups. Regenerated cartilage was not macroscopically different between the groups, however, a significant upregulation of mRNA for type-II collagen showed an enhance cartilage quality with the novel scaffold. µCT data revealed that the bone ingrowth was higher in the scaffold group, while bone voids remained in the control groups. Gait parameters were not affected by the choice of the treatment.CONCLUSIONS: Collectively, these data illustrate that the novel scaffold support bone ingrowth and a hyaline-like cartilage formation. Our results indicated that the addition of BMC to scaffold has some potentially beneficial effects on tissue regeneration but not on the functional endpoint of orthopaedic interest.

Bone tissue engineering presents a promising strategy for the reconstruction of large bone defects which still remains challenging for clinicians. Thanks to advances in technology and the development of new scaffold fabrication methods including three-dimensional printing, the ability to create constructs with controllable characteristics is provided.[1,2,3] The aim of this study was to investigate the potentiality of Extrusion-based 3D-printing (EBP) to fabricate polymer-ceramic composite bone substitutes. Using Polycaprolactone, 45S5 bioactive-glass (BG), and β-Tricalcium Phosphate (β-TCP) as raw materials, PCL/BG/TCP scaffolds with different ratio of BG/TCP (10/90, 70/30, and 90/10) were prepared by EBP. The effects of ceramic ratio on the rheology of printing ink and physicochemical properties of scaffolds were evaluated. Results showed that all compositions present a shear-thinning behavior making them appropriate for additive manufacturing. The higher percentage of β-TCP leads to a sticky state in the printing ink that is associated with reduced ink printability. Increasing the BG content decreased this fault and improved print performance. This observation can be assigned to the impact of the surface charge interaction of BG and β-TCP particles. Scanning electron microscopy observations revealed that different ink formulations could form a pre-designed interconnected porous construct, though 90/10 BG/TCP scaffold pores showed more uniform structure and approximately rectangular shape. However, increasing the BG percentage was associated with a slight decrease in mechanical properties. Finally, optimization of the composite formulation allowed controlling the morphology, porosity, and mechanical properties of the final scaffolds, and BG/TCP: 90/10 could be a suitable composition in preparation of bone scaffold.

DESIGN AND PREPARATION OF 3D-PRINTED MEDICAL DEVICES TO PREVENT AND TREAT BIOMATERIAL-ASSOCIATED INFECTIONS

David Martinez Perez[P][1]

[1] *Warsaw University of Technology*

Corresponding author's email: david.perez@pw.edu.pl

Modifying the surface of medical devices with antimicrobial coatings is one of the most effective approaches to prevent biomaterial-associated infections (BAIs).

Polymers are commonly used as antimicrobial coatings as they can be easily synthesized and loaded with different drugs. Generally, polylactic acid (PLA) and poly(lactic-co-glycolic) acid (PLGA) are commonly used for drug release due to the high biocompatibility and FDA approval for drug delivery applications.

Drop on demand (DOD) technology involves data-driven and non-contact techniques that enable high speed and precise deposition of nanoliter volumes of material on a specific target.

In this work we propose a novel approach, using a drop on demand 3D printing technique for the development of antimicrobial polymeric coatings on medical devices, such as titanium orthopaedic implants (commercial and 3D printed by SLM) and low-density polyethylene catheters.

The DOD coatings were developed by using a commercial 3D Printer (3DDiscovery, regenHU, Switzerland). A home-made stepper motor rotating device was designed and developed for coating the LDPE catheters and SLM Ti implants.

Ink formulations based on PDL or PLGA were developed in mixtures of different organic solvents, incorporating different antimicrobial compounds, such as rifampicin, niclosamide, and SAAP-148 (LL-37 derivative).

The printability and viscosity (DV-III Ultra, Brookfield, USA) of the formulations were studied at different polymer concentrations.

Experimental results show a small printability window of the ink viscosities, from 7 to 24 mPa-s.

The antimicrobial evaluation of PDL-PEG-Niclosamide coated catheters showed a 4 and 4.9 log reduction in biofilm formation on S.aureus. in vitro and in vivo respectively.

Peripheral nerve injuries often result in sensory and motor dysfunction in respective parts of the body. So far, peripheral nerve regeneration is often associated with poor functional recovery. Important facilitators of the regeneration process are Schwann cells (SCs), which basement membrane is chiefly comprised of laminin. Extracellular vesicles (EVs) are considered important for intercellular communication and transfer of biological information. Mesenchymal stem cell-derived EVs (MSC-EVs) have been identified as a new therapeutic option due to their function as a drug delivery system. However, the precise delivery of EVs to the site of interest upon administration remains challenging. To overcome this issue, overexpressed EV surface marker protein CD81, from the tetraspanin protein family, has been modified toward preferential binding of laminin.

This study was designed to achieve production of laminin-binding EVs derived from MSC by modification of the large extracellular loop (LEL) of CD81.

Specific CD81-LEL sequences are cloned into lentiviral vectors encoding the expression cassette for full-length CD81 proteins fused with eGFP or firefly luciferase under the control of human cytomegalovirus (CMV) promoter. Stable cell lines are obtained upon transformation of Wharton's Jelly MSCs and selected by sorting for high expressers. MSC-EVs are further isolated by ultracentrifugation and characterized by nanoparticle tracking analysis, flow cytometry and western blot.

Our results demonstrate the feasibility of production of designed laminin-binding EVs derived from MCSs. This study represents the basis for further investigation on EVs regarding their targeted binding to laminin, their internalization by SCs and their influence on peripheral nerve regeneration processes.

DEVELOPMENT OF NEW GENERATION HYDROCOLLOID BIO-INK FOR 3D BIOPRINTING

Ahu Arslan Yildiz[P][1]

[1] *Izmir Institute of Technology, Department of Bioengineering*

Corresponding author's email: arslanahu@gmail.com

Bioprinting enables the production of 3-dimensional (3D) structures by combining bioinks, living cells, extracellular matrix (ECM) components, biochemical factors, proteins, drugs; and it has recently become one of the most promising techniques in the field of tissue engineering. The successful production of the 3D structure to be created by 3D bioprinting technology depends on the properties of the bio-ink to be used. Hydrogel/hydrocolloid materials used as bio-inks are developed using synthetic and natural polymers where they have the necessary rheological properties for printing, they also have biocompatibility, low toxicity and support for cell attachment. Natural hydrogels, which have the ability to mimic the extracellular matrix structure and function at a high rate, are highly preferred bioink materials for bioprinting applications. Polysaccharide-based hydrogel/hydrocolloids are one of the largest subclasses of natural polymers and are commonly used in food industry, drug release and tissue engineering applications with their gelling and biocompatibility properties. Hydrocolloids obtained from the seeds of some plants are among the promising natural materials in tissue engineering applications and the development of new generation bio-inks with their high water holding capacity, anti-inflammatory, and antioxidant properties. Here we report development of a new generation polysaccharide-based bio-ink for 3D bioprinting applications. The bioink was obtained through "from waste to the bench-top" approach by utilizing quince seed as a raw material. It was shown that developed bioink demonstrates desirable properties including viscoelasticity and processability, biocompatibility and non-toxicity, as well easy to obtain and cost effective as a bioink.

Osteochondral defects in the adult human fail to heal, resulting osteoarthritis (OA). The onset of OA has been linked to a prolonged pro-inflammatory response induced by the injury or repetitive microtrauma. This may be caused by an imbalance in the signalling cascades during the transition from the pro-inflammatory to the pro-regenerative phase.

Small (Ø: 0.15mm, SD) or large (Ø: 1.5mm, LD) full-thickness osteochondral defects were created in the trochlear groove of 10-week old wild type (T-cell+) or T cell deficient (T-cell-) female rats. Healing was characterized up to twelve weeks. Pathological evaluation confirmed that the T-cell+-SD model displayed functional healing (OARSI score 0/4), T-cell+-LD resulted in moderate fibrosis (2/4) and Tcell--SD and Tcell--LD displayed mild (1/4) and severe (3/4) fibrosis, respectively. Analysis at one week confirmed a corresponding trend between the healing potential to extracellular matrix (ECM) production, progenitor- and inflammatory cell activation. Interestingly, scRNAseq confirmed a unique inflammatory-progenitor cell population present within the defect area in the Tcell+-SD model. Injection of in vitro cartilage-activated lymphocytes, placenta derived progenitor cells (PLCs) or a 24h co-cultured combination thereof 1 week post defect creation improved the healing. But only co-cultured cells completely regenerated the Tcell--SD and LD defects based on OARSI scoring and lubricin secretion.

These results confirm the integral role of the balanced activation of lymphocytes and progenitor cells for functional osteochondral regeneration. Furthermore, the presented findings show effective, stable articular cartilage regeneration after combined treatment of cartilage-activated lymphocytes and PLCs in moderate to large osteochondral defects.

BIOFABRICATION BY MAGNETIC LEVITATIONAL ASSEMBLY OF CELLS INTO DEFINED 3D CELLULAR STRUCTURES

Ahu Arslan Yildiz$_P$[1]

[1] *Izmir Institute of Technology, De*

Corresponding author's email: arslanahu@gmail.com

In the field of tissue engineering 3D (three dimensional) cell culture studies have increased over the years since they are the closest models of real tissues. Compared to the 2D models, there is a big improvement on cell growth, morphology, differentiation, gene and protein expression when 3D system is utilized. Because of these advantages 3D cell culture is commonly used for tissue engineering, artificial organ technologies, regenerative medicine, drug development, drug screening and stem cell studies. Despite promising advances in these areas, there are still unmet needs to completely fulfill all requirements. Sophisticated tools, methodologies and materials are still required for further development in tissue engineering; especially for cellular assembly, single cell level control, easy control over biofabrication system, direct forward cellular imaging and analysis. Recently, magnetic levitation technology that overcomes most of the above mentioned problems, has been utilized for the formation of 3D cellular structures. Magnetic levitational assembly of cells provide rapid, simple, cost-effective 3D cell culture formation while ensuring scaffold-free microenvironment.
This contribution summarizes our efforts in designing new setups and assembling cellular entities via contactless magnetic manipulation as functional biological units for 3D cell culture and tissue engineering. It has been demonstrated that especially cell-cell interactions are favored by utilizing magnetic levitational assembly. With the developed technology, employed models also provide us possibility to adapt several components into different platforms for further tissue engineering applications.

3D bioprinting is a promising method for generating cell- and tissue models and constructs for drug development, tissue engineering, and fundamental studies of cell-matrix interactions. The properties of the bioinks, comprising biomaterials and cells, determine printability, cell viability, and post-printing cell survival and behavior. Most current hydrogel-based bioinks provide limited possibilities to tune and alter the generated structures' properties after printing. Here, we describe a novel hyaluronan/poly(ethylene glycol) based hydrogel system for bioprinting that combines robust and tunable covalent bioorthogonal cross-linking strategy [1] with peptide-folding mediated interactions to enable dynamic modulation of hydrogel properties [1,2]. The peptides were de novo designed to homo- or heterodimerize and fold into a helix-loop-helix motif and dimerize into four-helix bundles. Peptide dimerization enabled dynamic modulation of cross-linking density and hydrogel functionality before, during, and after printing[2]. A toolbox of functionalized peptides with different functionalities was developed, which allowed for altering cell adhesion and enhancing retention of biofunctional enzymes. The latter was demonstrated by triggering enzyme-mediated biomineralization of the printed structures [1]. This flexible strategy for controlling and changing hydrogel properties can facilitate the development of 4D bioprinting techniques.

For developing tissue-engineered skeletal muscle three-dimensional scaffolds may provide a physical support. Among a variety of biomaterials developed and used for soft tissue engineering, elastomeric scaffolds remain promising due to their compatibility with the elastic properties of the host tissue. Elasticity, which implies recovery from deformation, is of particular importance in the context of dynamic tissues like muscle. We evaluated porous elastomeric 3D scaffolds from the family of poly(polyol sebacate) for survival, proliferation and differentiation of murine and human myoblasts. This family of soft, biodegradable chemically cross-linked elastomers are biocompatible and inexpensive [1]. They have already been studied in cardiac [2], [3] and vascular tissue engineering (reviewed in [4]) but not yet in skeletal muscle tissue engineering. Several compositions of elastomers were evaluated with alamar blue and live/dead assay for myoblast survival over 6 days and based on these results, PGS 1:1 was chosen for further differentiation analysis. Preliminary data on myoblast differentiation capacity when integrated in the PGS 1:1 scaffold was generated using human myoblasts. From confocal imaging performed after staining for the differentiation marker tropomyosin, we observed efficient differentiation into myofibers throughout the scaffold. PGS 1:1 is a suitable, biocompatible scaffold for skeletal muscle tissue engineering allowing for myofiber formation.

INTRAVASCULAR INFUSIBLE EXTRACELLULAR MATRIX MODULATES INFLAMMATORY RESPONSE IN MOUSE MODEL OF SYSTEMIC INFLAMMATION

Anne Lyons[P][1], Raymond Wang[1], Ryan Middleton[1], Mark Hepokoski[1], Karen Christman[1]
[1] *University of California San Diego, La Jolla, California, United States*
Corresponding author's email: anlyons@ucsd.edu

Introduction: Systemic inflammatory conditions (e.g. sepsis and severe viral infections like COVID-19) are characterized by an overwhelming innate immune response that leads to multi-organ failure [1]. Decellularized extracellular matrices (ECM) have previously demonstrated pro-regenerative properties through modulation of the immune response [2]. Infusible ECM (iECM) was developed for systemic delivery, targeting and treating sites of vascular injury. We hypothesized iECM delivery would dampen the systemic inflammatory response in a lipopolysaccharide (LPS) mouse model.

Methods: iECM was prepared from decellularized porcine left ventricle based on previous protocols [3]. C57BL6/J mice underwent dual intraperitoneal LPS injection and then tail vein injection of saline or iECM (10 mg/mL). Thirty hours post-LPS dose, mice were euthanized and heart, lungs, brain, kidneys, spleen, and liver were harvested (n = 6 mice/group). Tissues were processed for gene expression by qRT-PCR and Nanostring nCounter® Immunology Panels, immune cell identification by flow cytometry, and cytokines by LegendPlex® Mouse Inflammation Panels.

Results: qRT-PCR identified significant downregulation of Il1b and Il6 across multiple tissue types in iECM vs. saline-treated mice. Nanostring transcriptomic analysis confirmed downregulation of multiple inflammatory cytokines and chemokines. IL-6 cytokine expression was significantly reduced across multiple organs along with IL-1α and IFN-γ in the lungs, and IL-1β and IL-17A in the spleen.

Discussion: Results demonstrated iECM dampens the systemic inflammatory response to LPS, indicating its potential for treating conditions such as sepsis and COVID-19 pathology.

To explore noticeable immunomodulatory activity, angiogenic potential, and regenerative effects of menstrual blood-derived mesenchymal stem cells (MenSCs) in combination with the fabricated bilayer scaffold (bSC) in the healing of diabetic wound, here we show the effect of MenSCs-seeded on bSC in the treatment of diabetic wound created in the dorsal dermis of type-1 diabetic model of C57BL/6 mice was induced by streptozotocin in comparison to control treatments. The control groups included no treatment (NT), amniotic membrane treatment (AM), bSC treatment, foreskin-derived keratinocytes/fibroblasts seeded on bSC treatment (FK+bSC). Wound closure was inhibited by fixing a circular silicone splint to the skin to prevent rapid contracture of the wounds and simulate re-epithelialization. Wound healing evaluations in the diabetic mice model were studied at 3, 7 and 14 days after their treatment. On day 14 in the MenSCs+bSC group, the gross morphology, epithelialization, and histological changes in regenerated wound tissues showed the most similarity to intact skin. Moreover, the wound healing was typically faster in the MenSCs+bSC group compared to other diabetic groups. Immunofluorescence staining of mouse skin depicted higher levels of CD31 and von Willebrand factor (VWF), a higher ratio of M2/M1 macrophages, higher expression of involucrin as keratinocyte marker, and higher levels of the neural marker in the MenSCs+bSC group in comparison with other treatment groups. The dramatic effects of MenSCs as a promising adult stem cell population accompanied by the significant impact of fabricated bilayer scaffold sound to mediate a promoting and appropriate circumstance on wound healing and skin regeneration.

Long bones develop and regenerate through the process of endochondral ossification (EO); the replacement of a cartilage template with new bone. Dysregulation of EO can result in conditions such as fracture non-unions, chondrodysplasias and osteochondrosis. In addition, mimicking the process of EO is central to many next generation tissue engineering strategies to heal bone defects. Critical in EO is the interaction between cartilage and vasculature, yet our understanding of this essential interaction is limited (1). To address this problem, we have developed an advanced in vitro model of EO to study bone development and pathophysiology on a chip. To enable this, we introduce developing human bone organoids (engineered cartilage at different stages of maturation) into microfluidic devices containing perfusable vascular networks, with the goal of recreating and better understanding the complex interaction between developing bone and the vasculature during EO. The model is capable of predicting a number of key features of EO, including a cartilage phenotype dependent effect on vasculature. Specifically, we find that mature cartilage inhibits vascular invasion, which correlates with an upregulation of cartilage specific anti-angiogenic genes. Additionally, we observe upregulation of the pluripotency genes SOX2 and OCT4 in the presence of vasculature, providing support for the hypothesis of chondrocyte transdifferentiation during fracture healing (2). Predictive models of EO are fundamental to advancing our understanding of human bone (patho)physiology, and this model represents an advanced in vitro system to probe the mechanisms that underpin this essential process.

BIOMECHANICAL ANALYSIS OF NANOSTRUCTURED CALCIUM PHOSPHATE COATED PEEK AND COATED CF-PEEK IMPLANTS

Leena Jongpaiboonkit$_P$[1], Jeffrey Badura[1]

[1] *Medtronic*

Corresponding author's email: leena.jongpaiboonkit@medtronic.com

Introduction: Nanostructured calcium phosphate (CaP) coatings have the potential to produce osteostimulatory, bone forming characteristics on the surface of PEEK implants. This biomechanical study examines: 1) adhesion of a CaP coating to PEEK and Carbon Fiber Reinforced (CF) PEEK substrates, and 2) the impact of surface pre-treatment on the mechanical properties of both types of PEEK.

Methods: A coating was applied to PEEK and CF-PEEK cylinders through a proprietary coating process. Materials were subjected to surface pre-treatments and subsequently incubated in a pH adjusted coating solution for 4 days, resulting in a continuous, plate-like nanostructure coating. Implant insertion was replicated using Sawbones block 20PCF and controlled insertion torque. Coating adhesion on each substrate was then qualitatively assessed by SEM and Alizarin staining. A standard mechanical test was conducted to identify any difference in yield strength and compression modulus between coated and uncoated samples.

Results: Overall, insertion into Sawbones did not cause coating delamination, except where uneven insertion caused shearing of both the coating and the underlying PEEK under high torque. The compression tests demonstrated no significant change in compression modulus or yield strength between coated and uncoated samples.

Conclusion: These results suggest that this coating process may be used to apply calcium phosphate coatings to both forms of PEEK with adhesion characteristics that survive implant insertion torque. Furthermore, this coating process does not appear to have a detrimental effect on the mechanical properties of PEEK or CF-PEEK.

Intervertebral disc degeneration (IVDD) is a key public health issue and the leading cause of lower back pain1. IVDD is often associated with altered cellularity, absence of vacuolated nucleus pulposus cells (NPCs), and appearance of nested cells within the nucleus pulposus (NP) at the centre of the IVD2,3. Repopulating the degenerated IVD by regenerative NPCs for biological repair and restoration of disc function is extensively studied as an advanced therapy for IVDD within the iPSpine project. We sought to understand the cellular transition within the NP using single cell transcriptomics in canine NPCs. Dogs provide an informative species to conduct comparative analysis; both humans and dogs share the cellular changes within NP leading to IVDD during maturation and ageing3. To obtain in-depth knowledge of the NPC signature, we assess single cells from (a) canine primary NPCs and mature NPCs from healthy discs, and (b) cells that reside within the degenerated NP from canine patients and (c) NPCs from chondrodystrophic dogs that have a predisposition for IVDD. We present a simple strategy for obtaining single cells from NP tissue using enzymatic digestion and EDTA treatment. Cells are then subjected to Sort Seq; a single-cell sequencing platform using cell-capture plates and flow cytometry sorting; that makes it possible to analyze transcriptomics of live single-cell populations of interest. Our findings help define the transcriptomic landscapes of NPCs through health and disease. We reveal common and preserved denominators of NP cell fate and highlight the essential instructions for exploitation towards regenerative therapies.

Ageing is a risk factor for the development of cardiovascular diseases. Many of these diseases are caused or exacerbated by dysfunctional vasculature. The major hallmarks of vascular aging are the stiffening of the vasculature, resulting from changes in the extracellular matrix (ECM) and endothelial dysfunction due to a pro-inflammatory environment, increased oxidative stress and consequent accumulation of senescent cells [1-3]. Cell senescence, an important axis of vascular ageing, is described as a state of irreversible cell cycle arrest and it can be triggered by different factors, such as DNA damage, telomere exhaustion, oncogene activation and oxidative stress [4]. Currently our understanding about the ECM of senescent cells is limited. Here, we have investigated the composition of ECM from senescent smooth muscle cells (SMCs). SMC cultures of proliferative and irradiation-induced senescence were decellularized to obtain the ECM. Atomic force microscopy measurements showed that the decellularized ECM from senescent cells presented a higher Young's modulus than proliferative cells. Characterization of ECM from proliferative and senescent cells by proteomics showed significant differences in their protein content. ECM-related proteins, such as collagens, proteoglycans and fibulins were the mostly downregulated in senescent ECM. On the other hand, cell adhesion and cytoskeleton proteins, such as desmin, vimentin, talin, integrins and cadherins were upregulated in senescent ECM. Overall, our work demonstrates significant differences between ECM derived from senescent or proliferative SMCs.

Introduction: The development of in vitro model of skeletal muscle regeneration is extremely challenging. Muscle in vitro models often involves the use of mesenchymal stem cells from bone marrow (BM-MSCs) [1], however, optimum medium composition to promote myogenic commitment of stem cells has not yet reported. Despite growth factor mixture and their different concentrations in culture media is still under debate, bFGF was the most used at concentration of 10 ng/mL [2]. Furthermore, several studies reported 3D scaffolds as stem cells culture system and co-culture systems have been also proposed [3,4]. In the present work an in vitro model of myogenic commitment by using BM-MSCs and Myoblast co-culture with bFGF supplemented medium is proposed in both static and dynamic conditions to explore the potential paracrine effect of myoblasts on MSCs differentiation.

Materials and methods: In vitro culture of human Bone Marrow-Mesenchymal Stem cells (hBM-MSCs) and human Myoblasts allowed to study the paracrine effect of muscle cells on stem cells. The system was explored in both dynamic and static environment.

Results and Discussion: hBM-MSCs commitment towards a myogenic phenotype was confirmed both via immuno-histology that revealed Desmin fiber deposition and by q-RT-PCR that indicated the increase of gene expression of myogenic factors as Myf5, MyoG, MyoD, MFR4, Desmin and Myosin heavy chain II. The dynamic co-culture system developed can be used as highly predictive model to study skeletal muscle regeneration.

Background

Nasal chondrocytes (NC) have higher and more reproducible chondrogenetic capacity than articular chondrocytes, could thus achieve better clinical results, and were previously introduced in a first-in-human study (1.) to proof safety and feasibility.

Our aim was to create a new, single-stage and injectable therapeutic approach using autologous nasal chondrocytes.

Materials & Methods

Fresh nasal septal cartilage grafts were digested according to a new, rapid protocol, yielding "rapid isolated" nasal chondrocytes (p0 NCs). Cell yield, viability and proliferation rate were assessed.

The p0 NCs were either used for in vitro pellet culture, or seeded in PL-PEG gels (polyethylene glycol (PEG) gel enriched with pooled PRP extract – platelet lysate (PL)), in a low cell number, and cultured in vitro. Histological, immunofluorescence and biochemical analyses were carried out at day 0, after 1 and 4 weeks.

Results

Rapid isolated NCs show similar viability (mean 99.0±1.3% vs 98.4±1.6%) and proliferative capacity (mean 0.66±0.14 vs 0.78±0.25 doublings/day) as cells after standard digestion; however, cell yield is even higher after the new protocol. Pellet culture showed good chondrogenetic capacity. In vitro gel cultures showed proliferation of the cells with 6.33 ± 0.51 mean population doublings in 4 weeks. At the meantime, also cartilaginous matrix production was observed, with GAG/DNA ratio of mean 12.3±7.9.

Conclusions

Rapid isolation protocol resulted in viable NCs with good in vitro chondrogenic capacity. The cells, implanted in low-density in PL-PEG gel showed proliferation and chondrogenesis in vitro. This approach can lead to establish a new arthroscopic therapy for cartilage lesions.

Introduction: Treatment of hyaline cartilage lesions remains a major challenge owing to the avascular nature of itself, which prevents spontaneous healing. To date the use of Mesenchymal Stem Cells (MSC) and tissue engineering protocols represents an alternative strategy and offers great potential to improve joint therapy. The development of 3D scaffold able to stimulate the formation of a new cartilaginous tissue is crucial to the success of the therapeutic strategy. Collagen-based scaffolds have been described as appropriate to support the chondrocyte attachment because are more like natural ECM [1,4].

Methods: A three-dimensional (3D) collagen scaffold was assembled as biomimetic extracellular matrix for human Bone Marrow Mesenchymal Stem Cells (hBM-MSC) induction towards chondrogenic phenotype by dispersing poly-lactic-co-glycolic acid (PLGA) microcarriers, carrying and delivering Transforming Growth Factor (hTGF-β1) payload, within the 3D structure. Cultures were performed both in static than dynamic condition (perfusion).

Results: hBM-MSCs early commitment towards a chondrogenic phenotype was confirmed both via immuno-histology that revealed the type II collagen fiber deposition within the scaffold and by q-RT-PCR that indicated the increase of gene expression of SOX9 and COL2A1, after 16 days of culture. The dynamic culture by perfusion assured a better mass exchange and more effective scaffold matrix reshaping.

Discussion and Conclusions: The data suggested the effectiveness of 3D collagen scaffold carrying PLGA microspheres for drug delivery as highly predictive in vitro model and opened perspectives for its use as implantable advanced therapy device to promote cartilage regeneration.

ELECTROSPUN SCAFFOLDS WITH EXPANDED PORES TO SUPPORT CELLULAR INFILTRATION FOR SKIN REGENERATION

Tissue engineered skin substitutes have been developed in order to treat full-thickness skin injuries. Several substitutes are available on the market but they do not provide, on their own, full skin regeneration [1]. Therefore, the use of autografts continues to be involved in any treatment of severe wounds.
Electrospun mats have been widely used to create scaffolds for skin replacement due to their structural similarities to the extracellular matrix (ECM) of the tissue, to allow for cellular regeneration [2]. However, electrospun mats have relatively small pores and high packing density of the fibers that prevents cellular infiltration and, consequently, new tissue ingrowth. To overcome this limitation, in this work, two different approaches were used to expand the pores of electrospun mats. In one approach, chitosan (CS) grains were loaded in polycaprolactone (PCL) solution. In another approach, glucose grains with different dimensions (< 50 µm, 50-100 µm and 100-150 µm) and concentrations, loaded in a polyethylene oxide solution, were co-electrospun with polylactic acid (PLA) and leached out using distilled water. All scaffolds presented pores large enough to facilitate the infiltration of fibroblasts without compromising the mechanical stability of the structure as well as their fibrillar structure. Thus, by controlling the granule size and their concentration, it is possible to control the pore size and, consequently, the cellular infiltration within fibrous mats. This study demonstrated the ability of either glucose or CS grains to be used with electrospun mats to improve cell infiltration.

In situ vascular tissue engineering aims at regenerating vascular tissues in terms of form and function. Currently, some fundamental questions, e.g. how engineered tissues remodel after implantation and how a native-like organization can be achieved to enable proper functionality, remain to be answered. To address these challenges, a mechanistic understanding of the processes mediating functional vessel growth and remodeling in engineered tissues is needed, particularly concerning the interplay between mechanical cues and cell-cell signaling. Vascular smooth muscle cells (VSMCs) can switch their quiescent contractile phenotype to a synthetic phenotype for growth and remodeling. This switch is regulated by mechanical cues [1] and Notch signaling [2] which is mechanosensitive [3,4]. A computational model has predicted that the mechanosensitivity of Notch signaling leads to a phenotypic switch in VSMCs to establish homeostasis [4]. Yet, these computational findings are scarcely validated, and the interaction between mechanical cues and Notch signaling in the remodeling of engineered vascular tissues is poorly understood. In this study, control and Notch-inhibited synthetic and contractile VSMCs were equibiaxially stretched for 48 hours. IF imaging and qPCR were conducted to characterize the changes in cell phenotype, ECM production and Notch signaling activity. Our results showed that Notch signaling needs to be active for the maintenance of contractile phenotype. The application of strain resulted in a transition in contractile VSMCs towards the synthetic phenotype with a decreased Jagged1 expression. The current study suggests that Notch signaling has a key role in regulating strain-mediated changes in VSMC phenotype.

Existing clinical treatments of large osteochondral defects often use autografts and allografts as “gold standards”. Limitations include donor site morbidity and scarcity for large defects, risk of transfection and difficulty treating complex geometries. Implanted allografts possess reduced mechanical and biologic properties when compared with native tissue (1). Similarly, tissue engineered constructs are often produced using gels or polymers that are often too weak to withstand in vivo forces experienced by osteochondral tissue (2). We previously demonstrated that decellularized cartilage/ bone extracellular matrix (DCM) within a thermally protective polylactic acid (PLA) microsphere barrier can be 3D-printed within polycaprolactone (PCL) filament, maintaining the bioactivity of the DCM (3). In this study, a 6 mm osteochondral defect was treated in a Yucatan mini-pig model (protocol # IACUC2020-0081) with a biphasic, 3D-printed PCL scaffolds containing human bone and cartilage DCM encapsulated in PLA microspheres. Scaffolds with blank PLA microspheres and autografts were used as controls. After 3 months, preliminary histological results (H&E, Toluidine blue & Masson’s Trichrome) demonstrated formation of smooth, cartilage in the articular phase that appeared to integrate well with the underlying subchondral bone phase in the biphasic DCM scaffolds. The deeper osteo-conducive phase displayed evidence of bone tissue formation around the scaffold struts. The blank scaffolds showed formation of fibrocartilage tissue on the articulating surface with bone regeneration around the scaffold. The autografts showed cartilage with decreased GAG content in toluidine blue staining. Overall, the results demonstrated enhanced osteochondral regeneration in biphasic DCM scaffolds comparable with controls.

Introduction: The ability to repair damaged hyaline cartilage could revolutionize the treatment of sports injuries and end osteoarthritis. Methods: A canine bilateral medial femoral condyle cartilage defect model, using 12 adult male beagles, was used to evaluate the effectiveness of a 3D printed cellular matrix composed of fibrin glue, lyophilized human chondral cartilage (LCCM), and stem cells harvested from patients undergoing abdominal liposuction, for treating articular cartilage defects. Results: In contrast to the control groups, the defects treated with fibrin glue, LCCM and stem cells had striking visual, histological, immunochemistry and mechanical similarities to that of normal articular cartilage. The tissue in these defects appear to be developing centrally out to the periphery as well as to be healing from the periphery inward. At both 20 and 32 weeks much of the defect appears occupied by new thick white cartilage-like tissue. In addition, there appears to be lamellar structures within this tissue which blends with the existing normal cartilage. The mechanical stiffness of the new tissue was similar to that of normal cartilage. Upon microscopic examination, there was a well-defined surface layer covering the middle layer of chondrocytes which were surrounded by a matrix composed of Collagen I, Collagen II, and proteoglycans, all similar in appearance to the normal cartilage control. Discussion: The results of this study represent one of the best examples of articular cartilage healing in an animal model. A clinical trial is now underway using this new technology.

Aim: Present study focuses on the development and characterization of biodegradable collagen scaffolds functionalized with SDF-1a loaded heparin-based hydrogel and polyhexamethylene guanidine hydrochloride (PHMG) loaded alginate microspheres for promoting in vivo tissue regeneration.

Methods: The scaffolds were prepared by freeze-drying of bovine atelocollagen I solution containing polymer based on cross-linked modified heparin or PHMG loaded alginate microspheres. Bone marrow MSC were isolated from FVB-CgTg(GFPU) 5Nagy/J mice. Distribution of the cells within collagen scaffolds was studied by CLSM. The recruitment of MSCs was studied in allogenic transplantation model. The anti-microbial activity of developed PHMG loaded scaffolds was evaluated by agar diffusion method.

Results: The developed collagen scaffolds functionalized with heparin-based hydrogel can be efficiently loaded by recombinant SDF-1a. The maximum binding capacity observed was 14.83 ± 3.4 μg SDF-1a per 1 mg of hydrogel. It has been shown that developed hydrogel was able to provide gradual release of the protein within 72 hours in vitro. The developed scaffold with PHMG loaded alginate microspheres reduced microbial growth of gram-negative bacteria. Functionalization of collagen scaffold by SDF-1a loaded heparin-based hydrogel increases the seeding efficiency of MSC and promotes the colonization and remodeling of the scaffold both in vitro and in vivo.

Conclusions: The developed biodegradable collagen scaffolds functionalized with SDF-1a loaded hydrogel and PHMG loaded alginate microspheres can accelerate wound healing activity by prevention of bacterial infection and stimulation of host MSC recruitment.

The use of mesh in pelvic organ prolapse repair has improved outcomes associated with native tissue repairs. However, a significant number of women with mesh experience complications, often requiring surgical revision. This study demonstrates a method for modulating the early host macrophage response with interleukin-4 (IL-4) coated mesh to lessen the pro-inflammatory response and promote tissue integration. Studies were performed in an adapted lumbar colpopexy in rabbits. The host response and tissue remodeling outcomes were evaluated at 14 days and late stages 90 days. In vitro testing demonstrated that the IL-4 coating was bioactive following terminal sterilization of the coated mesh, promoting macrophage transition to an anti-inflammatory phenotype. When implanted, IL-4 coated mesh materials were shown to shift the host macrophage response towards a more anti-inflammatory, M2 macrophage phenotype at 14 days as compared to uncoated polypropylene mesh. This shift resulted in improved mesh integration, decreased tissue degradation, improved tissue mechanical strength, and a reduction in intraabdominal adhesions representing significant improvements in the remodeling outcome. These data demonstrate that modulation of the early host response to polypropylene mesh toward an M2 phenotype has the potential to result in significant improvements in mesh integration, reduction in tissue degradation and associated complications, and overall clinical success.

Decellularized tissues are promising materials that mainly consist of extracellular matrices generated by removing cells from biological tissues. As for physical decellularization method, high hydrostatic pressure (HHP) has been used to remove cells physically from organs or tissues rather than by biochemical reagents. However, ultrahigh hydrostatic pressure induces denaturation of the ECM structure. In this study, the effects of cyclic HHP on the structure of cell were examined to establish a novel decellularization method without the denaturation of the ECM. A decellularization device that enabled to impose cyclic HHP was developed. Human skin cell suspension was injected into a plastic bag to be subjected to cyclic HHP. After applying cyclic HHP, the amount of DNA and the morphological changes of the cells were evaluated. As a result, the amount of DNA decreased by the cyclic HHP application compared to the static HHP. Moreover, cyclic HHP was suggested to induce the denaturation of the structure of nuclear membrane. In summary, it was revealed that the cell structure could be denatured and destroyed by cyclic HHP application at a lower level than that of previous studies.

Angiogenesis, the outgrowth of blood vessels, is crucial in the stabilization of implanted tissue and regeneration of various clinical pathologies. Creating implantable blood vessels in vitro remains challenging because the capillary morphogenesis of endothelial cells (ECs) is controlled by multiple exogenous signals. Moreover, for clinical applications, such development requires a fully synthetic material with known concentration and bioavailability of each component. Recent advances in tissue engineering allowed for creating and maintaining stable vascular capillaries over periods of about one month in vitro in situ-forming matrix metalloproteinase-degradable starPEG-heparin hydrogels containing covalently bound integrin ligands and reversibly conjugated pro-angiogenic growth factors (SDF, bFGF, VEGF) [1]. But currently used technologies did not allow for the entire release of produced blood vessels from their culture platform. Our lab has established a technology that enables us to transfer any peptide crosslinked materials into a trigger responsive smart scaffold by including a thrombin cleavable five amino acid sequence into the peptides. In such material, the matrix metalloproteinase-degradable sequence allowed for the cell expansion and the formation of the blood vessels, and when the tissue is ready, the addition of the thrombin biorthogonality removes the scaffold allowing of the harvesting of the undamaged vessels. In a model experiment, we have shown how such smart material can be used to form, harvest, and transplant a vial capillary network. Although we focus on the blood vessels in our work, this“smart” material design can be utilized for tissue or organoids formation, gentle harvest, and transplantation with corresponding adjustments.

The mannose receptor (CD206) is a transmembrane protein expressed on most macrophages and kidney mesangial cells.1,2 CD206 is involved in many immunological processes; CD206 activation leads to the release of a variety of cytokines, like interleukin-6 and -10.3

To better understand the binding mechanisms underlying mannose receptor activation, we here propose synthetic supramolecular glycopolymers to target CD206 in both RAW 264.7 macrophages and human renal mesangial cells (hRMCs). These precisely-defined and tunable supramolecular assemblies allow us to assess the effect of a single microenvironment property (e.g. mannose concentration) on mannose receptor behavior. For the supramolecular glycopolymers, we propose several different mannose-decorated benzene-1,3,5-tricarboxamides (BTAs),4 which can self-assemble into fiber-like structures through a combination of hydrogen bonding, π- π interactions and the hydrophobic effect5,6. Here, we investigate the effect of multivalency (1, 2 or 3 mannose units) and secondly, we test the influence of accessibility (with or without ethylene glycol linker) on the binding affinity and cellular behavior.

It was demonstrated that CD206 is present on hRMCs in low amounts (~ 17%) and that ~ 50% of RAW 264.7 macrophages are CD206+. We then showed that the mannose BTA assemblies do not exhibit toxic effects towards hRMCs at 100 µM concentrations. Lastly, we observed a higher binding affinity towards CD206 for mannose-3 BTA (Kd ~ 20-50 µM) than for mannose-2 BTA (Kd of 200 µM), illustrating the multivalency effect. Next, we will assess the cellular effects of CD206 targeting. Eventually, our results will lead to better understanding of the cell-biomaterial interaction.

Human induced pluripotent stem cells (hiPSC) have a great potential in the development of novel cardiac therapies due to their high self-renewal capability and potential to differentiate into cardiomyocytes (CM). However, generated hiPSC-derived CM (hiPSC-CM) are still immature, and this has been limiting their application. Recent findings have demonstrated extracellular matrix (ECM) potential as a key regulator in the development, homeostasis, and injury of the in vivo cardiac microenvironment [1]. This work's objective was to assess the impact of human cardiac ECM in the maturation of hiPSC-CM. Human ECM was isolated from the myocardium of three healthy donors through physical decellularization. The ECM was cryomilled and characterized in terms of particle size and composition. These ECM particles were then incorporated in a 3D model of hiPSC-CM [2], cultured as aggregates in dynamic stirred culture. The hiPSC-CM were characterized after two weeks of culture.

The results showed that the cardiac tissue decellularization process reduced DNA content (>75%) and maintained ECM composition. The cardiac ECM particles were successfully incorporated in 3D hiPSC-CM aggregates (ECM+hiPSC-CM), with no impact on cell morphology, aggregate size, composition, and metabolic activity. The ECM+hiPSC-CM aggregates showed beating rates closer to physiologic values, more organized and longer sarcomeres, and improved calcium handling than standard hiPSC-CM aggregates.

This work shows for the first time that human cardiac ECM promotes the structural and functional maturation of hiPSC-CM. The knowledge generated provides important insights to strengthen the application of hiPSC-CM in cell therapy, drug discovery, and cardiac disease modeling.

Adipose-derived stem cells (ASCs) have been the subject of intensive basic research and clinical trials. These cells show many biological activities related to the secretion of multiple cytokines or growth factors, and immuno-regulatory effects. In clinical trials, ASCs are used in the treatment of many diseases, including tissue reconstruction and chronic wounds. ASCs may also serve as an in vitro model for studying the activity of drug candidates. In vitro, ASCs can be differentiated into adipocytes, chondrocytes and osteocytes, therefore, they are a good model for studying differentiation stimulants. In our study, we have shown that stem cells isolated from fat tissue (constituting medical waste after oncological surgery procedures) can be successfully used in the above-mentioned model. Bone morphogenetic proteins (BMPs) play an important role in the proliferation and differentiation of a many cells, especially bone and cartilage cells. BMPs also stimulate differentiation of mesenchymal stem cells into osteocytes and chondrocytes. In our research, we used chemically synthesized peptides with structure based on the human BMPs protein. Some of them in vitro stimulated proliferation, migration of ASCs and collagen synthesis. Their effect on ASCs differentiation was also evaluated. These peptides could potentially be used for in vitro stimulation of bone and cartilage formation for therapeutic purposes. Furthermore, they could be combined with scaffolds for transplantation in different orthopedic conditions related to bones and cartilages damage (fracture, loss, injury, inflammation).

Introduction: Hydrogel systems can be engineered with the aim of regenerating different tissues (e.g. bone and vascular). Protein-based hydrogels are appealing for their structural designability, specific biological functionality, and stimuli-responsiveness [1][2][3]. Here, we present 3D Poly (ethylene glycol)-laminin (PEG-LM) hydrogels for delivery of growth factors in a controlled manner.

Methods: 3D laminin-based hydrogels containing different concentrations of PEGylated human laminin with acrylates were crosslinked via photopolymerisation with two- or four-arm acrylate and a protease-degradable peptide (VPM). Human mesenchymal stem cells from bone marrow (hMSCs) and human umbilical vein endothelial cells (HUVECs) with different growth factors were incorporated into the laminin hybrid hydrogels to evaluate cell cytotoxicity, study the controlled release of the growth factors and their phenotypical potential to driven different cell linages.

Results: We studied the ability of the hybrid PEG-laminin hydrogels to promote regeneration of different tissues (e.g. bone and vascular) by delivering growth factors in a controlled manner. Immunofluorescence and qRT-PCR results of hMSC encapsulated in 3D LM/PEG hydrogels loaded with BMP-2 showed an upregulation of osteopontin expression at 14 days. More, LM/PEG hydrogels loaded with vascular endothelial growth factor (VEGF) showed a greater potential to promote endothelial cell sprouting after 4 days in culture.

Conclusion: We report on the development and characterization of hybrid 3D laminin hydrogels with tuneable mechanical and degradable properties and highly efficient growth factor presentation for potential tissue regeneration of bone and vascular tissues.

Hydrogels as one of smart materials that are controllably responsive to external (e.g. electrical or thermal) stimulation have become increasingly popular in recent years for simple, rapid and precise drug delivery that can be controlled by simply switching the external stimulus on or off. However, achieving highly uniform distribution of the hydrophobic electrically conductive materials throughout the hydrophilic three-dimensional (3D) hydrogel network remains a challenge, and is essential in achieving a well-connected electrical and thermal conducting path. This study investigated electrical and thermal-responsive hydrogels based on carbon nanotubes (CNTs) as the electrical/thermal conductor and core unit, chitosan (Chit) as a hydrophilic dispersant and shell unit, and poly(NIPAAm-co-BBVIm) (pNIBBIm) as a temperature-responsive copolymer and drug carrier. Uniform distribution and 3D connectivity of CNTs was improved by formulating the CNT-core and Chit-shell units and constructing a CNT sponge framework. The hydrogel based in the CNT sponge, namely the 3D framed CNT-Chit/pNIBBIm hydrogel, exhibited the best potential for future use in a drug delivery system. The physiochemical, mechanical, electrical, thermal, and biocompatibility characteristics of the 3D framed hydrogel led to remarkable electrical- and thermal-responsive properties that allowed for the development of an excellent controllable and switchable drug delivery platform for tissue engineering and regeneration applications.

MICROENVIRONMENTAL ARRAYS AND COMPUTATIONAL MODELLING TO DELINEATE CO-OPERATIVE EFFECTS OF NOTCH SIGNALING AND BIOMECHANICAL CUES IN PATTERNED LIVER DIFFERENTIATION

Ishita Jain[P][1], Gregory Underhill[1]

[1] *University of Illinois at Urbana Champaign*

The bipotential liver progenitors can differentiate into both hepatocytes and biliary epithelial cell fates. Previously, it has been shown that when these bipotential liver progenitor cells are cultured on a defined circular geometry, a patterned differentiation is observed. The peripheral cells differentiate into biliary epithelial cells, while the interior cells differentiate into hepatocytes. It was found that the cells on the periphery were more contractile and notch signaling was essential for the pattern. Since, notch has been implicated in various diseases such as the Alagille Syndrome, we perturb expressions of notch ligands DLL1 and Jagged-1 to further deduce their exact roles in combination with the cell-substrate interactions, in the differentiation pathway. Biliary differentiation on the circular islands significantly increased with DLL1 knockout (KO) cells whereas it diminished on Jag1 KO cells. A computational model was also developed by simulating the concentration of Notch receptor, active Notch intracellular domain and the 2 notch ligands in each cell. In addition to that, we incorporated cell-cell interaction and cell traction forces in the model with constant feedback between the neighbor cells. Overall, we found that Jagged-1 promotes biliary differentiation, while DLL1 limits it to the periphery. Secondly, we saw more biliary differentiation on the stiffer substrate when DLL1 is knocked out. Lastly, upon perturbation of the various ligand concentrations and traction force profiles in a computational model for the cell differentiation, we emulate our experimental results. Hence, our experimental observations and the computational model reports novel insights in the liver differentiation pathway.

DISSECTING THE MICROENVIRONMENTAL CONTROL OF LIVER STELLATE CELL EPIGENETICS AND FIBROGENIC PHENOTYPES

Ishita Jain[P1], Aidan Brougham-Cook[1], Gregory Underhill[1]

[1] *University of Illinois at Urbana Champaign*

Corresponding author's email: ij3@illinois.edu

Non-alcoholic steatohepatitis (NASH) is an emerging epidemic of liver disease and the basis for a rising incidence of fibrosis and hepatocellular carcinoma. Hepatic stellate cells (HSCs) have been identified as the primary drivers of liver fibrosis. Changes in the composition of the liver microenvironment during fibrosis results in a complex crosstalk of extracellular cues that promotes the activation, or differentiation, of HSCs from a quiescent, vitamin A storing phenotype to a myofibroblastic phenotype. Previously, we analyzed and found distinct phenotypic behaviors of HSCs in our high throughput analysis of various ECM combinations and substrate stiffness. Here, we further wanted to delineate the key mechanisms for those behaviors, namely the epigenetic state. Epigenetic mechanisms have been implicated in the activated phenotype of HSCs, however how they change with the dynamic microenvironment has not been quantified. we delineated the various epigenetic states of HSC's, specifically for those microenvironments that have shown 3 distinct phenotypic behaviors. This resulted in distinct epigenetic clusters, where the cells on the soft substrates had the most epigenetic activity. Lastly, we quantified nuclear shape parameters which have shown to guide chromatin function. One such parameter was nuclear volume, which was significantly higher in cell cultured on 1 kPa, signifying higher gene accessibility. Ongoing efforts are focused on getting a genome-wide epigenetic sequencing to figure out the key genes regulated by these markers.

Current mechanical stimulation bioreactor systems of engineered cardiac tissues (ECTs) utilize stiff anchorage points to stretch the tissues. Therefore, the ECTs in these systems can only undergo isometric contractions and are unable to produce work, which hinders their maturation and can lead to an upregulation of pathological fibrosis. Thus, we developed a high-throughput mechanical stimulation bioreactor system that uncouples mechanical stretch from the contractile function of uniaxially aligned 5mm long ECTs suspended on one flexible polydimethylsiloxane post and one immobile polydimethylsiloxane post. This engineered bioreactor system uniaxially stimulates 48 ECTs simultaneously from 0-25% strain and 1-5 Hz by deflecting the flexible post above the ECTs utilizing a stiff tab grid system that is not directly connected to the anchored ECTs. ECTs composed of embryonic chick cardiac cells were cultured statically for 7 days followed by two different stimulation regimens for an additional 7 days: 1) static (non-stretched) and 2) uniaxial constant cyclic stretch of 12.5% strain and 1 Hz frequency. The cyclically stretched ECTs and static ECTS maintained an average spontaneous beating frequency of 1.06 Hz and 0.27 Hz respectively and average resting lengths of 5mm and 3.2mm respectively. However, there was no statistically significant difference in overall spontaneous contractile force between stimulation groups. These results suggest constant mechanical stretch affects contractile frequency and the maintenance of resting length but not necessarily the force of spontaneous contractions. Future work aims to include duty cycles and increasing frequency regimens to study how varying mechanical stimulation parameters affect ECT functionality.

INFLUENCE OF MECHANICAL AND TGFB3 STIMULATION ON TENOGENIC DIFFERENTIATION OF TONSIL-DERIVED MESENCHYMAL STEM CELLS

Hyang Kim[P][1], Junghwa Choi[1], Saerom Jeong[2], Mi Na Choi[1], Sang-Jin Shin[2], Seung Yeol Lee[1,3]

The purpose of this study was to investigate the effects of mechanical strains and TGF-β3 on tenogenic differentiation of tonsil-derived mesenchymal stem cells (TMSCs) and to evaluate the expression of tendon-related genes and ECM components such as collagen. The tonsil-derived mesenchymal cells (TMSCs) were subjected to two types of treatment: TGF-β3 and mechanical strain for 1, 3, and 7 days. Under each condition, the mRNA expression level was measured by qRT-PCR and dsDNA was measured to assess cell proliferation and normalize collagen content as an end product. Collagen concentration was assessed using the Sircol Collagen Assay Kit. The mRNA expression of tenogenic genes such as SCX, Decorin, COL1, and COL3 was significantly higher when mechanical strain was applied than under the static condition. However, the mRNA expression of tenogenic genes was not significantly different according to the intensity of mechanical strain with TGF-β3. In cells without TGF-β3 treatment, dsDNA concentration decreased, while the amount of normalized collagen increased as the intensity of mechanical strain rose. Alternatively, in cells treated with TGF-β3, the collagen concentration did not change according to the intensity of the mechanical strain, while dsDNA concentration decreased when mechanical strain was applied. The mRNA expression of osteogenic and chondrogenic genes was not significantly different among the static, 2%, and 5% mechanical strain, regardless of TGF-β3 treatment. In conclusion, mechanical strain and TGF-β3 have significant effects on TMSC differentiation into tenocytes. However, a combination of the two does not have a synergistic effect on differentiation.

While skeletal muscle has remarkable capacity for repair following acute injuries, volumetric muscle loss (VML) injuries overwhelm endogenous repair mechanisms, leading to failed regeneration, fibrosis, and loss of function [1, 2]. Following injury, immune cell trafficking within the injury milieu is tightly coordinated with muscle regeneration [3]; thus, its regulation is crucial. We characterized the local infiltration and phenotypic complexity of immune cells responding to critically sized VML defects versus subcritical defects in a pre-clinical model to elucidate the cellular players underlying a pathological or functional outcome. We employed dimensionality reduction and pseudotime analysis on single-cell flow cytometry data from injured muscle to reconstruct cellular transitions and reveal heterogeneous subsets of immune populations plaguing critical injuries. We found significantly increased M2 macrophages co-expressing TNFα and TGFβ persisting within critical VML defects compared to subcritical defects, indicative of perturbed M1-to-M2 macrophage transitions which may induce fibrosis and impair regeneration [4]. Production of sphingosine-1-phosphate (S1P) and differential expression of its 5 receptors (S1PR1-5) within macrophages have potent effects on mediating a pro-reparative microenvironment [5]. We show that local delivery of VPC01091 (S1PR3 antagonist) from nanofibers to critical defects results in a reduction of inflammatory relative to anti-inflammatory macrophages, an expanded muscle stem cell pool, and increased bridging of regenerating myofibers across the defect. Not only do these findings reveal how unique immune cell phenotypes may contribute to VML pathology but further indicate how S1P receptor modulators can be re-purposed to locally target endogenous repair cells as a novel form of regenerative immunotherapy.

Corresponding author's email: tturner42@gatech.edu

Severe skeletal muscle trauma resulting from volumetric defects is an intractable problem involving the irrecoverable loss of tissue that results in dysfunction and disability [1]. Thus, identifying effective interventions to improve muscle regeneration following such an injury or disuse has immediate clinical value. The mechanistic link between muscle regeneration and the inflammatory cascade has been shown to be vital in the functional recovery of muscle tissue [2]. Specialized pro-resolving lipid mediators' (SPM) active role in the resolution of inflammation has opened up an exciting new avenue of a resolution-based approach to immunomodulatory regenerative medicine strategies [3]. However, the field of resolution pharmacology has only begun to consider the possibility of engineering tools for local and more highly successful SPM delivery. Previously, we have investigated the advantages the biomaterial-based release of SPMs, specifically Aspirin-Triggered Resolvin D1 (AT-RvD1), has in manipulating and directing the recruitment of pro-regenerative immune cell subsets in vivo for improved tissue regeneration [4]. Here, using LC-MS/MS analysis, we discover a dysregulated SPM metabolism after a critical volumetric muscle loss defect. Thus, we develop a PEG-MAL hydrogel platform for the delivery of AT-RvD1, and its SPM precursors, to a critical volumetric muscle loss (VML) injury model in the murine quadricep. We leverage novel dimensionality reduction and pseudotime analytical techniques to characterize the host immune response to this immunomodulatory hydrogel via in vivo high-dimensional single-cell flow cytometry. Notably, we observe enhanced inflammation resolution characterized by increased accumulation of anti-inflammatory monocytes and a regenerative phenotype of macrophages, while limiting neutrophil infiltration.

In the development of a cell-based construct, progenitor cells are crucial to integrate and form tissues with available host cells, stimulatory factors to direct cellular processes and biomaterials to provide cells with 3D cues. We aimed to develop a cell-based construct designed to mimic the endochondral fracture callus based on human periosteum derived cells (hPDCs), combined with a unique norbornene functionalized alginate system as a bioink. For the final assembly of the engineered callus, bioprinting was used to allow precise and controlled 3D deposition.

Preconditioned cells were seeded for condensation in a high throughput aggregation system and primed under normoxic or hypoxic conditions for 6 days followed by in vitro analysis and in vivo assessment. Synthetic biocompatible bioinks were developed based on a norbornene functionalized alginate system, resembling the specific extracellular matrix (ECM) stiffness present in the different zones of the endochondral callus. Based on statistical scoring, the cellular profiles in regard of cellular metabolism, marker genes and matrix formation, culture regimens that promoted early chondrogenic, late chondrogenic and osteogenic differentiation could be defined. When these cell populations were encapsulated in the biocompatible bioinks, tissue development was further supported. The final constructs were assembled through bioprinting in a spatially organized tissue followed by ectopic assessment, which led to further in vivo tissue development and maturation.

We herein report a bioinspired method for the in vitro engineering of a long bone fracture callus where step-wise in vitro priming prepares and steer cell differentiation, further supported in vivo by the framing biomaterials.

AFFINITY-CONTROLLED DELIVERY OF A THERMO-STABILIZED VARIANT OF CHONDROITINASE ABC AS A THERAPEUTIC STRATEGY FOR STROKE

Nitzan Letko Khait[P][1], Sabrina Zuccaro[1], Molly Shoichet[1,2,3]

Injuries to the central nervous system (CNS), including spinal cord injury and stroke, are characterized by the formation of a proteoglycan-rich glial scar, which limits the regenerative capacity of the tissue. The degradation of the scar has therefore been suggested as a therapeutic strategy to improve local plasticity and promote axonal regrowth.

The bacterial enzyme chondroitinase ABC (ChABC) can degrade chondroitin sulfate proteoglycans, a major component of the glial scar, and has been proposed as a therapeutic strategy for multiple disorders. Yet, its inherent thermal instability, characterized by a rapid loss of activity at physiological temperatures, limits its therapeutic potential. Moreover, prolonged delivery is needed to obtain significant improvements after stroke.

We previously reported an affinity-controlled delivery platform for ChABC, in which the enzyme is expressed as a fusion protein with a Src homology-3 (SH3) domain and encapsulated in an injectable cross-linked methylcellulose hydrogel modified with SH3 binding peptides.[1] In order to address the intrinsic instability of ChABC, we designed a thermo-stable, 37 mutation, ChABC (ChABC-37-SH3) using computational remodeling and then tested it experimentally.[2] The ChABC-37-SH3 demonstrated a 6.5 times longer half-life than the native enzyme, with a higher melting temperature, and increased activity for its substrate. We are now, for the first time, evaluating a minimally invasive, sustained release strategy of this thermo-stabilized enzyme in vivo, using an endothelin-1-induced stroke injury model in rats. The in vivo efficacy of this strategy will be described in terms of tissue benefit, including mechanism of action and degradation of the glial scar.

Keywords

Stroke; glial scar; immunomodulation

INTERFACIAL PHENOMENON AND NANOMECHANICS OF WOUND DRESSING HYDROGELS

Praveena Manimunda[P][1], Douglas Stauffer[1]

[1] *Bruker Nano Surfaces*

Corresponding author's email: Praveena.Manimunda@bruker.com

Hydrogels have become an integral part of regenerative medicine and tissue engineering.[1] The high-water content of hydrogels can present an exemplar atmosphere for cell survival, and the three-dimensional (3D) networks of cross- linked hydrophilic polymers provide the much-needed mechanical strength. Hydrogels are also used as a wound dressing material. They provide hydration to the wound cite and absorb exudates and can be applied as a permanent or temporary dressing material. Along with biocompatibility, stiffness of the hydrogels determine sensitization. As the healing of the injured epidermis starts, the mechanical properties, especially stiffness of the hydrogels are expected to vary. In this study, a new methodology was adopted to probe the mechanical property gradients in wound dressing materials. In situ confocal imaging in combination with nanoindentation was used to probe the local mechanical property variations in polyethylene glycol (PEG) hydrogels. Further the methodology was extended to study the stiffness changes at different loading rates and hydration levels.

ASSESSING THE ROLE OF BRANCHED CHAIN AMINO ACIDS IN ATHEROSCLEROSIS USING A HUMAN VASCULAR MICROPHYSIOLOGICAL SYSTEM

Metabolomic studies show that elevated serum levels of the branched chain amino acids (BCAA) leucine, isoleucine, and valine are associated with increased risk of cardiovascular and metabolic diseases. While in vitro experiments have shown that elevated leucine levels inhibit endothelial autophagy, induce oxidative stress, and inhibit nitric oxide release, these levels are 50-75 times higher than those observed in vivo during disease. To test the hypothesis that elevated BCAA plus a pro-oxidative environment induce endothelial dysfunction and increase the development of atherosclerosis, we perfused human tissue engineered blood vessels (TEBVs) with normal BCAA media for 7 days at a shear stress of 0.4 Pa. Vasoconstriction was measured after 1 µM phenylephrine exposure and vasodilation was measured after 1 µM acetylcholine exposure. After 7 days of perfusion, TEBVs were treated with 1x106 monocytes/ml in new media and the following of 4 treatment conditions: normal or elevated (5X higher than normal levels) BCAA media, with or without 50 µg/ml oxidized low density lipoprotein (oxLDL). After 48 h perfusion with the various treatments, no significant effect of oxLDL or BCAA was observed on vasoconstriction. Two-way analysis of variance indicated that elevated BCAA and oxLDL interact to significantly reduce endothelial-mediated vasodilation (**p=0.0087). Monocyte accumulation is greater in the elevated BCAA media with 50 µg/ml oxLDL than in normal BCAA media with 50 µg/ml oxLDL, suggesting that the combination of oxLDL and elevated BCAA can cause EC dysfunction and accelerate events in atherosclerosis.

MODELING SKELETAL MUSCLE FIBROSIS USING A HUMAN MICROPHYSIOLOGICAL SYSTEM

George Truskey$_P$[1], Anandita Ananthakumar[1]

[1] *Department of Biomedical Engineering, Duke University*

Corresponding author's email: gtruskey@duke.edu

diabetes, sarcopenia, and rheumatoid arthritis and is characterized by scarring, which impairs muscle contractile function and causes severe pain, affecting an individual's range of motion and quality of life. Muscular fibrosis is attributed to excessive deposition of extracellular matrix (ECM) in the skeletal muscle. We used human skeletal muscle engineered muscle bundles (myobundles) to examine factors which can promote loss of muscle function. To examine fibrosis, we matured myobundles for 7 days, added 1, 5 and 10 ng/ml transforming growth factor beta (TGF-beta) for 3 days, and measured mechanical properties and active contractile force. The tetanus force was significantly reduced at all concentrations of TGF-beta for 3 different donors. Interestingly, the bundle elastic modulus only increased at 10 ng/ml TGF-beta for 2 of the donors. This higher stiffness was associated with increased production of collagen 1,4 and 5 and fibronectin determined by RT-PCR and immunofluorescence. Fibroblasts were confined to the periphery and did not increase in number after TGF-beta treatment. An inhibitor (SB525334) of the downstream Smad pathway reduced the inhibitory effect of TGF-beta on force and the increase in collagen production. Interestingly, the inhibitor increased force in control myobundles not exposed to TGF-beta, which is consistent with measured secretion of TGF-beta by myobundles. These results suggest that TGF-beta induces fibrosis, altering both the passive and active mechanical behavior of skeletal muscle. Inhibiting steps in Smad signaling can restore function, opening possible treatment options.

VAPOR DEPOSITION TO CONSTRUCT PARTICLES AND SCAFFOLDING MATERIALS FOR REGENERATIVE MEDICINE

Hsien-Yeh Chen[P][1]

[1] *National Taiwan University*

Corresponding author's email: hsychen@ntu.edu.tw

Functionalized poly(p-xylylenes) can be deposited via chemical vapor deposition (CVD) polymerization to generate ultra thin films as conformal coatings and, due to the pre-defined chemical functionalities, provide a flexible solution to surface engineering challenges as they decouple surface design from bulk properties. Hence, the technology comprises essentially a one-step coating procedure to generate functionalized surfaces without requiring any kind of post-treatment once the films are deposited. Recently, three-dimensional porous structures are constructed via vapor deposition onto a sublimating solid template. Construction upon deposition of vapor-phase material occurs at a dynamic vapor–solid interface and is directed by the solid surface vanishing by sublimation. A proof-of-concept demonstration showed vapor depositions of poly-para-xylylenes on sublimating templates, including ice and mixtures with ethanol and hexane. The material construction macroscopically produces a replica architecture of the parent template. Characteristics of the pore structures are formed during the construction process as a result of the gas vapor and the space that is vacated by sublimation, thus enabling control of the porosity through regulation of the sublimation speed and/or the thermodynamic properties of the templates. The technology introduced herein provides a novel approach for 3D porous material manufacturing and overturns the notion that vapor deposition necessarily forms dense thin films on substrates. Applications of using the vapor sublimation and deposition process were demonstrated for the productions of hierarchical micro- and nano-particles and shaped scaffolding materials with customizable interface and bulk properties, and potentials of applying these materials for regenerative medicine were also highlighted.

Spinal disc degeneration is the most frequent factor associated with the inexplicable low back and neck pain, and accounted for the pain resulted disability worldwide. On current stage, available treatments for disc degeneration disease (DDD) are mostly symptomatic, and no single treatment has been found to directly control intervertebral disc (IVD) cell homeostasis. We hypothesize that if introduce a MSC source expressing cartilage-anabolic factors in the traumatic cavity may stimulate the mucoid materials secreted from nucleus pulposus and maintain the hydration content providing mechanical strength to decelerate the disc degeneration progression. In this study, a cartilage-anabolic factor runx-1 was expressed by baculoviral vector (BV) transduced MSCs through a Cre/LoxP gene recombination system for sustained recombinant protein production. Baculoviral vector possesses highly safety on the gene transduction in mammalian cells, can be manipulated in the biosafety level 1 facilities. The Cre/LoxP recombinant BV genetically modified MSCs were delivered by hyaluronan hydrogel encapsulation and transplanted to a coccygeal disc punctured model in rat through micro-injection, followed with x-ray radiographic examination, MRI-T2 hydration content evaluation and histological analysis at the end-point of 8-weeks post-transplantation. Our data revealed the Cre/LoxP recombinant BV system mediated long-termed runx-1 gene expression scenario, possessing good biosafety concern in the in vitro cell transduction and in vivo MSCs transplantation, and maintained superior hydration content in the disc than that of non-treatment. This methodology would fulfill the need of implanting therapeutic cells accompanied with discography, and could be further promoted to pre-clinical translational study in a large mammalian animal model.

ENGINEERED 3D HUMAN BONE MARROW MODELS

Dilara Perver[P][1], Viola Vogel[1]

[1] *Laboratory of Applied Mechanobiology, Institute of Translational Medicine, ETH Zürich, Switzerland*

Corresponding author's email: dilara.perver@hest.ethz.ch

The generation of sophisticated tissue structures with biological fidelity and organization is no longer science fiction, and human bone marrow (BM) is no exception.

Driving needs of timely available and targeted production of human hematopoietic stem and progenitor cells (HSPCs) required by transplantation therapies have fostered the BM-tissue engineering applications to unravel the ongoing debate on the niche-centric versus stem cell-centric vies of hematopoiesis and to use the outcoming cues for HSPC expansion. However, the challenges of BM-mimicry due to modeling constraints associated with its complexity still exist, and an adequate in vitro BM model providing a powerful platform for basic science and the clinical translation is still lacking. In fact, many existing tissue-engineered BM models cannot restate all the BM features at once. The models that have achieved the highest mimicry fidelity cannot bypass the use of animals. Besides, translation of those models to expand clinically relevant HSPCs with sufficient quality and amount is still a significant problem.

In this study, we first aimed at closing this gap by developing a novel xeno-free 3D BM model where the structural and compositional compartmentalization of BM is mimicked successfully, enabling the maintenance of HSPCs with functional properties. Further, this model is proved to be one of the most potent candidates to mimic the medullary cavity and host HSPCs, which allowed us successfully study HSPCs regulation over selected BM niche components with a high translational relevance by challenging the current methods of the widely applied 2D and gold-standard 3D suspension cultures.

Insulin gene enhancer protein (ISL1) is a nuclear marker, expressed on neuronal and cardiac progenitor cells. Regenerative therapies have targeted ISL1+ cell surface markers for cell isolation and implantation. Innervating cardiac ganglia can be identified by ISL1. ISL1+ cells of cardiac and neurological lineage co-locate in similar areas of the developing mammalian heart. These findings present the question of whether ISL1 identifies cardiac progenitor cells, cardiac ganglia or both in humans. Proper identification of ISL1+ cells could determine their application in the areas of myocardial regeneration or cardiac electrophysiology. In this study, we isolated ISL1+ clusters from human 1st and 2nd trimester hearts. Immunofluorescence (IF) staining of cardiac tissues identified two distinct cluster types (C1) (C2) and the sinoatrial node as ISL1+ containing tissues. ISL1+ tissues were isolated using laser capture microdissection. Next Generation Sequencing (NGS) and proteomics analysis were performed, as well as Raman analysis and IF staining for neuronal and cardiac markers. NGS and proteomics data were analyzed for pathway enrichment using the Ingenuity Pathway Analysis software. Raman analysis showed that C1 and C2 ISL1+ cells have a very similar molecular profile when compared to SAN ISL1+ cells; however, C1 1st trimester and C1 2nd trimester differed, which was seen with C2 as well. NGS and proteomics analysis showed that C1 and C2 enriched predominantly neural pathways when compared to the SAN, which enriched cardiac pathways. This data suggests that ISL1 plays a larger role in the innervation of the developing heart; however, considerably more work is required.

SYNTHETIC 3D MATRIX UNVEILS THE ROLE OF STRESS STIFFENING AND AVB3 INTEGRINS IN BONE FORMATION

Jung Un (Ally) Choi[P][1], Amanda W Kijas[1], Jan Lauko[1], Alan E Rowan[1]

[1] *Australian Institute for Bioengineering and Nanotechnology, The University of Queensland, Brisbane, Australia*

Corresponding author's email: jung.choi@uq.edu.au

Bone is constantly remodelled by bone-forming osteoblast and bone-resorbing osteoclast activities. This process is primarily regulated by the most abundant bone cells called osteocytes which they are able to sense their surrounding environment in the extracellular matrix (ECM) via αVβ3 integrins, localised along the dendritic cell processes. Despite the importance of matrix-driven cellular responses in bone homeostasis, osteocytes were understudied due to the lack of appropriate in vitro model. By employing αVβ3-integrin specific ligand in a tuneable synthetic biomimetic hydrogel ECM, we can interrogate individual parameters of ECM ligand adhesion and mechanical properties to establish in vivo like osteocyte morphology. We demonstrate that αVβ3 integrin-mediated adhesions in osteocytes promote bone formation by down-regulating key osteocyte-specific signalling proteins. Furthermore, the level of key secreted signalling molecules can be controlled by mechanical stress-stiffening properties of the synthetic matrices. This model represents the first physiologically relevant model for investigating this master regulator of bone homeostasis.

Numerous intervention strategies have been developed to promote functional tissue repair following experimental spinal cord injury (SCI), including the bridging of lesion-induced cystic cavities with bioengineered scaffolds. Integration between implanted scaffolds and the lesioned host spinal cord is pivotal for the bridging function of such implantable scaffolds. Here, morphological studies have been conducted on 2mm long resection injuries of the adult rat cervical spinal cord lateral funiculus, followed by simple dural closure or the implantation of a microstructured type-I collagen scaffold. Immunohistochemistry revealed that, at 10 weeks post injury/implantation, relatively little integration could be observed between the scaffold and the surrounding host spinal tissues, as indicated by the paucity of regenerating axonal profiles or astrocytic processes within the scaffold. This was associated with the appearance of thin sheets of tightly packed and intensely zona occludens-1 immunoreactive fibroblast-like cells along the inner dura mater surface of control animals, and also forming a barrier around the implanted collagen scaffold. Transmission electron microscopy demonstrated uniform ultrastructural features including numerous tight junctions and caveolae at the plasma membrane, as well as a partial basal lamina surrounding the tightly packed cells. These striking ultrastructural features and the anatomical continuity of the sheets of scarring cells with local, damaged spinal nerve roots strongly suggest their identity to be migrating perineurial-like cells. This novel aspect of the cellular composition of reactive tissues highlights the unexpectedly complex nature of fibroadhesive scarring to traumatic SCI as well as to the implantation of bioengineered collagen scaffolds.

INFLUENCE OF PERACETIC ACID STERILISATION ON THE BIOMECHANICAL PROPERTIES OF HUMAN TENDONS

Volker Eras[P][1], Kassandra Hoetzel[1], Jan Brune[1]

[1] *German Institute for Cell- and Tissue Replacement, DIZG gGmbH - Non-Profit (Berlin)*

Corresponding author's email: n_ahmed@dizg.de

Human allograft tendons are used in a variety of indications in the fields of sports medicine, foot and ankle as well as trauma surgery. Peracetic acid (PAA) sterilisation has been shown to preserve tissue biomechanics of bone-patella tendon-bone constructs [1]. This study aims to evaluate the influence of PAA-sterilisation on the biomechanical properties of human tendons.

Pairs of tibialis anterior (TA) and posterior (TP) tendons were explanted and frozen according to tissue banking standards. For each pair, one tendon was sterilised in PAA leaving the contralateral tendon frozen. Tensile tests were performed on an InspektTableBlue (H&P, Germany). Samples were looped around bolts and cryoclamped on both ends while the midsubstance of the tendons remained free, adhering to material testing standards. Tendons received a 10-cycle preconditioning between 50 N and 250 N, a 5-minute load relaxation and a failure test with 50 mm/s speed.

Out of 27 donors tested, tendons of nine pairs (TP: 5; TA:4) exhibited a valid failure mode of rupture at the midsubstance and hence were included in the analysis. There was no significant difference between PAA treated and fresh frozen (FF) TA and TP tendons in terms of failure load (PAA: 2557 ± 401 N vs. FF: 2394 ± 614 N). Additionally, both types of treatment revealed similar load relaxation behaviour (PAA: 17.0 ± 4.2 % vs. 18.4 ± 5.9 %).

PAA-sterilisation does not negatively influence biomechanical properties of human tendons in terms of relaxation and failure loads allowing for a safe and biomechanically reliable graft.

Abstract **#2020**

ABSORPTION CAPACITY OF BONE-BASED CARRIER-GRAFTS

Jan Brune[P][1], Anja Hanke[1], Volker Eras[1], Norus Ahmed[1]
[1] German Institute for Cell- and Tissue Replacement, DIZG gGmbH - Non-Profit (Berlin)
Corresponding author's email: n_ahmed@dizg.de

Delivery of cells and expensive growth-factor containing liquids to their intended site of action is difficult as these transferred cells and fluids are easily washed away during surgery and often removed via homeostasis [1]. Future treatments involving cell therapy and tissue engineering products mandate suitable carriers for efficient retention of cells and fluids in situ.

Here, we analysed human tissue scaffolds including specifically designed high absorption and high surface area carrier-grafts, for their interstitial and matrix-linked absorption capabilities.

Eight groups of carrier grafts were analysed. Two groups of high surface area cortical fiber grafts, demineralized bone matrix (1–2 mm), cortical granules (1–2 mm), three different densities of mineralized cancellous bone and demineralized cancellous bone. All were rehydrated with phosphate-buffered saline (PBS) to a final volume of 0.4 cc.

Total absorption – both demineralized cancellous bone (0.844 ± 0.083 ml/cc) and cortical fibers (0.599 ± 0.025 ml/cc) absorbed a significantly larger volume of total PBS compared to the amount absorbed by cortical granules (1-2 mm; 0.376 ± 0.042 ml/cc).
Matrix absorption – The largest absorption capacity of the tissue matrix was observed in the cortical fibers (88.82 ± 2.99%) while low-density cancellous bone displayed the smallest matrix-linked absorption capacity (0.95 ± 1.07%).
Interstitial spaces – Investigating the uptake of PBS into interstitial spaces, revealed that demineralised cancellous bone absorbed the largest amount of PBS into the Interstitial spaces (84.4 ± 3.84%).

Cortical fibers displayed high absorption capabilities and may provide as a valuable addition to the regenerative medicine toolkit.

The limitations of obtaining pancreatic islets from different sources as animal models or human donors complicate the study of type 2 diabetes (T2D) in vitro. Immortalized cell lines as the insulin-producing INS1E β-cells appeared as a valid alternative to model insulin-related diseases. The formation of 3D structures to promote cell aggregations from single cells is a handy tool to generate resemblance islet-like pseudoislets. Traditionally used hydrogel encapsulation methods induce a lack of nutrient and oxygen diffusion for pancreatic tissue engineering. Here, we use cryogelation technology to develop a more resemblance scaffold with the mechanical and physical properties needed to engineer pancreatic tissue. This study shows that carboxymethyl cellulose (CMC) cryogels prompted cells to generate β-cell clusters. The high porosity achieved with this approach allowed us to create specific range pseudoislets. However, gelatin-based scaffolds did not induce this cell organization. Pseudoislets formed within CMC-scaffolds showed cell viability for up to 7 days and responded better to the glucose over conventional monolayer cultures. Overall, our results demonstrate that CMC-scaffolds can be used to control the organization and function of insulin-producing β-cells, representing a suitable technique to generate β-cell clusters to study pancreatic islet function.

The current clinical routines such as autograft and allograft transplantation have drawbacks for healing bone defects, mostly due to the limited convenient sources, donor rejection, and risk of infection [1]. Tissue engineering strategies are innovative and remarkable that utilize the potential of bone progenitors, especially stem cells, to differentiate into functional bone cells. Scaffolds have an important function in tissue engineering application, they not only contribute as structural support for specific cells but also contribute as a matrix to guide new tissue growth. In the present study, the feasibility of fabricating Mg-Al layered double hydroxide (LDH)- reinforced GelMA/Silk fibroin-based nanohybrid scaffolds was explored. Verifying the mineralization and differentiation potential of stem cell-laden nanohybrid scaffolds was aimed. For this purpose, firstly, stem cell-laden scaffolds were prepared by micro-molding technique under the UV light. After the 14 and 21 days of culture, cell viability, proliferation potential, metabolic activity, and ALP activiy were evaluated and analyzed. Alizarin Red, Hematoksilen & Eosin, Masson Trichrome, and immunofluorescence stainings were performed. Our findings confirmed the use of LDH nanoparticle- reinforced nanohybrid scaffolds as a composite matrix for bone tissue engineering applications, being capable of supporting natural bone regeneration as well as mineralized- matrix deposition and triggering a functional bone tissue regeneration.

This work was suporrted by The Scientific and Technological Research Council of Turkey (TUBITAK) [Project Number: 118S549].

MICROFLUIDICS-ENHANCED BIOPRINTING FOR TISSUE FABRICATION

Y. Shrike Zhang[P][1]

[1] *Harvard Medical School*

Corresponding author's email: yszhang@research.bwh.harvard.edu

Over the last decades, the fabrication of three-dimensional (3D) tissues has become commonplace. However, conventional 3D fabrication techniques are limited in their capacity to produce complex tissue constructs with the required precision and controllability that are needed to replicate their native counterparts. To this end, 3D bioprinting offers great versatility in the fabrication of biomimetic volumetric tissues that are structurally and functionally relevant. It enables accurate control of the composition, spatial distribution, and architecture of bioprinted constructs facilitating the recapitulation of the delicate shapes and structures of target organs and tissues. This talk will primarily discuss our recent efforts in developing microfluidics-enhanced bioprinting methods that enable unconventional bioprinting applications not quite possible or convenient in traditional approaches. These platform technologies are likely to provide new opportunities in constructing functional tissues to facilitate regeneration, as well as in generating microtissue models for promoting personalized medicine.

Increased fracture rates and nonunion defects occur in several chronic inflammatory conditions (1). Delayed bone healing can be reversed by the inhibition of inflammatory cytokines and by enhancing osteoblast activity (2), however, this process is too complicated and involves a plethora of biomolecules and pathways. Controlling the microenvironment of the bone defect may be more efficient and feasible strategy. Guided Bone Regeneration uses membranes that act as a barrier to prevent soft-tissue invasion and to promote bone regeneration. However, in large defects, bone formation occurs only to the marginal zone and use of grafting materials is required; which limited their use in orthopedic surgeries. In this study, we propose the use of a 3D bioprinted construct made by mineralized collagen and pre-osteoblast cells as barrier construct.
Methods: We prepared constructs of collagen and hydroxyapatite and HEPM cells using 3D bioprinting. We used histology, SEM, TEM and mechanical testing to characterize the structure. Constructs were incubated with cytokines to measure adsorption. The production of chemokines and cytokines was assessed.
Results: The fabrication of the 3D construct using 3D bioprinting was not toxic and did not alter the viability, proliferation and cytokines expression of HEPM cells. Constructs served as a barrier and did not absorb any of the cytokines measured GM-CSF, IL-12, IL-1α, IL-6, IL-8, MIP-1b, RANTES, or TNF-α.
Conclusion: The 3D construct is osteoconductive and act as a 3D barrier to surrounding anti-osteogenic mediators.This barrier can be used in patients with chronic inflammation conditions.

Iatrogenic preterm premature rupture of membranes (iPPROM) is seen as the Achilles' heel of minimal invasive fetal surgery as it is a strong trigger for premature birth, subsequently increasing the risk of morbidity and mortality for the baby. As fetal membrane defects do not heal spontaneously, we developed a biocompatible, fetoscopically applicable collagen plug with shape memory, which expands directly upon employment by an entropy-driven force to seal the fetal membranes, hence preventing amniotic fluid leakage and plausibly iPPROM.

Plugs were constructed by a process consisting of casting, freezing, and lyophilization of a type I collagen suspension. Lyophilized collagen plugs were given shape memory and fitted through the fetoscope shaft (ø3.3 mm). Expansion of the plug was examined in PBS. The quality of sealing was studied ex vivo using human fetal membranes, and using a high pressure in situ porcine bladder model.

The crimped plug expanded to the energetically favorable state, and tripled in diameter within 1 min when placed into PBS, so it will be able to fill the entire endoscopic entry point. In comparison, collagen plugs without shape memory did not expand beyond 3 mm within 1 hour. In both human fetal membranes and a porcine bladder, the plug expanded in the defect, secured itself and sealed the defect. No substantial leakage nor rupture were observed. In conclusion, a collagen plug with shape memory is a promising medical device that can rapidly seal a fetoscopic defect in fetal membranes at the endoscopic entry point, and may prevent iPPROM.

Skin grafting is standard treatment of extensive wounds, despite frequently resulting in poor cosmetic and functional outcome. To mitigate this problem, tissue engineered skin substitutes comprised of a combination of cells and biomaterials have been suggested. Rapid cell expansion and subsequent transplantation is desirable, preferably without the use of enzymes. The present study aimed at investigating transplantation of keratinocytes and fibroblasts seeded on microcarriers in a porcine full-thickness wound model.

Cells were isolated from skin biopsies taken from pigs (N = 8), expanded, and seeded on Porcine Gelatin Microcarriers. Resulting tissue constructs were transplanted to 120 surgical wounds (2 cm diameter). Treatment groups included NaCl control, microcarriers, and microcarriers seeded with fibroblasts, keratinocytes or both. Wounds were excised after one, two, four or eight weeks for histological and immunohistochemical analysis. All animal procedures were approved by the Regional Ethical Review Board (protocol ID534).

Quantifying cells on microcarriers revealed optimal cell density 24-96h after seeding. Following transplantation, microcarriers were incorporated into the granulation tissue, with complete degradation after two weeks. The first two weeks after transplantation, microcarriers seeded with cells resulted in significantly thicker neoepidermis compared to microcarriers and NaCl controls ($p < 0.05$). Four and eight weeks after transplantation, no significant differences could be observed.

In conclusion, experiments performed illustrate the successful use of PGMs as a biodegradable cell carrier for transplantation of fibroblasts and keratinocytes. The proposed method may be useful for cell expansion and transplantation, enabling delivery of large numbers of cells without the use of enzymes.

Early fetal wounds heal with regeneration instead of scarring and amniotic fluid (AF) containing hyaluronic acid (HA) is thought to be an important factor for this. In this study we aimed to analyze the gene expression in keratinocytes during stimulation with human AF.

Human primary keratinocyte cultures were serum-starved for twelve hours, then cultured in DMEM alone or with 50% AF or with 50% FCS. RNA was collected and pooled and gene expression was analyzed using Affymetrix U133A plus 2 microarray with enrichment analysis performed in Enrichr and WebGestalt.

About 2,000 distinct genes were differentially regulated between DMEM and AF groups, and about 1,500 genes between FCS and DMEM groups. About 600 distinct genes were differentially regulated between AF and FCS. The AF and FCS treatments resulted in enrichment of terms relating to the epidermis and keratinocyte biology. In particular, p63, AP-1 and NFE2L2 (Nrf2) associated genes were found significantly regulated in both treatments. Genes regulated by FCS treatment were more associated with TNF, NFkB and inflammatory signaling while AF treatment was more associated with molecular establishment of epidermis, enhanced lipid metabolism and tissue architecture.

In conclusion, our results indicate that AF may trigger a differentiation program that includes a higher degree of regeneration than the adult wound bed supports which could explain the positive effects on human wound healing found in AF. This study might serve as a source for further understanding the potential therapeutic tole of AF in wounds that are reluctant to heal.

The current threat of antibiotic resistance coupled with slow development of novel antimicrobial treatments calls for new methods for rapid and reproducible evaluation of potential therapeutics. The aim of the present study was to develop a standardized ex vivo infected wound model. The model was then used to evaluate antimicrobial treatment in regards to reduction of infection and reepithelialization.

Normal skin was obtained from patients undergoing routine surgery (Swedish Ethical Review Authority no. 2018/97-31). Full-thickness disks (8 mm diameter) with a central partial-thickness wound (4 mm diameter) were created using biopsy punches. The wounds were inoculated with 10E7 Staphylococcus aureus (ATCC 29213), and maintained under standard conditions. Tissue infection was monitored using quantitative cultures and immunohistochemical staining using antibodies against S. aureus and pancytokeratin. Topical gentamicin administration (1 mg/ml) was evaluated in regards to eradication of infection using the infected wound model.

Quantitative cultures revealed a wound infection three days after inoculation of approximately 10E7 colony forming units (CFU)/g of tissue, increasing to 10E9 CFU/g twelve days after inoculation. Immunohistochemical staining confirmed the bacteria to be S. aureus, and revealed the spread of infection down in to the dermis. Antimicrobial treatment using topical gentamicin completely eradicated the wound infection.

The current study describes the establishment of an infected wound model based on viable human skin. The model is reproducible and provides rapid screening of novel antimicrobial treatments, assessing reduction of infection as well as reepithelialization over time. Further development of the infected wound model will include other clinically relevant pathogens.

ZONAL DESIGN OF CARTILAGE IMPLANTS: MECHANOTOLERANCE OF CHONDROCYTES AS A SELECTION CRITERIUM FOR IMPLANT DESIGN

Janine Lueckgen[1], Elisabeth Kraemer[1], Tobias Reiner[2], Wiltrud Richter[1]

[1] *Research Center for Experimental Orthopaedics, Heidelberg University Hospital*

[2] *Department of Orthopaedic and Trauma Surgery, Heidelberg University Hospital*

Corresponding author's email: Janine.lueckgen@med.uni-heidelberg.de

Current cartilage replacement strategies often display mechanical failure, impeding proper joint function. A zonal design of implants for cartilage regeneration improved integration and mechanical stability over non-zonal approaches. Chondrocytes in the upper zone enable functionality of the cartilage layer and may be obtained in limited quantity from articular cartilage (AC) or rather unlimited from mesenchymal stroma cells (MSC) differentiated towards the chondrogenic lineage. So far it remains unknown, whether an MSC-derived chondrocyte layer tolerates mechanical loading equally well as an AC-derived zone and is, therefore, promising as upper zone of cartilage constructs. Aim of this study was to compare the mechano-response of engineered AC- and MSC-derived zonal implants to physiological loading.

Implants were generated by seeding human AC or MSC in a collagen I/III scaffold attached to a beta-TCP block. After 21 days of chondrogenic maturation, 3h of cyclic compression was applied in a bioreactor. Matrix synthesis, gene and protein-expression were analyzed.

MSC-derived cartilage reacted with a lower load-induced upregulation of multiple mechano-response genes and loading disturbed cartilage matrix synthesis which was not seen with AC. Load-induced BMP2- and BMP6-induction was higher in the AC-group, but BMP-stimulation of MSC during loading did not eliminate the disturbance of matrix synthesis. Differences in NFkB-signaling between AC and MSC suggested a link of the differential response to the NFkB-pathway.

In conclusion, MSC-derived osteochondral implants displayed a reduced tolerance to physiological loading compared to AC with disturbance of matrix synthesis, suggesting the cell-source for the cartilage layer of zonal implants should be carefully considered.

Non-alcoholic fatty liver disease (NAFLD) affects 1 in 4 people worldwide. It ranges from simple steatosis to non-alcoholic steatohepatitis, which may progress to cirrhosis, and hepatocellular carcinoma. From 30 to 70% of patients with NAFLD suffer from generalised loss of skeletal muscle (SM) mass (sarcopenia). Why and how skeletal muscle mass influences the development of NAFLD is not completely elucidated. Here, we present a three-dimensional model of fatty liver and subsequent loss of SM in vitro.

Mouse hepatocytes and AML2 and SM C2C12 were encapsulated in solution of gelatin methacryloyl and sodium carboxymethylcellulose at concentration of 5 and 1%, respectively. The photo-initiator LAP was then added at concentration of 0.1% and the polymer exposed at UV light for 30 seconds. The fatty liver is induced upon incubation of the cell with non-esterified fatty acids (NEFAs) for various timepoints. The supernatant from those cells were then incubated with SM cells.

Hepatocytes showed lipid accumulation, nuclei distortion and cell death after 48h of culture with NEFAs assessed by confocal and bright microscopy. Albumin and urea cycle enzymes levels also showed a time dependent decrease at protein and mRNA levels. The SM cells in contact with supernatant from fatty hepatocytes displayed loss of cytoplasmatic mass, metabolic activity and efficiency in time dependent manner as showed by H&E staining and MTS assay, respectively.

Liver and SM are connected at cellular level during the development of NAFLD, pinpointing to a broader therapeutic approach to the disease.

Cells are exquisitely sensitive to their biomaterial microenvironment, producing integrated responses to a myriad of biochemical and biophysical cues so as to direct tissue growth and physiology. This responsiveness can be leveraged in regenerative medicine therapies by providing the cells with the right cocktail of biochemical factors, biomaterial cues, and biophysical stimuli to guide their fate and function. Fully realizing this potential is challenging, however, because the effects of multiple interacting soluble and biophysical stimuli are complex and difficult to measure and optimize. To address this need, we have developed microfabricated deformable membrane platforms that uniquely enable dynamic mechanical stretch and biomechanical monitoring of arrayed 3D biomaterial constructs. We combine these platforms with statistical modeling to systematically probe multifactorial regulation of cell mechanobiological responses. In this talk, I will present our recent studies that use this strategy to define biomaterial design parameters and novel mechanical loading protocols that promote maintenance of stem cell pluripotency and tissue regeneration by mesenchymal stem cells.

Regenerative medicine has developed over last decades a new interdisciplinary approach to urinary bladder wall regeneration based on biomaterial scaffolds intended to activate intrinsic regeneration mechanisms. To date, urinary bladder reconstruction applying this strategy has been tested in 141 patients (1). Nevertheless, none of them was successfully translated into clinics due to high complication rate and lack of reliable long lasting function.

The aim of the study was to create and evaluate UROGRAFT- a new bioconfigurable, composite graft for urinary bladder wall regeneration.

The impact of the UROGRAFT configuration on its mechanical properties and potential for regeneration of reconstructed urinary bladder wall was assessed. For this purpose, a numerical modeling technique based on the Finite Element Method was used. Selected UROGRAFT configuration (30cm2) was used for augmentation cystoplasty in pigs (n=5). Bladder acellular matrix (BAM) in a circle shape (30cm2) was used for augmentation cystoplasty as a control (n=5). The follow-up of the study was 6 months. Reconstructed bladders were subjected to radiological, macroscopic, histological and molecular evaluations.

All animals survived the 6 months follow-up. Tissue engineered bladder function was normal without any signs of post voiding urine residual in bladder and in the upper urinary tracts. Macroscopically, bladder wall reconstructed with UROGRAFT mimicked native urinary bladder tissues. Graft shrinkage and fibrosis were observed in control group. Histological and molecular analysis confirmed that UROGRAFT enhanced regeneration of reconstructed bladder wall.

The present work was supported by the National Center for Research and Development (NCBR) in Poland under agreement no. LIDER/48/0195/L-9/17/NCBR/2018

TRANSLATION OF A NERVE GUIDE FROM SMALL ANIMALS TO LARGE ANIMALS TO HUMANS

Kacey Marra[P][1]

[1] *University of Pittsburgh*

Corresponding author's email: marrak@upmc.edu

Severe injuries to peripheral nerves are challenging to repair. For nerve gaps >one inch, the standard of care is autografting; however, autografting can result in neuroma formation, loss of sensory function at the donor site, and increased operative time. To address the need for an off-the-shelf synthetic nerve conduit to treat large nerve gaps, we developed a biodegradable conduit comprised of poly(caprolactone), (PCL). The inner portion of the PCL nerve conduit was embedded with double-walled poly(lactic-co-glycolic acid)/poly(L-lactic acid), (PLGA)/(PLLA) microspheres encapsulating glial cell line-derived neurotrophic factor (GDNF). Functional, electrophysiological and histological assessments demonstrated the efficacious bridging of a long gap in a non-human primate 5-cm median nerve defect model. The next steps (e.g. clinical translation) for those in academia can be particularly challenging. This talk describes the 20-year journey from biomaterials fabrication and characterization, to in vitro cell studies, to small animal studies, to large animal studies, GMP manufacturing, ISO 10993 biocompatibility testing, regulatory approval, and clinical trials.

Introduction:

The bottom up approach in the field of tissue engineering requires small and modular building block units which can ideally self-assemble together [1]. The work here represents an alternative option to create those building blocks by combining spheroids with micro-size polymeric scaffolds produced using multi-photon lithography (MPL).

Experimental methods:

Photo-polymerizable resin is based on a multifunctional acrylate-endcapped urethane-based poly(caprolactone) (AUP-PCL) [2] dissolved in THF with M2CMK at 10mM as photo-initiator. Micro-size scaffolds were printed using MPL, with a femtosecond laser at 800nm, 10x microscope objective, at intensities ranging from 20 to 300 mW at 1000 mm.s-1. Each microscaffold was incubated with a suspension of human-adipose derived stem cells (hASC), in agarose molds, until formation of spheroids. Morphological features along with the self-assembly property of the structures were assessed microscopically and compared with normal spheroids.

Results and Discussion:

Under low-binding condition, individual spheroids could be formed within each of the microscaffolds. Importantly, the presence of the polymeric structures permits the fabrication of tissues through self-assembly, superior in size, stability and control in terms of shape compared to conventional spheroid-based tissues. The next step is now to upscale the MPL fabrication and the spheroids sorting necessary to envision any bench-to-bed translation.

Conclusions:

Microscaffolds built using MPL combined with spheroids possess excellent properties to generate building blocks for large-size tissue self-assembly. This synergetic tissue engineering strategy offers unprecedented opportunities compared to scaffold-free and scaffold-based approaches, with great perspectives to reconstitute complex tissue defects [3].

MULTI-CELLULAR SPHEROID ENGINEERING USING BIOINSPIRED MATERIALS

Heungsoo Shin[P][1]

[1] *Hanyang University*

Corresponding author's email: hshin@hanyang.ac.kr

Recently, technologies to culture one or more cell types in 3D conditions have attracted a great deal of attention in tissue engineering. In particular, stem cell spheroids have been reported for improved viability, self-renewal capacity, and differentiation potential. However, for the use of multi-cellular spheroids in tissue engineering, modulation of spheroid functions with instructive signals is critical. We have been developing ECM-mimicking fibrous materials decorated with cell-instructive cues, which were incorporated within 3D stem cell spheroids to tune their functions as modular building blocks for bottom-up tissue-engineering applications. In this presentation, engineering ECM-mimicking materials and their use in 3D spheroid fabrication would be discussed with utilizing human-adipose-derived stem cells (hADSCs) with aims of enhanced bone regeneration.

CURVATURE: A POTENT DYNAMIC REGULATOR OF CELL PHENOTYPE AND MIGRATION

Nicholas Kurniawan[P][1]

[1] *Eindhoven University of Technology*

Corresponding author's email: kurniawan@tue.nl

The intrinsic architecture of tissues subject cells to geometrical cues in the form of mesoscale curvatures. While the effect of nano- and micro-scale topographical cues have been extensively studied for decades, surprisingly little is known about the cellular response to substrate curvatures. To study the effect of curvature in a systematic and high-throughput manner, we developed "2.5D curvo-chips": microfabricated chips containing arrays of concave and convex geometrical structures with a wide range of sizes (µm to mm). We observed distinct cell adhesion morphologies on convex and concave structures that are accompanied by changes in the phosphorylated myosin, nuclear lamin-A, and F-actin levels, suggesting a compensation mechanism due to curvature-driven impairment of F-actin assembly to maintain cellular contractility. These resulted in distinct cell migration modes that depended solely on the instantaneous curvature 'perceived' by the cells. Furthermore, we developed two methods to simultaneously present competing curvature and contact-guidance cues to the cells. The results show a clear 'dose-dependent' curvature sensing by the cells. Intriguingly, repeating these experiments with a variety of cell types (fibroblasts, mesenchymal stromal cells, endothelial cells, epithelial cells, keratocytes) reveals that the ability of cells to sense and respond to mesoscale substrate curvatures is universal, but highly cell-type-specific. Our findings establish mesoscale curvature as a potent regulator of cell phenotype and behavior, and demonstrate a complex interplay between the dynamics of actin stress fiber (re)organization and force generation, nucleus mechanics, and adhesion morphology in dynamically guiding cell phenotype and migration behavior on physiologically-relevant 3D structures.

DECONSTRUCTING REGENERATIVE THERAPEUTICS: CELLS, EXTRACELLULAR VESICLES AND NONCODING RNA

Eduardo Marban[P][1]

[1] *Smidt Heart Institute, Cedars-Sinai Medical Center*

Corresponding author's email: eduardo.marban@cshs.org

The development of regenerative therapy has benefited greatly from serendipity. Cell therapies have some promise, but cell products vary in potency and can be difficult to manufacture. In the process of mechanistic investigations into cell therapies for heart disease, we discovered a central role for extracellular vesicles (EVs) as paracrine mediators of therapeutic bioactivity. EVs reproduce the benefits of cells, and they are easy to isolate, store and deliver, making them viable cell-free therapeutic candidates. But EVs may also have value as a discovery platform for biologically-active molecules. EVs work by delivering RNA and protein payloads to target cells, so it is logical to mine EV contents in a search for defined factors. In so doing we have found several noncoding RNA species, including fragments of Y RNA, which themselves have intriguing biological actions. The next generations of cell-free biologics (EVs and noncoding RNAs) may provide the benefits of cell therapy without the intrinsic limitations.

PHOTOBIOENGINEERING: TWO SYNERGISTIC BIOTECHNOLOGIES FOR REGENERATIVE MEDICINE

Praveen Arany[P][1]

[1] *University at Buffalo*

Corresponding author's email: prarany@buffalo.edu

A major focus in tissue engineering today is mimicking nature's pristine design with a particular emphasis on embryonic development that serves as a roadmap for regenerative medicine. The spatiotemporal presentation of morphogens, both soluble (biomolecules) and insoluble (matrix) serve as first principles for tissue engineering. Our research has focused on two discrete and synergistic fields, biomaterials and biophotonics. First, we utilize biomaterial systems to provide engineered niches for directed differentiation of stem cells. This encompasses defining topological biomaterial interfaces (insoluble, varying spatial scales) using electrospinning, gas-foaming and 3D printing as well as polymeric controlled release systems with agonist-antagonist combinations to generate synthetic morphogen fields. Second, we have investigated the ability of light-activated biological pathways in driving therapeutic biological responses. This use of non-thermal, non-surgical low dose biophotonics treatments is termed Photobiomodulation (PBM) Therapy. The ability to utilize PBM treatments as a non-invasive, easily customizable, and potent biophysical therapy has been noted to target fundamental disease pathophysiological responses such as pain, inflammation, immune responses, and tissue healing and regeneration. This has enabled a significant breadth of PBM clinical applications from concussion, Alzheimer's to wounds and mucositis among many others. Our work has demonstrated key roles for several photoactivated signaling pathways such as TGF-β1, NFκB, and ATF-4. These biological insights are being utilized to develop safe and effective clinical translational protocols for reproducible PBM clinical therapeutic outcomes. Finally, this talk focuses on brief overviews of our recent attempts at combing these two synergistic approaches to direct biological response for therapeutic clinical outcomes.

BACTERIA-BASED MATERIALS FOR STEM CELL ENGINEERING

Manuel Salmeron-Sanchez[P][1]

[1] *University of Glasgow*

Corresponding author's email: manuel.salmeron-sanchez@glasgow.ac.uk

A new generation of materials has been developed over the last few years with highly dynamic properties that recapitulate properties of the extracellular matrix. These materials are not only highly dynamic but also very responsive to external stimuli to modulate their biophysical properties and biological functionalities, including sustained delivery of proteins upon external stimuli, mechanical properties that change as a function of time and self-healing capacity. These living materials are based either on advanced chemical functionalities (e.g. self-assembling peptides) or, alternatively, through the radical approach of using living cells that have been genetically modified and incorporated as living parts of the material. Particularly exciting are advances in using genetically modified microorganisms to achieve high functionalities, such as light-triggerable expression of adhesive peptides secretion of growth factors.

In this talk, we present bacteria-based materials as a new concept that supports stem cell engineering. We demonstrate that non-pathogenic bacteria such as Lactococcus Lactis can be engineered to expresses membrane proteins that present adhesion domains for mammalian cells (e.g. a fibronectin fragment that contains the integrin binding region) and also secrete growth factors and cytokines in a temporally regulated manner triggered by external stimuli. We present examples of bacteria-based materials that control the differentiation of mesenchymal stem cells towards osteogenic lineages both in 2D and 3D and also new bacteria-based materials that contribute to create a dynamic bone-marrow niche like environment that support the growth of mesenchymal stem cells.

SILK FIBROIN BIOINKS FOR DIGITAL LIGHT PROCESSING (DLP) 3D BIOPRINTING

Chanhum Park[P][1,2]

[1] *Hallym University*

[2] *Nano bio regenerative medical institute*

Corresponding author's email*:* hlpch@paran.com

Three-dimensional (3D) bioprinting has been a highly influential technology in the field of tissue engineering to enable speedy and precise spatial patterning of cells, growth factors, and biomaterials. Bioink is one of the main factors in 3D bioprinting, and hydrogels are excellent matrix type by means of bioinks for 3D bioprinting. Recently, stereolithographic bioprinting via digital light processing (DLP) that allows high spatial resolution and rapid printing time of complex structures have attracted many studies. However, a small number of bioinks have been applied to DLP bioprinting in comparison with bioinks for other bioprinters. We developed a novel bioink based on silk fibroin that has been extensively used in biomedical fields due to its positive biological and biochemical properties as biomaterials. In this chapter, we summarized the silk fibroin basics and various applications of silk fibroin as a printing material. Also, the fabrication and performance of silk-based bioink for DLP bioprinter were discussed.

ELECTRICAL APPROACHES FOR TISSUE REGENERATION

Sarah Cartmell$_P$[1]

[1] *The University of Manchester*

Corresponding author's email: sarah.cartmell@manchester.ac.uk

In the Cartmell laboratory, we have been developing different in vitro bioreactors that can apply different electrical regimes to cells and tissues with a view to influence cell activity: proliferation, differentiation and extracellular matrix production. This presentation will discuss the background evidence for using electrical regimes to influence cell and tissue activity as well as present our data on its use for bone, neural and skin regeneration.

Our research approach has also allowed us to further study the mechanism by which the activity of primary human mesenchymal stem cells are altered both in terms of cell proliferation and differentiation. A novel finding of the importance of the faradic by product of H2O2 proximal to the cathode as result of the direct electrical stimulus will be presented and its subsequent role in influencing primary mesenchymal stem cell proliferation. The morphology of primary cilia on these cells after electrical stimulation has been applied will also be discussed, in addition to the effect of varying electrical regime on cell response. The use of conducting polymers and piezoelectric materials to apply electrical regimes to the cells will be discussed.

This presentation will also present data on influence of electricity for chronic wound healing and on peripheral nerve repair.

Additive Manufacturing (AM) consists of a multitude of different technologies, offering different materials, with different quality outputs. However, all current AM technologies share the same major limitation: a three-dimensional object is fabricated layer after layer. The layered approach greatly limits the 3D design freedom and productivity in AM. It is no different in bioprinting where the tools to print cells are all based on a layered approach: extrusion, inkjet, laser induced forward transfer (LIFT) and Stereolithography.We pioneered a novel approach in bioprinting to overcome this layered approach to directly create objects in their 3D shape that we call volumetric printing by reverse tomography [1,2,3]. The method consists of sending dynamic light patterns from multiple angles corresponding to the projection of the 3D objects. The cell loaded photosensitive hydrogel accumulates the 3D distributed light dose and above a certain dose threshold, the hydrogel solidifies and forms a 3D scaffold. We have demonstrated the fabrication of a variety of complex 3D shapes with no restrictions on 3D design and with materials whose properties range from extremely soft (hydrogels) to hard (polymer acrylics) [1,3].Because this technique is based on 3D light dose accumulation, it is well suited for a control feedback loop, whereby the 3D dose is adjusted while the part is forming. We call this “intelligent” as it is controlling the manufacturing of the 3D object as it is built. We show the implementation of such a feedback loop and demonstrate experimentally a substantial gain in part fidelity.

INTEGRATED HUMAN MULTI-ORGAN PLATFORMS FOR MODELING SYSTEMIC PATHOLOGIES

Gordana Vunjak-Novakovic[P][1]

[1] *Columbia University*

Corresponding author's email: gv2131@columbia.edu

Bioengineered “organs on a chip” platforms are evolving into a new paradigm for modeling human pathophysiology, with utility in both biological and preclinical studies. Establishing physiological communication between different tissues while preserving their individual phenotypes is a challenge that needs to be addressed to allow modeling of whole-body physiology in health and disease. An approach to meet these conflicting requirements is to establish a modular, configurable multi-organ platform in which each human tissue is cultured in its own optimized environment and linked to other tissues by vascular perfusion. We showed that under these conditions, the connected tissues (heart, liver, skin, bone) can maintain their molecular, structural and functional phenotypes over four weeks of culture. The platform allows individualized studies, as all tissues, endothelium and circulating cells can be derived from the same source of iPS cells. To illustrate the utility of this approach, we use two examples: (i) a simple liver-tumor platform that recapitulated clinical efficacy and toxicity for an anticancer drug, and (ii) a multi-organ platform that recapitulated the toxicity of doxorubicin observed in pediatric and adult clinical studies. Finally, we outline some of the opportunities and challenges for using these platforms in studies of development, physiology and disease.

HARNESSING THE EXTRACELLULAR MATRIX FOR DRIVING TISSUE REPAIR

Martin C. Harmsen[P][1]

[1] *University of Groningen, University Medical Center Groningen, Department of Pathology and Medical Biology*

Corresponding author's email: m.c.harmsen@umcg.nl

Our body is equipped with the spatiotemporally tightly-regulated process of wound healing to cope with tissue damage in an organ-specific fashion. Dysregulated wound healing causes scarring and fibrosis in which excessive extracellular matrix (ECM) is deposited which usually causes organ failure. Given the dynamic and versatile nature of ECM and its instrumental role in tissue generation and regeneration, the relevance to understand and apply ECM in a therapeutic context stands to reason.

In homeostasis, ECM comprises of fibrous and sheet-like proteins such as collagens that are embedded in a water-retaining gel of highly negatively charged polysaccharides such as glycosaminoglycans. Essentially these 'reinforced hydrogels' instruct tissue cells, via adhesion motives and bound growth factors. We argued that isolated organ-specific ECM, formulated as

hydrogels and charged with therapeutic factors or their producing cells such as MSCs, would replicate nature's own use of ECM in tissue repair and regeneration.

Indeed adipose tissue-derived and cardiac left ventricular-derived ECM hydrogels not only efficiently bound the factors in the secretome of adipose tissue-derived stromal cells (ASCs) but also released these in a time-dependent sustained fashion. Cardiac hydrogels loaded with ASCs alleviated severe oncostatic drug-induced cardiomyopathy. Moreover, dermal-derived ECM hydrogels contributed to dermal healing in rats. In vitro, cardiac and skin-derived ECM hydrogels supported and stabilized formation of long-term vascular endothelial networks without the need of accessory cells such as pericytes. While virtually all tissue regeneration processes rely on adequate perfusion the application of pre-vascularized organ-specific ECM hydrogels offer an opportunity to augment healing.

Increasing demand of clinical-grade cells is a great challenge to developers and to the cell and gene therapy industry that will eventually industrialize production. This could be seen as an opportunity to evaluate existing bioprocessing technologies already tested in the production of vaccines and biologicals with great success. Herein we analyze the transition from manual cell expansion 2D methodologies to scalable and automated volumetric production platforms with the capacity to yield large numbers of cells per batch within established specifications in a robust, reproducible and cost-effective manner in compliance with current Good Manufacturing Practices. Moreover, Quality and Regulatory compliance must be addressed from bioprocess design and implementation to routine work. This presentation will review current trends and challenges of different manufacturing platforms, paying special attention to those supporting expansion of multipotent mesenchymal stromal cells in single-use bioreactors for further use in tissue engineering applications.

Recent advances in fluidic systems and 3D printing help to push the limits of in vitro models by adding a new layer of complexity: the connection between multiple organs. During the proposed symposium we aim to explore the most innovative and challenging aspects of the connection between multiple organoids and tissues by fluidic networks, spanning from the macro to micro integration in the vascular network to the propagation of vascularized organoids at clinically relevant dimensions. We will present the first-of-a-kind 3D model of spontaneous breast cancer metastasis to the bone and in particular the technological platform featuring two connected organoids in clinically relevant dimensions (cm3) and with an extensive network of capillaries that penetrate the whole mass. The connecting network between the organoids mimics the physiological blood circulation, with self-assembled micro-sized capillaries merging with bioprinted macro-sized vessels. Such in vitro platform recapitulates physiological tissue-level complexity with organoids comprising several million cells and therefore constitutes a more clinically relevant environment for in-depth studies.

B2B FET-OPEN project has selected the metastatic process of breast cancer to the bone as its first application and aims to provide a breakthrough technology to investigate metastasis longitudinally and at the single cell level. Therefore, in the B2B device a patient-derived breast cancer lesion is connected to an in vitro reconstructed bone, a marrow-containing ossicle. We will also highlight the B2B potential applications to study mechanism that rely on the inter-organ crosstalk.

The use of acellular resorbable synthetic scaffolds for replacing diseased cardiovascular tissues, such as heart valves and blood vessels, is an attractive strategy that has shown great promise in recent preclinical studies and ongoing clinical trials. These scaffolds are designed to instantaneously take over the functionality of the replaced tissue upon implantation, and maintain functionality while they are gradually resorbed and replaced by autologous new tissue by infiltrating cells, directly in situ [1]. The interdependent processes of scaffold degradation and tissue formation are hypothesized to be orchestrated by macrophages, in cross-talk with myofibroblasts. However, our lack of fundamental insight into macrophage-driven regeneration under the influence of environmental factors, such as hemodynamic loads and patient-specific conditions, has led to unpredictable variability in outcome. In this presentation, I will share our recent efforts in the understanding and controlling of the in situ formation of functional new cardiovascular tissues (i.e. blood vessels and heart valves) by modulating the host immune response using resorbable supramolecular elastomers. Specifically, I will elaborate on our recent results regarding the influence of the local biomechanical loads, as well as the influence of patient-specific comorbidities, on the inflammatory and regenerative processes in response to such scaffolds, and how these may dictate tissue formation and remodelling.

2 Technical University of Catalonia (UPC)

Corresponding author's email: eengel@ibecbarcelona.eu

Efficient vascularization of tissue engineered grafts is still nowadays one of the main drawbacks for successful medical applications. Several strategies have been explored to promote angiogenesis and vascularization on tissue engineering scaffolds. From stem and progenitor cells, to growth factors or other biomolecules. Thus, ions have also been widely studied to activate residing cells to induce new vessels formation. However, the mechanisms involved in this process are not well understood. We have been exploring biomaterials that can activate angiogenesis in situ. The fabrication of scaffolds that can recreate instructive environments will send the specific signals to cells to produce a fast and equilibrated vascularization. In this talk I would review the effect of degradation products from the scaffolds on angiogenesis and will explore different models to evaluate this effect.

DEVELOPMENT OF A HUMAN BONE MARROW BIOMIMICRY

Sakis Mantalaris[P][1]

[1] *Georgia Institute of Technology*

Corresponding author's email: sakis.mantalaris@gatech.edu

Cellular microenvironments provide stimuli including paracrine and autocrine growth factors and physico-chemical cues, which support efficient in vivo cell production unmatched by current in vitro biomanufacturing platforms. While three-dimensional (3D) culture systems aim to recapitulate niche architecture and function of the target tissue/organ, they are limited in accessing spatiotemporal information to evaluate and optimize in situ cell/tissue process development. Herein, we present a human bone marrow biomimicry, which was optimized using a mathematical modelling framework that was parameterized by single-cell phenotypic imaging and multiplexed biochemical assays to simulate the non-uniform tissue distribution of nutrients/metabolites and growth factors in cell niche environments. The model was applied to a bone marrow mimicry 3D perfusion bioreactor containing dense stromal and hematopoietic tissue with limited red blood cell (RBC) egress. The model characterized an imbalance between endogenous cytokine production and nutrient starvation within the microenvironmental niches, and recommended increased cell inoculum density and enhanced medium exchange, guiding the development of a miniaturized prototype bioreactor. The second-generation prototype improved the distribution of nutrients and growth factors and supported a 50-fold increase in RBC production efficiency. This image-informed bioprocess modelling framework leverages spatiotemporal niche information to enhance biochemical factor utilization and improve cell manufacturing in 3D systems.

NOVEL BIODEGRADABLE MATERIALS AND BIOINKS FOR THE BIOPRINTING AND REGENERATION OF DIFFERENT TISSUES

Rui L. Reis[P][1]

[1] *3B´s Research Group - Biomaterials, Biodegradables and Biomimetics, I3Bs, University of Minho, Guimarães, Portugal*

Corresponding author's email: ruilgreis@gmail.com

The selection of a proper material to be used as a scaffold or as a bioink in 3D bioprinting approaches in order to support or encapsulate cells is both a critical and a difficult choice that will determine the success of failure of any tissue engineering and regenerative medicine (TERM) strategy.

In our research group we have been using natural origin polymers, including a wide range of marine origin materials, for many different approaches that allow for the regeneration of different tissues. Several innovative bioinks with quite specific properties were proposed. We have also been optimizing the respective formulations for using these novel materials in distinct biomanufacturing strategies. This will be presented and discussed during the keynote talk.

Furthermore, an adequate cell source should be selected. In many cases efficient cell isolation, expansion and differentiation methodologies should be developed and optimized. We have been using different human cell sources namely: mesenchymal stem cells from bone marrow, mesenchymal stem cells from human adipose tissue, human cells from amniotic fluids and membranes and cells obtained from human umbilical cords.

The potential of each combination materials/cells, as related to different manufacturing technologies, with details focusing on bioprinting, to be used to develop novel useful regeneration therapies will be discussed. The use of different cells and new ways to assess their interactions with different natural origin degradable scaffolds and bioinks will be described. Several examples of TERM strategies to regenerate different types of tissues will be presented.

INDUCTION OF TISSUE REPAIR BY ACTIVATION OF ENDOGENOUS STEM / PROGENITOR CELLS

Ranieri Cancedda[P][1]

[1] *University of Genova, Italy*

Corresponding author's email: ranieri.cancedda@unige.it

For repair of chronic or difficult to heal tissue deficits, major constraints exist to a broad application of cell therapy and tissue engineering approaches, i.e. transplantation of “ex vivo” expanded autologous stem/progenitor cells, alone or associated to carrier biomaterials. In order to enable a large number of patients to benefit from a Regenerative Medicine approach, new strategies and new products should be considered. To develop innovative regenerative therapies, we should learn from Mother Nature. In all injured tissues - apart few tissues such as hyaline cartilage - there is a common initial stage after the damage, that is characterized by hematoma, clot formation and platelet activation. Platelets, activated by the injured tissue contact, release a variety of growth factors and bioactive molecules via a degranulation process. These factors and molecules play a significant role in triggering the healing process and are crucial for regulating immune cell migration and the creation of an inflammatory microenvironment at the site of the wound. Following this first inflammatory phase, repair or regeneration of the tissue may occur through paracrine signals activating the revascularization of the wound and recruiting or turning on at the wound site cells with healing potential, such as stem cells, progenitors or undifferentiated cells derived from tissue differentiated cells. Given the triggering role played by platelets in the tissue healing process, we developed new platelet derived products and we propose their local application to treat chronic or acute, often severe, damages in different organ districts.

DUAL CROSS-LINK HYDROGELS WITH TUNABLE VISCOELASTICITY CONTROL STEM CELL DIFFERENTIATION.

Chiara Pizzolitto$_P$[1]

[1] *University of Trieste*

Corresponding author's email: psacco@units.it

Mechanotransduction recapitulates the conversion of external mechanical information into intracellular biochemical response. To this, it was recently recognized that stem cell fate can be markedly influenced by surrounding extracellular matrix (ECM) mechanics. Most of our knowledge in cell mechanobiology has been built using purely elastic materials as model of ECM. However, native tissues do not exhibit purely elastic response but manifest viscoelasticity, that is a time- and frequency-dependence to loading. In fact, recent works have proved that stress-relaxation or plasticity, and more broadly, viscosity-driven processes can be considered as potent modulators of stem cell behavior. To recapitulate native tissue mechanics and provide a more realistic ECM model, here we present unprecedented viscoelastic substrates showing adaptable viscoelasticity. In particular, I will present an innovative dual cross-link gel system based on a chitosan derivative, shortly named CTL, assembled via both temporary and permanent cross-linkers.[1] Concepts related to macromolecular chemistry and physics will be disclosed. Of note, temporary junctions are exploited to finely tune material viscoelasticity. I will show how resulting hydrogels result optimal substrates for cell anchoring upon coating with ECM proteins. Though endowed with similar elasticity, a viscosity-cell function relationship will be unveiled, identifying high viscosity hydrogels as superior materials in fostering stem cell differentiation toward a bone-like phenotype with respect to more elastic counterparts. Taken together, these results lay the groundwork for additional investigations on the role played by substrate viscoelasticity in directing cell-fate decisions.

SUBSTRATE DISSIPATION ENERGY REGULATES CELL ADHESION AND SPREADING

Pasquale Sacco[1], Chiara Pizzolitto[1]

[1] *University of Trieste*

Corresponding author's email: chiara.pizzolitto@phd.units.it

Recent evidences have led to hypothesize that dissipation of energy through viscoelastic extracellular matrix (ECM) could play a cardinal role in directing cell-fate decisions, but whether and how it correlates with specific cell response has remained unclear up to date. In this talk I will introduce substrate dissipation energy as novel cell-fate controller.[1] Specifically, I will illustrate recent findings about viscoelastic and plastic chitosan-based substrates endowed with different dissipative energies capable of modulating cell behavior in terms of adhesion and spreading. While keeping constant stress relaxation and systematically decoupling overall stiffness from linear elongation, we have introduced an energy dissipation term (J/mol), that is the molar energy required to deviate from linear stress-strain regime and enter into plastic region. Strikingly, we have unveiled an inverse relationship between substrate energy dissipation and cell response, with high adhesion/high spreading and low adhesion/no spreading detected for substrates at low and high dissipation energy, respectively. We concluded that cells decide how to react depending on the effective energy they can earmark for their functions. Of note, I will show how combinations of facing 5-consecutive sugars (pentads) composing substrates are essential in damping shear stress, thus behaving as cell traction forces dampers. Collectively, in this talk I will illustrate how the crosstalk between cells and ECM can be considered as energetic in origin.

Introduction: Dysfunctional endothelial cells (EC) can restrict flow in the extremities, leading to limb ischemia. We aim to improving revascularization of ischemic limbs using cell therapy, augmented with spatially patterned scaffolds that promote survival. The purpose was to evaluate the effect spatially patterned scaffolds on endothelial cell survival. Methods: The biophysical parameters of collagen scaffolds (alignment, crosslinking, and fibril diameter) were characterized with atomic force microscopy and degradation assays. Cytoskeletal arrangement of primary human coronary artery ECs and human induced pluripotent stem cell (iPSC)-derived ECs on collagen scaffolds was evaluated by F-actin staining. To evaluate the effect of mechanical properties on cell viability in vitro, Live/Dead and MTS assays were used. Cell seeded scaffolds were implanted into a mouse hindlimb ischemia model, and cell survival was tracked by bioluminescent imaging. Results: Both primary EC and iPSC-ECs reorganized their F-actin cytoskeleton corresponding to the alignment of the fibrils, irrespective of crosslinking degree, stiffness or fibril diameter. When cells were grown in hypoxic mimicking ischemia however, viability was improved using aligned scaffolds with 200 nm fibril diameter. Degradation assays showed that scaffolds with higher crosslinking had significantly more durability. When cell-seeded scaffolds were implanted to the ischemic limb, the aligned scaffolds with 200nm fibril diameter had the highest survival, confirming in vitro studies. Conclusions: Aligned collagen scaffolds with 200nm fibril diameter and high cross-linking degree led to improved viability of primary and iPSC-ECs in a mouse model of PAD.

ENGINEERED BIOMIMETIC HYDROGELS WITH COMBINATORIAL CELL ADHESIVE LIGANDS FOR ANGIOGENESIS

Ngan Huang[P][1], Mahdis Shayan[1], Riley Suhar[1], Sarah C Heilshorn[1]

[1] *Stanford University*

Corresponding author's email: ngantina@stanford.edu

Vascular endothelial cells are a promising cell type for treating ischemic cardiovascular tissues. However, the low survival of transplanted cells is a bottleneck of stem cell therapy. To enhance cell survival and function, we developed a new family of engineered ECMs with independently tunable cell-adhesive biochemical domains. Elastin-like proteins (ELPs) are genetically engineered proteins that promote cell adhesion through customizable amino acid sequences for cell adhesion and provides elasticity and structural support through its elastin-like domain, derived from the elastin VPGXG sequence. ELPs with adhesive ligands (RGD, YIGSR, PLAEIDGIELTY) and non-adhesive ligands (RDG) were developed. We investigated the effect of three cell adhesive ligands (RGD, YIGSR, PLAEIDGIELTY) on endothelial cell survival using. To control the density of adhesive ligands, ELPs containing adhesive ligands were mixed with RDG-ELP at different ratios while maintaining the constant 10mg/ml ELP concentration. We used a systematic Design of Experiment (DOE) approach to determine the individual and combinatorial effects of three ligand concentrations for the survival and function of endothelial cells. Human microvascular endothelial cells were seeded onto ELP arrays and their survival and phenotype were analyzed under conditions of hypoxia (1% O2) and reduced nutrients (1% fetal bovine serum), as is present in ischemic injury sites. We identified combinatorial ELP-RGD and ELP- PLAEIDGIELTY improves cell survival and CD31 phenotype expression in comparison to YIGSR-ELP and individual ELPs. These results suggest that optimal combinatorial ELPs improve the survival and function of endothelial cells under hypoxia conditions and hold great promise for cell delivery for ischemic tissues.

EXTRACELLULAR MATRIX CUES MODULATE ENDOTHELIAL-TO-MESENCHYMAL TRANSITION

Ngan Huang$_P$[1], Maedeh Zamani[1]

[1] *Stanford University*

Corresponding author's email: ngantina@stanford.edu

Introduction: Recent studies demonstrate the occurrence of endothelial-to-mesenchymal transition (EndoMT) within atherosclerotic plaques. The aim of this study is to investigate the effect of mechanical properties of the underlying matrix on progression of EndoMT under inflammatory condition associated with atherosclerosis. We hypothesize that EndoMT is modulated by the stiffness of the underlying extracellular matrix. Materials and Methods: Human coronary artery endothelial cells (HCAECs) were cultured on fibronectin-modified polyacrylamide gels (4 kPa or 100 kPa) or tissue culture plastic (TC, 105 kPa) in endothelial basal media (Lonza) with/without exposure to the inducing agent, transforming growth factor-β (TGF-β (20ng/ml). qPCR and immunostaining of endothelial, mesenchymal, and EndoMT markers, were investigated at for up to 6 days.

Results and Discussion: Results demonstrated that at day 6, HCAECs expressed mesenchymal (α-SMA, SM22, Calponin) and EndoMT (SNAIL,TWIST) markers in a stiffness-dependent manner, where stiffer substrates induced more phenotypic transition. Interestingly, in the presence of TGF- β which is known to induce EndoMT, the hydrogels with physiological stiffness could partially abrogate the expression of mesenchymal markers. Immunofluorescence staining showed that increasing the substrate stiffness, SM22 and calponin protein expression was notably increased. Semi-quantitative analysis of SNAIL expression demonstrated that SNAIL expression was mainly localized in cytoplasm of HCAECs seeded on hydrogels, compared to the cells seeded on TC with higher levels of nuclear expression. Conclusions: Substrate stiffness mediates EndoMT and should be considered in treating atherosclerosis.

SPATIALLY PATTERNED SCAFFOLDS DRIVE ORGANIZED VASCULAR REGENERATION

Ngan Huang$_P$[1], Karina Nakayama[2], Cynthia Alcazar[3], Caroline Hu[3], Thomas Rando[1]

[1] *Stanford University*

[2] *Oregon Health Sciences University*

[3] *Veterans Affairs Palo Alto Health Care System*

Corresponding author's email: ngantina@stanford.edu

Ischemic cardiovascular diseases such as peripheral arterial disease (PAD) can lead to severe occlusion of the blood vessels within the skeletal muscle in the extremities. A successful therapeutic intervention must not only restore tissue vasculature, but also the physiological anatomical structure of microvascular networks. Towards this goal, we developed spatially patterned scaffolds to promote the organized formation of aligned microvascular networks in vivo. Three-dimensional collagen scaffolds having parallel-aligned or randomly-oriented nanofibrils were fabricated and seeded with mouse myoblasts and human microvascular endothelial cells (ECs). The co-cultured cells within parallel-aligned nanofibrillar scaffolds produced endothelialized and aligned myotubes with highly synchronized muscle contractility, as well as cellular alignment along the direction of the parallel-aligned nanofibrils, compared to co-cultured cells on randomly-oriented scaffolds. When co-seeded with myoblasts in aligned scaffolds, ECs secreted significantly more angiogenic and/or myogenic cytokines, than when co-cultured in randomly oriented scaffolds. Transplantation of co-cultured cells on aligned scaffolds into ablated muscle resulted in the formation of parallel-aligned myofibers interspersed with parallel-aligned microvasculature networks, along with significantly greater vascular perfusion, compared to treatment of co-cultures on randomly-oriented scaffolds. This work demonstrates that endothelialized and aligned engineered skeletal muscle promotes organized microvascular network formation, and has therapeutic significance for the treatment of PAD.

Corresponding author's email: ngantina@stanford.edu

Muscle regeneration can be irreversibly impaired by traumatic injuries, despite the high regenerative capacity of skeletal muscle. The objective of this study is to modulate and enhance the regenerative process via myogenic growth factors and in conjunction with rehabilitative exercise for the treatment of volumetric muscle loss. To enhance the regenerative potential of injured skeletal muscle, insulin growth factor-like-1 (IGF-1)-laden nano-patterned anisotropic scaffolds were fabricated by an extrusion process, followed by overnight incubation with IGF-1. Individual scaffolds released a cumulative total of 1250 ng $\pm$ 150 ng of IGF-1 in vitro over the course of 21 days. When implanted into a murine injury model by ablation of the tibialis anterior muscle, the growth factor laden scaffolds in conjunction with voluntary caged wheel exercise could significantly improve the density of isolectin+/CD31+ perfused microvessels by greater than 3-fold in comparison to treatment of constructs without IGF-1. Enhanced myogenesis was also observed in the muscle treated with the IGF-1 laden scaffolds combined with exercise compared to the same IGF-1 laden scaffolds transplanted into mice that did not receive exercise. Furthermore, the abundance of neuromuscular junctions was greater when treated with IGF-1 laden scaffolds in conjunction with exercise, in comparison to the same treatment without exercise. These findings demonstrate that voluntary exercise improved the regenerative effect of growth factor-laden scaffolds by augmenting vascular regeneration and myogenesis, and has important translational implications in the therapeutic design of off-the-shelf therapeutics for the treatment of traumatic muscle injury.

Abstract **#2061**

A PRELIMINARY STUDY OF DECELLULARIZED WHOLE-ORGAN PRE-VASCULARIZATION: A NOVEL APPROACH FOR ORGANOGENESIS

PURPOSE. To examine the suitability of pre-vascularized whole-liver ECM as a site for pancreatic islet transplantation.
METHODS. Whole-Livers from male Lewis rats were decellularized through arterial perfusion of detergents. The decellularized liver scaffold was implanted into Lewis rats and an arteriovenous bundle was passed through the scaffold. At the time of implantation, fresh bone marrow preparation (BM; n=3) or adipose-derived stem cells (ADSCs; n=4), or HBSS (n=4) was injected into the scaffold through the portal vein. After 5 weeks, around 2,600 IEQ of islets were injected through portal vein of the scaffold. The recipient rats were made diabetic by injection of 65 mg/kg STZ i.v., and were followed up by measuring blood glucose and body weight for 30 days. Intravenous glucose tolerance test was performed in the cured animals and samples were collected for immunohistochemical analysis (IHC). Micro-CT images were obtained from one rat in each group for representation.
RESULTS. Two rats in the BM group and one rat in the ADSCs group showed normalization of blood glucose, while one rat from each group showed partial correction of blood glucose. In contrast, no rats were cured in the HBSS group. Micro-CT showed evidence of sprouting from the arteriovenous bundle inside the scaffold. IHC for insulin, BrdU, and vWF is currently ongoing and the results will be provided.
CONCLUSION. Despite the limited numbers, the study showed the promising potential of the pre-vascularized whole-organ scaffold as a novel approach for islet transplantation. Both BM and ADSCs were superior to the acellular scaffold.

CHALLENGES AND OPPORTUNITIES IN CLINICAL TRANSLATION OF HYDROGELS

Jöns Hilborn$_P$[1]

[1] *Uppsala University*

Corresponding author's email: jons.hilborn@kemi.uu.se

We selected hyaluronic acid (HA) as suitable starting material for the design of tissue inductive hydrogel systems with potential for clinical translation. Key decisive factors included earlier demonstrated safety, the possibility of sterilization, non-immunogenicity, quality assurance, IPR and cost-effectiveness. HA was derivatized to permit surgically acceptable sterile handling with mixing, injection and suitable gel formation by click type hydrazide/hydrazone formation. Growth factor stability, cytotoxicity, genotoxicity and preclinical toxicity studies proceeded translation to bone regeneration and MSC based therapies. Interestingly, calcium phosphate filler in HA gels allow rapid angiogenesis and facile large bone formation even with limited amounts of growth factors which were not predictable from in-vitro evaluations. In general, extrapolation from in vitro data to in vivo responses is often inappropriate. Therefore, we employed an iterative strategy including early in vivo screening, e.g. multiple subcutaneous injections in the rat model allowing reference in the same animal, to adjust our system before large animal studies. We took utterly care of our pigs to assure low-stress levels as stress known to influence the outcome. Our learning is that reducing complexity is a must when facing the roadblocks of reality when moving towards translation. Also, HA-based hydrogels, and many other gels, have inherent limitations that include unwanted swelling in vivo and low mechanical strength. They are rarely strong enough to be attached to tissues with current surgical techniques or even to shape-holding prefabricated structures.

AI-MEETS CELL MORPHOLOGY: A NEW BIOLOGICAL BIG DATA FOR CELL EVALUATION

Ryuji Kato[P][1]

[1] *Graduate School of Pharmaceutical Sciences, Nagoya University*

Corresponding author's email: kato-r@ps.nagoya-u.ac.jp

Morphology of cells has been important and trustworthy information to monitor cellular status non-invasively. From the beginning of cell culture history till now, such cellular morphological information is one of the most practically used techniques in cell culture, and it is still an essential skill for cell biologists to control cellular quality. However, such morphological information had long been evaluated subjectively by the intentionally measured parameters or by champion image selected from the culture vessel.

However, by the advances of hardware technology that enable automatic and comprehensive imaging, combined with other rapid growing technologies in artificial intelligence (AI)-related technologies, such image-derived morphological information is now becoming to be expected as a new biomarker to non-invasively evaluate the cells quantitatively.

Our group has long been reporting various applications of such AI-guided morphological cell evaluation methods for cellular quality evaluation [1,2]. This technique is now strongly expected as one of the most effective tools to monitor cellular quality during the massive cell manufacturing in cell therapies.

We here summarize the application possibilities and its technological advancements in such AI-guided morphological cell evaluation technology and introduces its important applicability in understanding the scaffold design for more effective tissue engineering.

Monocyte chemoattractant protein-1 (MCP-1) is one of the pro-inflammatory chemokine that is positively expressed in atherosclerotic plaque and in the intimal area during arterial injury. Selection of the suitable chemokines with the combination of cytokines may have a promising effect on halting the progression of intimal hyperplasia. The objective of this study was to determine the effect of MCP-1 in enhancing macrophage and monocyte cell adhesion. 10ml of venous blood was acquired from adult healthy volunteers after obtaining written consent. PBMCs isolation was performed within 1 hour of blood collection using SepMate tubes. Isolated PBMCs were resuspended in the endothelial cells growth medium and seeded onto 48-well plate, that were firstly coated with either 1ng/ml, 20ng/ml or 50 ng/ml of MCP-1. The cells with a seeding density of 1.2 × 105 cells per well were incubated for 90 minutes at 37°C. Non-adherent cells were removed and attached cells were fixed and mounted. Photomicrographs of the adherent cells were captured and quantified manually in ten representative fields per well. After 90 minutes of incubation, the cultured cells in the plate coated with 50ng/ml of MCP-1 showed significantly higher cell attachment (32794.12 ± 19007.28 cell/cm2) compared to the cells cultured on 20ng/ml (25500 ± 10697.96 cell/cm2), 1ng/ml (21156.86 ± 7833.85 cell/cm2) of MCP-1 and control group without coating (11617.65 ± 3045.24 cell/cm2), respectively. Hence, we concluded that MCP-1 chemokines coating provides the suitable niche environment in enhancing macrophage and monocyte cell adhesion, which could potentially be used for future vascular re-endothelialisation.

TISSUE-ENGINEERING THE UPPER RESPIRATORY TRACT

Nick Hamilton[P][1]

[1] *University College London*

Corresponding author's email: nick.hamilton@ucl.ac.uk

Cases of human bioengineered circumferential tracheal implants have been complicated by poor mucosalization following implantation resulting in infection, mucostasis and airway obstruction. We investigated methods of regenerating a respiratory epithelial graft that could be used as part of a bioengineered transplant to replace a damaged section of the upper airway.

The optimal extracellular matrix environment for respiratory epithelial cell attachment and proliferation was examined. Collagen IV was shown to be the leading protein mediating epithelial attachment acting via the integrin α2β1 and a Src and FAK mediated intracellular pathway. Laminin played a key role in respiratory epithelial cell proliferation and was dependent on an integrin pathway containing the subunit β1.

Biological, synthetic and biomimetic scaffolds were compared for their suitability to sustain and differentiate a respiratory epithelial layer. A human dermis scaffold was found to preserve a collagen IV and laminin layer following decellularization and was used to successfully regenerate a full thickness human respiratory epithelial layer containing mucus secreting goblet cells and motile ciliated epithelium.

The regenerated layer was implanted onto a section of pre-vascularized decellularized trachea in-vivo, although differentiation markers were lost following one week of implantation. This demonstrated the limitations of implanting full-thickness layers and led to an alternative strategy utilizing respiratory basal cells protected in a dehydrated collagen matrix. Trials using this method successfully established a long-term epithelial layer on decellularized trachea in-vivo.

This approach provides an effective method for re-epithelizing hollow-organs and overcomes the key rate-limiting step of an inadequate epithelial barrier following implantation.

Fractalkine (CX3CL1) is a type of chemokines that plays a substantial role in inflammatory vascular disorders. Cytokine and chemokine have the potential to be utilised as recruitment factors to target inflammatory related diseases. Thus, this study aims to evaluate the effect of different concentration of CX3CL1 in promoting macrophage and monocyte adhesion. 10ml of venous blood collected with consent from healthy subjects. Peripheral blood mononuclear cells (PBMCs) was isolated using SepMate tubes and resuspended in endothelial cells growth medium. PBMCs were then seeded onto 48-well plate that was pre-coated with 1ng/ml, 20ng/ml and 50 ng/ml of CX3CL1. The cells with a seeding density of 1.2 × 105 cells per well were incubated for 90 minutes at 37°C. Non-adherent cells were removed and attached cells were fixed and mounted. Photomicrographs of the adherent cells were captured and quantified manually in ten representative high-powered image fields (40X magnification) per well. Cell quantification shows that plate coated with 1ng/ml of CX3CL1 exhibit higher monocyte/macrophage attachment (28764.71 ± 1373.66 cell/cm2) as compared to plates coated with 20ng/ml (24823.52 ± 15983.59 cell/cm2) and 50ng/ml (20941.17 ± 12886.83 cell/cm2) of CX3CL1. The control group without coating display the lowest cell yield (16470.58 ± 645.27 cell/cm2). As a conclusion, this preliminary data suggests that CX3CL1 promotes macrophage and monocyte adhesion at a minute concentration of 1ng/ml and has the potential to be applied in vascular graft re-endothelisation and repair.

Corresponding author's email: ragh@zhaw.ch

All cultured cells were in a context of other cells and a meshwork of extracellular matrix (ECM) that was richly decorated with growth factors, exosomes, and matricellular ligands. Abruptly removed from their former microenvironment, cells must survive in vitro on stiff plastic and hold onto adhesive proteins adsorbed from serum or coatings. As cells have co-evolved with ECM, they developed respective receptors, such as integrins. Obviously, these receptors did not evolve to recognise titanium alloys, thermoplastic polymers, or hydrogels. Therefore, these materials need to be endowed with peptide sequences that represent recognition signals for receptors mediating cell adhesion. In all the excitement about new components and shapes of biomaterials and their "functionalisation", the ability of the cells to make their own microenvironments has been widely neglected. Ironically, cells in culture can make ample ECM microenvironments, but our standard aqueous culture conditions do not let them. This can be remedied by recreating conditions of macromolecular crowding (MMC). Following up on John Bateman's work in the early 90ies, I have been developing MMC systematically for tissue engineering to empower cells to make their own microenvironments. Using MMC we have been able to create substantial ultraflat 3D matrix environments that greatly influence stem cell differentiation via dynamic cell-matrix reciprocity. MMC-treated monolayer cultures show cells embedded in ECM cocoons, reflected by surround expression of focal adhesions, even on top of cells. This mechanobiological feature, brought about by MMC, is able to unlock a brown differentiation repertoire in human bone marrow-derived stem cells.

Joint surface defects in articulating joints have limited healing potential and can extend into the underlying subchondral bone. In most patients, osteochondral defects evolve into chronic osteoarthritic disease, when left untreated. Tissue engineering strategies therefore aim at treatment of joint surface defects in an early stage. One approach focuses on cell-based 3D constructs capable of regenerating damaged tissue. However, lacking process reproducibility and limiting design complexities have hampered translation into clinically relevant products. Recent advances in additive manufacturing have paved the way for extrusion-based bioprinting, an enabling technology that could overcome these limitations. In this study, methacrylated gelatin (gelMA) was combined with human iPSC-derived chondrocytes, as a bioink to produce cartilaginous tissue analogs. After crosslinking the bioink with Li-TPO-L photo-initiator (365nm) in polytetrafluorethene moulds, cell-laden gel constructs (4x4x2mm³) were cultured in chondrogenic medium for 28 days. Histology showed homogeneous cell distribution, with increasing amount of cells, as also confirmed by DNA quantification. The cell-laden constructs were Alcian Blue- and Safranin O-positive, showing sulphated glycosaminoglycan (GAG) deposition uniformly distributed throughout the construct. Pericellular collagen type II deposition throughout the constructs was shown with immunohistological stainings, whereas collagen type I was only present on the outer surface. Gene expression corroborated with histology, showing upregulation of ACAN, COL2A1 and COL1A1. Taken together, these data indicated that hiPSC-derived chondrocytes encapsulated in gelMA are able to maintain their phenotype and produce cartilage matrix in vitro. This suggests that the formulation can serve as a promising bioink for bioprinting strategies aiming to produce stable cartilage implants.

WHAT INDUSTRY NEEDS FROM RESEARCHERS FOR A SUCCESSFUL HARD/SOFT TISSUE ADHESIVE PRODUCT?

Jens Thies[P][1]

[1] *DSM Biomedical*

Corresponding author's email: jens.thies@dsm.com

Whilst there are many exciting and promising lines of biomaterials research that may lead to the breakthroughs of tomorrow, one of the greatest challenges today is how to commercially translate these successfully from lab to patient. The requirements for an evidence-based approach and the new MDR requirements make disruptive innovation in biomaterials harder today than ever.

One of the clinical dreams is a tissue adhesive that could enable clinicians to easily and safely repair a broad range of tissue types. There have been many candidates proposed over the last 50 years. These fall broadly into two groups: synthetic chemically engineered and bioinspired biomimetic adhesives. Example of the former are n-butyl cyanoacrylates and novel polyurethanes whilst the latter includes adhesives derived from biology such as fibrin glues and adhesive proteins from a range of animal and plant sources. The mechanisms of adhesion differ and some may fall into drug regulation and others may be considered devices.

The human body contains a broad range of tissue types and despite the advances in surgical techniques and materials there are many unmet clinical needs where an adhesive technology would augment or even replace current state of the art materials. Examples such as meniscal tear repair where sutures are the main attachment strategy and a safe and effective adhesive technology would transform each procedure.

Any new paradigm of treatment with an adhesive has to have a well thought out patient journey that clearly demonstrates the clinical benefit to patient, surgeon and ultimately the healthcare providers.

MECHANISTIC MATHEMATICAL MODELLING FOR REGENERATIVE MEDICINE

Sarah Waters[P][1]

[1] *Mathematical Institute, University of Oxford*

Corresponding author's email: waters@maths.ox.ac.uk

Successful clinical translation of regenerative medicine therapies requires robust preclinical tools for safety and efficacy. Typically, preclinical toolkits integrate in vitro and in vivo approaches. In this talk, I will showcase how mathematical modelling, in combination with in vitro and in vivo experimental approaches, can enhance the predictive capability of preclinical research and facilitate the optimisation of safe clinical cell therapies. We demonstrate the enormous potential for embedding in silico predictive mathematical modelling into preclinical toolkits to boost the clinical translation of preclinical research.We consider mathematical modelling of cell therapies. In cell therapies, stem cells are delivered to damaged tissues to promote their regeneration. We show how a mechanistic mathematical approach can model how cells reach the injury site, e.g. by labelling cells with magnetic particles and using externally applied magnetic fields to guide the cells to the target site; provide insights into the immune response; assess the degree of cell engraftment within the injury site; and determine how the cells can be modified, e.g., via encapsulation, to optimise their therapeutic role.

REGENERATIVE INTERVENTIONS USING STEM CELLS SECRETOME IN INJURY AND DEGENERATION OF THE CENTRAL NERVOUS SYSTEM

Antonio J Salgado[P][1]

[1] *ICVS, School of Medicine, University of Minho, Braga, Portugal*

Corresponding author's email: asalgado@med.uminho.pt

The low regeneration potential of the central nervous system (CNS) represents a challenge for the development of new therapeutic strategies. Mesenchymal stem cells (MSCs) have been proposed as a possible therapeutic tool for CNS disorders, namely due to the beneficial actions of their secretome. Indeed, the latter possesses a broad range of neuroregulatory factors that promote an increase in neurogenesis, inhibition of apoptosis/glial scar, immunomodulation, angiogenesis, neuronal and glial cell survival, as well as relevant neuroprotective actions into different pathophysiological contexts. Considering their protective action in lesioned sites, MSCs, and their secretome, might also improve the integration of local progenitor cells in neuroregeneration processes. In this sense their use could represent an important vehicle for the establishment of future CNS regenerative therapies. In the present talk the role of MSCs, and their secretome, on phenomena such as in vitro and in vivo neuronal/glial survival will be addressed. Additionally, their possible applications, for Parkinson's Diseases and Spinal Cord Injury regenerative medicine will also be presented.

Abstract **#2073**

NOVEL LIPOSOMAL DRUG DELIVERY AND TARGETING APPROACHES FOR TISSUE REGENERATION

Sophia G Antimisiaris[P][1,2]

[1] *University of Patras, Greece*

[2] *FORTH/ICES, Greece*

Corresponding author's email: santimis@upatras.gr

The application of liposomal nanotechnology for the development of advanced drug delivery systems, has led to systems with exceptional advantages in terms of the therapeutic effect achieved. Many problems for administration of drugs, that are related with either the low stability and/or unfavorable physicochemical properties (high molecular weight, low permeability through biological barriers, low solubility), can be solved by innovative liposomal nanomedicines.
In the last years the use of liposomal systems for delivery of bioactive agents, such as growth factors, antibiotics, small molecule drugs, etc. as a strategy to enhance tissue regeneration, has been initiated. Liposomes may be used as independent drug delivery systems for administration of bioactives, or they may be associated/immobilized or embedded with or on different types of biomaterials (such as stents, catheters, injectable in situ forming gels, electrospun membranes, etc). The different possibilities, related methodologies, together with examples of the advantages towards tissue regeneration, will be analyzed.

Abstract **#2074**

CELLULAR SENESCENCE, SENOLYTICS, AND PROGENITOR FUNCTION: IMPLICATIONS FOR TISSUE REGENERATION AND TRANSPLANTATION

James L. Kirkland$_P$[1]

[1] *Mayo Clinic*

Corresponding author's email: kirkland.james@mayo.edu

Senescent cells (SC) accumulate in multiple tissues with aging and at etiologic sites of numerous diseases. Some SC release pro-apoptotic, inflammatory, tissue-damaging factors and spread senescence to normal cells, the “senescence-associated secretory phenotype” (SASP). SCs are resistant to apoptosis. SC can contribute to wound healing, but pre-existing or persistent SCs may delay this. SC and the SASP can cause stem cell/progenitor dysfunction. Adipose mesenchymal stem cell replication and differentiation into insulin-responsive adipocytes are interfered with by SASP factors. SCs interfere with cardiac and bone progenitor function and neurogenesis. Transplanting SCs into younger mice such that 1/10,000 cells are transplanted SCs causes frailty, accelerated onset of age-related diseases, and early mortality. Hearts transplanted from old into young mice function less effectively than hearts transplanted from young mice, related to mitochondrial DNA release by SCs in the old transplanted organ, inducing tissue dysfunction, immune activation, and rejection, further interfering with repair.

Senolytic agents promote apoptosis of SCs selectively. Intermittent senolytics alleviate multiple age- and chronic disease-related conditions in mice. Senolytics prevent frailty, accelerated chronic disease onset, and early death caused by transplanting SCs into younger mice. Senolytics improve function of hearts transplanted from old mice. In old mice, senolytics improve physical function, delay age-related diseases as a group, and increase remaining median lifespan. Early clinical trials demonstrated senolytics remove SCs from adipose tissue of diabetic humans and might reduce frailty in patients with idiopathic pulmonary fibrosis. Clinical trials of senolytics for several chronic diseases, geriatric syndromes, and impaired physical resilience are underway.

Despite considerable research in developing biological wound dressings in enhancing the injury closure in the short term, their potential in reducing the formation of scars is limited. Here, using 3D printing we developed biomimetically designed medical-grade polycaprolactone (mPCL) dressings with critically adjusted pore size and anisotropic mechanical characteristic which favor skin wound healing. Melt electrowritten mPCL dressings were seeded with human gingival tissue multipotent mesenchymal stem/stromal cells (MSC) and cryopreserved using a clinically approved method of cryopreservation. Next, the regenerative potential of fresh or frozen cell-seeded mPCL dressing was assessed in a splinted full-thickness excisional wound in a rat model over six weeks. Application of mPCL dressings delayed the wound contraction and led to skin regeneration through granulation and re-epithelialization. Together, the use of bioactive mPCL dressings able to induce contractile forces and promote active wound closure with reduced scar tissue formation and ultimately improves patient outcomes.

CLINICAL APPLICATION OF FIBRIN-AGAROSE BASED HUMAN BIOARTIFICIAL TISSUES

Antonio Campos[P][1,2]

[1] *Department of Histology and Tissue Engineering*

[2] *University of Granada. Spain*

Corresponding author's email: acampos@ugr.es

Several models of human bioartificial tissues and organs have been described and evaluated ex vivo. However, very few of these models have been translated to the clinical setting as advanced therapies medicinal products (ATMP). One of the biomaterials showing promising results is the combination of human fibrin and 0.1% agarose, which demonstrated to be highly biocompatible and fulfils the requirements for clinical translation. In this regard, the Tissue Engineering Group of the University of Granada was able to design and fabricate in the laboratory different types of bioartificial human tissues based on fibrin-agarose biomaterials, and performed a thorough preclinical characterization of these tissues for clinical use. As a result of this preclinical characterization, we were able to implement a clinical trial to evaluate a novel model of human bioengineered cornea in patients with severe corneal ulcers (ClinicalTrials.gov Identifier: NCT01765244), and we obtained approval from the Spanish National Medicines Agency for compassionate use of a model of human skin that is currently used for the clinical treatment of severely burnt patients. Preliminary results of both models are promising and support the clinical use of tissues generated by tissue engineering as ATMP.

[2] *Stem Cell Institute, University of Minnesota-Twin Cities*

[3] *Institute for Engineering in Medicine, University of Minnesota-Twin Cities*

Corresponding author's email: ogle@umn.edu

Cardiac tissue engineering has emerged as a means to create living, human, cardiac tissue outside the body as a model system in the near term and as a clinical replacement for diseased or damaged cardiac muscle in the long term. One goal of cardiac tissue engineering is the generation of a living, human pump in vitro that could replace animal models and eventually serve as an in vivo therapeutic. Models that replicate the geometrically complex structure of the heart, harboring chambers and large vessels with soft biomaterials, can be achieved using 3-dimensional bioprinting. Yet, inclusion of contiguous, living muscle to support pump function has not been achieved. We optimized a photo-crosslinkable formulation of native ECM (extracellular matrix) proteins and used this bioink to 3-dimensionally print human induced pluripotent stem cell-laden structures with 2 chambers and a vessel inlet and outlet. After human induced pluripotent stem cells proliferated to a sufficient density, we differentiated the cells within the structure and demonstrated function of the resultant human chambered muscle pump. Human chambered muscle pumps demonstrated macroscale beating and continuous action potential propagation with responsiveness to drugs and pacing. The connected chambers allowed for perfusion and enabled replication of pressure/volume relationships fundamental to the study of heart function and remodeling with health, disease, and interventional therapeutics.

mRNA-BASED THERAPEUTICS: NEW CLASS OF MEDICINES IN REGENERATIVE MEDICINE

Elizabeth Rosado Balmayor[P1,2]

[1] *MERLN Institute for Technology-Inspired Regenerative Medicine, Maastricht University, Maastricht, the Netherlands*

[2] *Musculoskeletal Gene Therapy Research Laboratory, Mayo Clinic, Rochester, USA*

Corresponding author's email: e.rosadobalmayor@maastrichtuniversity.nl

Increasing attention is being paid to the use of RNA as agents to facilitate tissue healing. Messenger RNAs (mRNAs) introduced into the cell induce synthesis of their encoded proteins. This approach holds advantages over traditional DNA-based gene therapy including improved cell internalization and higher transfection efficiencies, without disruption of the host genome. In the context of tissue engineering and regenerative medicine, the eventual turnover of the exogenous RNA is a further advantage. Because conventional RNAs have strong immunogenicity and low stability, chemical modifications are needed to facilitate their therapeutic application. Moreover, efficient delivery systems are of crucial importance for efficient cell internalization. This talk will cover progress on mRNA therapeutics with a focus on tissue engineering and regenerative medicine. Particular interest will be placed on applications of mRNA for musculoskeletal regeneration. The presentation will transit from mRNA biology and biochemistry to internalization of RNA using different biomaterials and non-viral delivery systems, ending with novel applications reported for the regeneration of diverse tissues. In terms of chemical modifications, use of modified nucleotides, UTRs, optimized poly(A) tails among others will be reviewed. Regarding RNA delivery, examples of novel lipid and polymer delivery systems will be shown. Also, advantages of mRNA internalization techniques (magnetofection) will be highlighted. Finally, examples of preclinical studies on mRNA applications to enhance the regeneration of tissues including bone and tendon will be discussed. Overall, this talk will give an overview of the cmRNA technology from basic aspects to preclinical proof of concepts.

Supplement-free induction of macrophage polarization solely through the topography of materials is an auspicious strategy but has so far significantly lacked behind the efficiency and intensity of media-supplementation based protocols. The project Design2Heal was initiated in 2013 with the aim to identify structural design criteria for the fabrication of scaffolds with strong topographic immunomodulation for human monocyte-derived macrophages. We started by applying Melt-Electrowriting (MEW) for the fabrication of fibrous 3D scaffolds made from poly(ε-caprolactone) (PCL) and advanced the precisely defined inter-fiber spacing from 100 µm down to 40 µm for a variety of pore geometries (rectangular, triangular and round). These scaffolds did facilitate primary human macrophage differentiation towards the M2 type, which was most pronounced for box-shaped pores with 40 µm inter-fiber spacing, but not with the desired efficiency. We then found that human monocyte-derived macrophages show a strong M2a like pro-healing polarization when cultured on type I rat-tail collagen fibers but not on collagen I films. Therefore, we hypothesized that highly aligned nanofibrils also of synthetic polymers, if packed into larger bundles in 3D topographical biomimetic similarity to native collagen I fibers, would induce a localized macrophage polarization. Through integration of flow directed polymer phase separation into MEW we developed Melt-Electrofibrillation, a process that yields nano-fiber bundles with a remarkable structural similarity to native collagen I fibers, particularly for medical grade PCL. These biomimetic fibrillar structures indeed induce a pronounced elongation of human monocyte-derived macrophages and unprecedentedly triggered their M2-like polarization similar in efficacy as IL-4 cytokine treatment.

Recently, we have seen a dramatic increase in groups using 3D culture to study cell behaviour. We now have a plethora of options for cell encapsulation and recent developments have provided elegant models incorporating one or more features such as multiple cell types, optogenetic control, microfluidics, high-throughput culture and complex analyses. For our group, the next challenge has been to understand what local interactions and forces encapsulated cells are experiencing. To achieve this, we have developed an interdisciplinary tool-box, allowing us to build then interrogate 3D cell-matrix models. We make use of induced pluripotent stem cell (iPSC) lines engineered to produce modified matrix, focusing primarily on glycosaminoglycans. We typically encapsulate these in a synthetic, self-assembling peptide hydrogel that we can functionalise with specific matrix components but which also allows us to study matrix deposition on a blank canvas background. We are also part of a team building a new instrument, that combines light sheet microscopy, optical trapping and multi-plane imaging (http://nu-sense.ac.uk). We can image live encapsulated cells in 3D at depth with good resolution over multiple days. If we incorporate beads into the gels, multiplane imaging allows us to record the Brownian motion of a bead in the z-axis, as well as in the x, y imaging plane, sensing the full 3D micro-rheology of the matrix. This allows us to probe local variations in the rheological properties of matrix close to the cells and to test the impact of differential matrix secretion by encapsulated cells, linking to their biological response.

CHALLENGES AND OPPORTUNITIES IN BIOENGINEERING AND BETA CELLS REPLACEMENT DEVICES

Aart van Apeldoorn[P][1,2]

[1] *Maastricht University*

[2] *MERLN institute for technology-inspired regenerative medicine*

Corresponding author's email: a.vanapeldoorn@maastrichtuniversity.nl

In the past decade a lot of new advances have been made regarding beta cell replacement devices. Developments in stem cell derived beta cell research have created opportunities to use these as an alternative to primary human islets. The consensus in the field is that beta cells still need to be delivered to patients with the help of a tailor-made implant. There is a current trend in the field where a shift in interest can be seen from immunoprotective closed devices, to open devices which allow the transplanted cell to be connected directly to the patient's vasculature. Both these strategies have advantages and disadvantages, the closed devices allow for protection against immune rejection omitting the use of immunosuppressive therapy, but with potential diminished mass transport to and from the transplanted cells, while the open devices allow for good mass transport and a more direct response of beta cells to changing glucose levels, but also come with the downside of immunosuppressive therapy. In the same time there is also growing interest in how perhaps the cell biomaterial interactions of materials used in these devices can be improved by the addition of biological factors. The goal is to give a comprehensive overview of the current trends and discuss opportunities how these challenges can potentially be addressed to improve beta cell replacement therapy to tackle type 1 diabetes.

BIOARTIFICIAL PANCREAS DEVICES FOR TREATMENT OF DIABETES – AN INTERDISCIPLINARY CHALLENGE

Barbara Ludwig[P][1]

[1] *University Hospital Carl Gustav Carus Dresden at the Technische Universität Dresden*

Corresponding author's email: barbara.ludwig@uniklinikum-dresden.de

The treatment options for diabetes mellitus have expanded considerably in recent years. In the next decade, a combined and concerted application of pharmacological, biotechnological and cell-based treatment strategies could revolutionize therapy. The decisive factor here is the interaction of fundamentally oriented and clinically active scientists in the fields of diabetology, cell biology, immunology and transplantation medicine, but also of materials scientists and biotechnologists. The common goal should be to establish individualized and safe forms of therapy for a broad patient population. The therapy goals are based on quality of life and prolongation of life without relevant late complications.
Islet transplantation has evolved into an established therapy for patients with type 1 diabetes. However, a widespread application is hampered by mandatory requirement of life-long immunosuppression, the shortage of cadaveric donor pancreata, and the limited lomg-term survival of transplanted cells. Therefore, eliminating immunosuppression, safe utilization of alternative insulin-producing cells and promoting long-term islet survival are key features for moving this therapy to larger scale application. Macroencapsulation devices as a delivery strategy could potentially target all three aims. Numerous encapsulation devices have been designed that combine immunoprotective properties and allow for free exchange of effector molecules. Major advances have been achieved in encapsulation technology, and some strategies are in translation to clinical application. However, there are still issues that need to be resolved associated with biocompatibility, graft oxygenation, immunprotection, inflammatory response, and the applicable islet mass.

ENGINEERED BIOMATERIALS FOR IN SITU TISSUE REGENERATION

Akhilesh K Gaharwar[P][1]

[1] *Texas A&M University*

Corresponding author's email: gaharwar@tamu.edu

Biomaterials engineered with tunable biophysical properties, specific biochemical cues, and complex architecture have emerged as powerful tools for regeneration medicine. These cues are required to induce regeneration by modulating extracellular microenvironment for in situ tissue repair. In this talk, I will outline some of the biomaterial approaches that we have developed to control and direct the body's regenerative capacity for tissue-specific regeneration. Specifically, we have utilized genome wide sequencing assays (transcriptomics) to understand complex cell-biomaterials interactions. These omics-based approaches provide an unbiased global view of the cellular activity with pivotal insights about the affected cellular pathways to optimize synthetic biomaterials for tissue engineering. In addition, I will discuss biomaterials loaded with bioactive cues that prime endogenous cells to perform tissue-specific regeneration. Furthermore, I will also show some of our recent work on 3D bioprinting to develop physiologically relevant tissue structures for disease modeling (vascular pathophysiology) and tissue engineering (bone and cartilage regeneration).

PERFUSION AND ENDOTHELIALIZATION OF ENGINEERED TISSUES WITH PATTERNED VASCULAR NETWORKS

Jordan S Miller[P][1]

[1] *Rice University*

Corresponding author's email: jmil@rice.edu

As engineered tissues progress toward therapeutically relevant length scales and cell densities, it is critical to deliver oxygen and nutrients throughout the tissue volume via perfusion through vascular networks. Furthermore, seeding of endothelial cells within these networks can recapitulate the barrier function and vascular physiology of native blood vessels. Here, we describe how to fabricate and assemble customizable open-source tissue perfusion chambers and catheterize tissue constructs inside them. Human endothelial cells are seeded along the lumenal surfaces of the tissue constructs, which are subsequently connected to fluid pumping equipment. The protocol is agnostic with respect to biofabrication methodology as well as cell and material composition, and thus can enable a wide variety of experimental designs. It takes ~14 h over the course of 3 d to prepare perfusion chambers and begin a perfusion experiment. We envision that this work will facilitate the adoption and standardization of perfusion tissue culture methods across the fields of biomaterials and tissue engineering.

Myotonic dystrophy type 1 (DM1) is the most common hereditary myopathy in adults. The disease is characterized by progressive skeletal muscle degeneration that produces severe disability. There is still no effective treatment for DM1 patients, but new therapeutic strategies are being tested. Animal models and in vitro 2D cell cultures have been essential for these advances. However, these models cannot reproduce the biological complexity of the disease. Biofabrication tools can be applied to engineer human 3D culture systems that complement current preclinical research models.

Here, we describe the development of the first in vitro 3D model of DM1 human skeletal muscle. Patient-derived cells were encapsulated in micromolded gelatin methacryloyl-carboxymethyl cellulose methacrylate (GelMA-CMCMA) hydrogels through photomold patterning. These hydrogels present a microstructured topography that promotes myoblast alignment and differentiation, resulting in highly aligned myotubes from healthy and DM1 cells. The DM1 3D microtissues present the molecular alterations detected in patient biopsies. Importantly, fusion index analyses demonstrate that 3D micropatterning significantly improved DM1 cell differentiation into multinucleated myotubes compared to standard cell cultures. Moreover, characterization of the 3D cultures of DM1 myotubes detects a reduced thickness of myotubes that can be used for drug screening. Therefore, we evaluated the therapeutic effect of antagomiR-23b administration on bioengineered DM1 skeletal muscle microtissues. AntagomiR-23b treatment rescues both molecular DM1 hallmarks and structural phenotype, restoring myotube diameter to healthy control sizes. Overall, these new microtissues represent an improvement over conventional models and can be used as biomimetic platforms to establish preclinical studies for myotonic dystrophy.

DIGESTION DEGREE IS A KEY FACTOR TO REGULATE THE PRINTABILITY OF PURE TENDON DECELLULARIZED EXTRACELLULAR MATRIX BIO-INK IN EXTRUSION-BASED 3D CELL PRINTING

Fengyuan Zhao[P][1]

[1] *Department of sports medicine, Peking university third hospital.*

Corresponding author's email: fengyuanzhaopku@gmail.com

Improving the printability of pure, decellularized extracellular matrix (dECM) bio-ink without altering its physiological components has been a challenge in three-dimensional (3D) cell printing. To improve the printability of the bio-ink, we first investigated the digestion process of powdered dECM material obtained from porcine tendons. We manifested the digestion process of tendon derived dECM powders, which includes dissolution, gelatinization and solubilization. After a short dissolution period (around 10 min), we observed a 'High viscosity slurry' status (3 h) of the dECM precursors, i.e. the gelatinization process, followed by the solubilization processes, i.e. a 'Medium viscosity slurry' period (12 h) and a 'Low viscosity slurry' period (72 h). Although the 'Low viscosity slurry' status of the dECM bio-ink has been reported to be extrudable, it has poor printability. This study explores the printability of the 'High viscosity slurry' status of the dECM bio-ink, which has not been addressed thus far. The results demonstrate that this less digested status of the dECM bio-ink yields higher shape fidelity and stacking accuracy than the traditional over-digested status of the dECM bio-ink; this indicates better printability of this less digested dECM bio-ink. Bone marrow mesenchymal stem cells derived from rats was printed using the 'High viscosity slurry' status of the dECM bio-ink, yielding high cellular viability lasting for 7 d after printing. Thus, the 'High viscosity slurry' status of tendon dECM bio-ink can be utilized to fabricate complicated 3D organoid structures; it also shows promise for applications such as regenerative medicine and biomimetic tissue engineering.

Tendinopathy is a common injury in human and equine athletes and the poor success with conventional therapy supports the need for novel treatments. Representative in vitro models are mandatory to facilitate translation of fundamental research into clinical therapies. Natural biomaterials provide favourable cell binding characteristics and are therefore appropriate to establish such a model. In this study, we seeded equine tenocytes onto four different hydrogels: methacrylated gelatin (gel-MA, 100% degree of substitution, DS), norbornene-functionalized gelatin (gel-NB, 85% and 55% DS) crosslinked with DTT and gel-NB (85% DS) crosslinked with thiolated gelatin (gel-SH, 75% DS). The physico-chemical properties (1H-NMR spectroscopy, gel fraction, swelling ratio, and storage modulus), cell characteristics (proliferation, viability, and morphology) and functionality (RT-qPCR) were evaluated and compared to tissue culture plastic (TCP). The thiol-ene based hydrogels showed a lower gel fraction/storage modulus and a higher swelling ratio compared to gel-MA. Viability on all hydrogels exceeded 95%, indicating excellent biocompatibility. At 14 days, significantly less tenocytes were observed on gel-MA compared to the thiol-ene crosslinked gelatin, and tenocytes on gel-NB85/DTT and gel-NB55/DTT showed the characteristic elongated morphology more in contrast to TCP and gel-MA. No significant difference in extracellular matrix gene expression (COL1A1, COL3A1, TNC & DCN) was observed on gelatin discs vs TCP, confirming the suitability of gelatin for tenocyte culture. In conclusion, thiol-ene crosslinked gelatins are preferred over gel-MA when considering physico-chemical characteristics and cell responses. These data improve our knowledge on the interaction between natural biomaterials and tenocytes, essential to establish a representative tendon model.

AN ECHO IN CARTILAGE BIOLOGY: COMBINATORIAL TREATMENTS INDUCE A SWITCH BETWEEN TRANSIENT AND PERMANENT CARTILAGE PHENOTYPES

Sakshi KhuranaP[1], Jacqueline Plass[1], Stefano Schivo[2], Marcel Karperien[1], Janine Post[1]

One of the fundamental questions in cartilage biology is: what determines the switch between permanent cartilage found in the articular joints and transient hypertrophic cartilage in the growth plate that functions as a template for bone? This switch is observed both in a subset of osteoarthritis patients that develop osteophytes, as well as in cell-based tissue engineering strategies for joint repair. Cell based cartilage repair strategies suffer from inefficient chondrogenesis and hypertrophy1,2. A thorough understanding of the mechanisms regulating cell fate will provide opportunities for treatment of cartilage disease as well as in tissue engineering strategies.

Because of the inherent complexity of regulatory networks, they cannot be efficiently analysed and understood without computational assistance. To obtain insight into the function of such complex networks we developed a dynamic computational model of chondrocytes, the Executable CHOndrocyte or ECHO3. This signaling network integrates 8 signal transduction pathways: WNT, BMP, TGFβ, IHH, IGF, PTHrP, HIF1, and the FGF. The entire network is represented by ~100 nodes and ~300 interactions. This model gives output in the form of SOX9+ and RUNX2+ active states, representing the permanent articular and hypertrophic phenotype of chondrocytes, respectively.

We used model checking in ECHO to predict combinatorial treatments that induce the switch from a transient cartilage to permanent cartilage and vice versa. Here, we show experimental validation of the computer model predictions ex vivo (metatarsals) and in vitro (cell culture) and provide insight into processes determining cartilage cell fate.

In tissue engineering, research and development of biofabrication is attracting attention as one of the promising approaches for producing tissues and organs with the aids of computers and machines. However, several multiple processing steps are required to produce hierarchal, matured and functional tissues and organs. In this study, we designed and prototyped the devices that would carry out several essential processes for producing hierarchal vascular grafts as follows; scaffold fabrication, cell seeding, assembly, culture, and maturation. At first, we designed and prepared the support for fabricating tubular structures using 3D printer, and then, prototyped the coating devise for covering the support with photo-crosslinkable hydrogel, gelatin methacrylate (GelMA). Using this device, pre-gel of GelMA was uniformly coated by rotating the support. After coating, a stiff tube-shaped gel scaffold was obtained by UV irradiation. Next, we prototyped the cell seeding device, which enables cell seeding rotationally inside a tubular gel scaffold and cell culture subsequently. After seeding endothelial cells, cell adhesion throughout the inner wall of the tubular scaffold was recognized on day 3. In our previous study, we made cell fibers as bioparts. And we prototyped an assembly device to wind up the cell fiber. Using this device, we attempted to reproduce the multi-layered structure of vascular tissue by wrapping cell fibers around a GelMA pre-coated support and then culturing it. Finally, endothelial cells were seeded into the structural lumen. To construct a vascular tissue with a multi-layered structure, bioprocessing technology is required to carry out a number of necessary steps.

The study aim was a preclinical in vivo estimation of cell product based on human bone marrow MSCs and polyethylene glycol (PEG)-fibrin gel in vocal fold scar restoration.

We unilaterally injected 0,5ml of 5:1 ratio PEG-fibrin gel containing 5 x 105 MSCs (MSCs+GEL) into the rabbit vocal fold wound after excision of the mature scar. In control groups: MSCs in solution (MSCs), gel without cells (GEL), saline solution (SS) were similarly implanted (n=6 for each group). During the operation and post-operatively, bleeding intensity and respiratory disorders were assessed (point-scale); three days post implantation - cell survival rate, in three months, after animals painless sacrificing - vocal folds morphology and tissue Young's modulus.

In the MSCs+GEL and GEL groups the bleeding intensity was significantly lower comparing with MSCs and SS ($p=0.03945$), while the risk of the respiratory disorders in all groups was out of significant difference. On the third day cell survival rate was higher in the MSCs+GEL group. Morphology criteria analysis revealed significant difference between MSCs+GEL and SS groups in collagen fibers irregularity, density, muscle tissue fibrosis, with alteration predominance in SS ($p<0.05$). Lamina propria thickness in SS group was significantly higher when compared to MSCs, GEL ($p<0.05$) and MSCs+GEL ($p<0,0001$). Young's modulus in MSCs and MSCs+GEL was significantly lower comparing to group SS ($p<0.05$).

PEG-fibrin gel scaffold for MSCs reduces the intraoperative bleeding without respiratory disorders increase, facilitates cell surviving and improves the restoration of vocal fold morphology and mechanics. This study was financially supported by RSF № 21-15-00339.

Human malignant hematopoietic stem and progenitor cells (HSPCs) reside in bone marrow (BM) niches, which remain challenging to explore due to limited in vivo accessibility and constraints with humanized animal models. Several in vitro systems have been established to culture patient-derived HSPCs in specific microenvironments, but they do not fully recapitulate the complex features of native bone marrow. Our group previously reported that human osteoblastic BM niches (O-N), engineered by culturing mesenchymal stromal cells within 3D porous scaffolds under perfusion flow in a bioreactor system, are capable of maintaining, expanding and functionally regulating healthy human cord blood-derived HSPCs. Here, we first demonstrate that these 3D osteoblastic niches can sustain malignant CD34+ cells from acute myeloid leukemia (AML) and myeloproliferative neoplasms (MPN) patients for up to 3 weeks. Moreover, human malignant cells distribute in the bioreactor system mimicking the spatial distribution found in native BM tissue, where most HPCs remain linked to the niches and mature cells are released to the circulation. In order to exemplify the possibility to engineer environments with customized features, we used human adipose tissue-derived stromal vascular fraction (SVF) cells to generate a stromal-vascular niche (SV-N). Our findings indicate that the O-N and SV-N provide different niche signals that reduce leukemic UCSD-AML1 cell expansion while promoting differentiation. The possibility to culture patient-derived malignant hematopoietic cells within customizable microenvironments capturing the complexity and cellular diversity of human BM niches could be exploited to investigate mechanisms of blood cancer development and to test effectiveness of personalized therapeutic strategies.

Low back pain (LBP) episodes are common and affect everyday life. A major cause for chronic LBP is intervertebral disc degeneration. Notochordal cells (NCs) possess regenerative potential that could be exploited for therapeutic approaches. Extracellular vesicles (EVs) secreted by NCs may mediate this effect. To facilitate proper EV characterization a bead-based western technology was conducted to identify NC-derived EV-associated protein markers.

NC-conditioned medium (NCCM) was generated by culturing NC-rich tissue of porcine, canine, and human origin. EVs were isolated through differential centrifugation followed by size exclusion chromatography and characterized using DigiWest technology, a high-throughput bead-based multiplex platform. DigiWest analysis of porcine and canine NCCM-derived EVs revealed the presence of 12 proteins in common. In human NCCM-derived EVs, only 2 proteins were identified, most probably due to technical limitations related to low starting protein quantities. These proteins were also present in porcine/canine NCCM. Other proteins that can be recovered with EVs (co-isolated or contaminant proteins) were not detected, while they were detectable in positive control samples, indicating that they were absent in EV samples.

Altogether, for porcine and canine NCCM-derived EVs, we identified transmembrane, GPI-anchored, and cytosolic proteins that are required for EV characterization according to the standards of the International Society for Extracellular vesicles. Isolated EVs were devoid of contamination based on the absence of non-vesicular components. Based on these results, a panel of 19 proteins was composed for characterization of NC-derived EVs from different species.

This project received funding from the European Union's Horizon 2020 program iPSpine (No. 825925).

ANALYSIS OF SAPHENOUS VEIN GRAFTS IN CABG LUMEN DIAMETER, WALL THICKNESS AND INTIMA MEDIA THICKNESS RATIO

ATIQAH HARON[P][1]

[1] *Center of Tissue Engineering and Regenerative Medicine*

Corresponding author's email: atiqahnur717@gmail.com

Background and Aims: Saphenous vein (SV), are the most used graft covering around 70-75% of coronary bypass grafting (CABG). Unfortunately, SV graft patency are proven to be poor with 50% graft failure observed at 5 years after CABG bypasses. We hypothesized that existing intimal hyperplasia SV contributes to its lower patency. Therefore, this study aims to analyses the prevalence of intimal hyperplasia in SV graft collected from CABG surgery. Methods: Surplus SV from CABG surgery at Hospital Canselor Tuanku Mukhriz (HCTM) were collected and the lumen diameter, intima media thickness (IMT) and intimal hyperplasia ratio were quantified via histological sections stained with H&E and EVG. Results: The veins were successfully fixing, processing, embedding and cutting. The thickness of the sample approximately 3-5 µ? were cut by using microtome. We found that all the vein samples show differences in the morphology either lumen area or wall thickness. Most of the sample's diameter were about 12.5mm to 18.5mm length. However, four samples were outliers either the vein have thicker intimal hyperplasia or none of it. IMT between samples were not as homogenous as diameter observed. The thickness of intimal hyperplasia prominent in some samples where the length was measured up to >0.4mm in length compared to others. Conclusions: Most of the samples collected was not too healthy as the patency of graft from CABG surgery will be decrease. The inconsistency between diameter of vessel and IMT variation shows the possible formation of intimal hyperplasia.

Almost all tissues consist of an epithelial lining which can be key to the appropriate function of organs. Among these organs are esophagus, trachea, cornea and skin. A lack of epithelium in hollow organs can lead to stenosis, collapse and infection that restrict patency. Hence, to successfully engineer artificial tissue for clinical application, it is crucial to regenerate a functional epithelium. This can be achieved by providing surfaces that are favorable to the migration and polarization of epithelial cells. Here, we show that the incorporation of a thin fiber layer with an adsorbed protein mixture can guide epithelial cell response. Specifically, aligned polycaprolactone/heparin blend fibers are electrospun then adsorbed with a mixture of collagen IV and laminin proteins to mimic both the physical properties and chemical composition of the native basement membrane. Our in vitro cell studies show that these constructs modulate better attachment of epithelial cells, their migration to the scaffold structure, and an increased rate of epithelial cell differentiation. Furthermore, electrospinning on a widely used implant (Medpor, stryker) for head and neck reconstruction resulted in a well integrated composite where the fibers were well adhered to the implant surface. Thus, this fiber layer construct is a component that can be incorporated to the epithelial surface side of tissue engineered replacements to help with the epithelialization of large surface areas.

Background and Aims: Saphenous vein (SV), are the most used graft covering around 70-75% of coronary bypass grafting (CABG). Unfortunately, SV graft patency are proven to be poor with 50% graft failure observed at 5 years after CABG bypasses. We hypothesized that existing intimal hyperplasia SV contributes to its lower patency. Therefore, this study aims to analyses the prevalence of intimal hyperplasia in SV graft collected from CABG surgery. Methods: Surplus SV from CABG surgery at Hospital Canselor Tuanku Mukhriz (HCTM) were collected and the lumen diameter, intima media thickness (IMT) and intimal hyperplasia ratio were quantified via histological sections stained with H&E and EVG. Results: The veins were successfully fixing, processing, embedding and cutting. The thickness of the sample approximately 3-5 µ? were cut by using microtome. We found that all the vein samples show differences in the morphology either lumen area or wall thickness. Most of the sample's diameter were about 12.5mm to 18.5mm length. However, four samples were outliers either the vein have thicker intimal hyperplasia or none of it. IMT between samples were not as homogenous as diameter observed. The thickness of intimal hyperplasia prominent in some samples where the length was measured up to >0.4mm in length compared to others. Conclusions: Most of the samples collected was not too healthy as the patency of graft from CABG surgery will be decrease. The inconsistency between diameter of vessel and IMT variation shows the possible formation of intimal hyperplasia.

Recombinant limb engineering is a technique that allows the analysis of the morphogenetic potential of cells derived from limb bud mesenchyme under the ectodermal influence. Mammalian cells grafted in an avian environment respond fully to the local molecular cues and differentiate along the predicted pathways. We use the recombinant limb technique to produce an organized higher structure from recombinant limbs of chicken and mouse mesenchymal cell aggregates by incorporating limb bud mesenchymal cells from wild-type mice and chicken ectodermal jacket of the chicken.

The mesenchymal stem cells are isolated from the limb bud mesenchyme of chicken embryos at HH stages 19-23 and then inserted into the chicken ectodermal jacket collected from the same stage embryos. Next, the recombinant limb is transplanted into the flank region of the chicken embryo at HH stage 19-23 or placed on the chorioallantoic membrane.

The growing limbs will be characterized using histological staining and in situ hybridization methods to monitor the efficiency of the ectopic limb development.
In the next steps, mouse limb bud mesenchyme and eventually human-derived iPSC will be evaluated in this model system.

BIOFABRICATION OF BIFUNCTIONAL HYDROGEL SCAFFOLDS FOR NEURAL TISSUE DAMAGE REPAIR

Ozgul Gok$_P$[1], İleyna Sevde Uvak[1]
[1] *ACIBADEM MEHMET ALI AYDINLAR UNIV*
Corresponding author's email: ozgul.gok@acibadem.edu.tr

INTRODUCTION:
3D hydrogels with physically or chemically cross-linked networks and high water-uptake capacity can be utilized as artificial cell-hosting scaffolds together with being ideal porous structures for sustained therapeutics release. In this study, UV-curable natural polymer based hydrogels were prepared and loaded with an anti-inflammatory drug for neural tissue damage repair and also immobilized with a neural-cell adhesion peptide for specific cell adhesion.1
METHOD:

Methacrylated Hyaluronic acid (HA-MA) polymer was synthesized and cross-linked under UV light (365nm) to obtain hydrogels with compatible stiffness for neural tissue. For nerve repair, anti-inflammatory drug, Ibuprofen, was encapsulated into this structure for sustained release. During 3D-Bioprinting process of this hydrogel, methacrylated IKVAV peptide was introduced into hydrogel structure in a patterned structure.
RESULTS:
IKVAV-immobilized and hyaluronic acid-based hydrogels were prepared and successfully 3D-printed in aligned pattern structure for neural cell adhesion. Also ibuprofen was loaded with a high capacity for neural tissue damage repair.
DISCUSSION AND CONCLUSION:
The obtained hydrogels were characterized by FT-IR for their functional groups and mechanical behavior was analyzed by reometer. SEM results indicated that all hydrogels have porous structure and they were shown to liberate drug molecules slowly within a week. Peptide immobilized regions of this hydrogel scaffold provides selective adhesion for nerve cells compared to fibroblasts.
ACKNOWLEDGEMENTS:
This research has been supported by TUBITAK 119Z637.

MECHANOBIOLOGY OF TISSUE REPAIR

Viola Vogel[P][1,2]

[1] *ETH Zurich*

[2] *Laboratory of Applied Mechanobiology*

Corresponding author's email: viola.vogel@hest.ethz.ch

From the first steps in blood coagulation all the way to functional tissue repair, how to recreate homeostasis after injury or disease is a holy grail in Regenerative Medicine. While the roles of niche-specific biomarkers, transcriptomic, epigenetic profiles, as well as secretomes in directing cell-cell communication have been broadly studied, cells furthermore utilize a range of physical stimuli to communicate with each other and their environments as revealed by the rapidly growing fields of Mechanobiology and Nano-/Mechanomedicine. Bidirectional mechanical communication through cell-cell junctions, cell-ECM linkages and ECM fiber stretching is a major coordinator to either maintain homeostasis, or drive cell niches towards tissue repair or pathological transformations. Towards guiding regenerative processes, we now discovered that platelets not just initiate thrombus formation after injury, but that they actively assemble the first provisional fibronectin matrix using the platelet integrin αIIbβ3, instead of α5β1 as fibroblasts do. As cells pull on ECM fibers, they stretch them which can activate or destroy crucial binding sites for other ECM components and cytokines. With a newly developed peptide probe, we now discovered that the fibronectin fibers are kept under high tension in most healthy organ tissues probed, but are structurally relaxed or proteolytically cleaved in inflamed tissues, including cancer and virally infected lymph nodes. To understand the underpinning mechanisms how the mechano-communication of cells with ECM fibers directs either the maintenance of tissue homeostasis, or if perturbed drives pathological ECM transformations, we will also report on our recent insights obtained from de novo grown microtissue platforms.

In recent times biophotonic techniques are often used in applications of tissue engineering. A promising approach is laser creation of new implant materials, which stimulate the proliferation of cells during tissue formation. At present, technologies are being actively developed to replace lost or poorly functioning human tissues with biocompatible and bioactive artificial structures. The need for such structures is especially acute in the case of cardiovascular diseases. This work proposes the research physicochemical and biological properties of biopolymer structures: albumin, collagen, and chitosan with networks of single-walled carbon nanotubes. The morphology features for the biopolymer structures, which are fabricated due to the phase transition of aqueous dispersions under the action of laser radiation, have been determined. The biopolymer structures fabricated by laser demonstrated conductivity that were higher (12.4 S/m) than those for structures by thermostat (4.7 S/m). The hardness of the biopolymer structures by laser was 482±10, 425±10, and 407±15 MPa for albumin, collagen and chitosan, respectively. The hardness of the thermostat layers was less than 100 MPa. The viability of endothelial cells и cardiac fibroblasts in biopolymer structures was improved. The biopolymer structures ensured a normal level of hemolysis during interaction with erythrocytes. Thus, biopolymer structures can be fabricated in various shapes to create independent implantable tissue-engineering structures in the heart or coatings for cardiovascular devices. This is proved by the results of studies of the morphology, electrical conductivity, as well as the bio- and hemocompatibility of the layers.

Critical-size bone defects are unable to heal by themselves. Autologous bone graft is the gold standard to treat such defects, but it shows some limitation. To address this issue, we designed three scaffolds (cylinders 25mm long and Ø14mm) with different geometries to repair a long-segmental critical-size defect in a sheep metatarsal bone: (i) geometry Lines with 880µm cubic pores and a central cylinder hole (Ø5mm) ; (ii) geometry Gyroid, with 1mm gyroid pores and a central cylinder hole of Ø5mm ; (iii) geometry Double Lines, with 1.2mm cubic pores in the outer of the cylinder while its center (Ø7mm) had a gyroid pore shape with 2mm pores. The three geometries all presented a different effective surface. The 3D-printed scaffolds made of clinical-grade PLA were coated with a polyelectrolyte film and loaded with BMP-2 at a targeted surface dose of 9.2 µg/cm². BMP-2 quantification showed that the geometry Lines had the lowest incorporated BMP-2 surface dose while the geometry Gyroid had the highest. Surprisingly, the scaffolds with different surfaces had incorporated similar total quantity of BMP-2, suggesting that scaffold geometry influenced BMP-2 incorporation in the polyelectrolyte film. Interestingly, X-ray radiographs, µCT scans, and histology showed that despite its lowest incorporated BMP-2 surface dose, the geometry Lines presented the fastest and strongest bone formation. The geometry Double Lines did not allow bone repair. As the total quantity of BMP-2 was similar in every scaffolds, this suggests that the scaffold geometry influenced bone regeneration kinetics and the amount of new bone formed.

The development of bioresorbable scaffolds to treat critical-sized defects has been widely studied; a generally accepted consensus on desirable properties has been achieved but the material selection has not. The gold standard for the treatment of bone defects, autologous bone grafts, has had relative success however there are fundamental weaknesses, namely lack of native bone and possible donor site morbidity. 3D printing using thermoplastics such as poly(e-caprolactone) (PCL), poly(lactic acid) (PLA), and poly(lactic-co-glycolic acid) (PLGA) has allowed for the development of tuneable patient-specific bio-scaffolds that can vary in architecture, resorption time, and mechanical properties. However, these thermoplastics lack the osteoconductivity and osteoinductivity necessary to regenerate sufficient bone for full healing. Therefore, the development of a composite osteogenic scaffold is necessary. This research aims to produce a 3d printed PLGA scaffold containing strontium doped TCP filler which will enhance bone formation in bone defects. Strontium, an alkaline earth metal, has high biological relevance in tissue regeneration, it has been shown to increase mineralization and osteogenic markers in multiple studies. This combined with β-TCP, proven to be biocompatible and osteoconductive, has the potential to overcome issues arising from pure thermoplastic scaffolds. Three scaffolds of varying Sr-TCP wt% (0, 10, 20wt%) will be produced with analysis on the physio-chemical, mechanical, and biological performance. Including characterization of the compressive and Youngs' modulus, cell culture tests (on the effect on mineralization and osteogenic markers) as well as in vitro degradation studies.

BIOFABRICATION OF PHOTO-CROSSLINKED CONSTRUCTS WITH HIGHLY ALIGNED MICROSTRUCTURE FOR TISSUE ENGINEERING

Hao Liu[P][1], Riccardo Rizzo[1], Marcy Zenobi-Wong[1]

[1] *Tissue Engineering + Biofabrication Laboratory, Department of Health Sciences & Technology, ETH Zürich*

Biomaterials with cell instructive properties are key to being able to develop highly functional aligned tissues like muscle, tendon and nerves. Highly aligned fibers have been achieved by electrospinning and melt electrowriting techniques. However, fabrication of these fiber use solvents and/or high voltage which is not compatible with presence of cells, and cells cannot be encapsulated within the scaffold subsequently [1, 2]. Extrusion-based bioprinting has been performed to create highly aligned polymer strands [3], but these strands are generally several hundred microns in diameter which are too large to have significant cell guiding properties. Two-photon polymerization methods can produce 3D models with subcellular resolution, but the manufacture of large structures in the presence of living cells is challenging with poor cell biocompatibility [4]. Here we have developed a method to print 3D hydrogel structures which are composed of highly aligned 10-30 µm diameter microbeams using photo-crosslinked bioresin. The microbeams are similar in size to the cell, which provides physical cues for cell alignment. These printed structures are highly customizable on a macro level and precise control of multi-cell type and/or multi-materials can be achieved. Moreover, the aligned microbeams provide the printed structure with ideal mechanical properties that allow for the application of tensile loading required for the maturation of muscle and tendon tissue. Finally, the encapsulated human fibroblasts showed highly viable (>95%) and confirmed the production of highly aligned collagen fibers under the guidance of microbeams. This biofabrication approach shows great promise for multiple applications including fascicular tissue engineering.

Since the turn of the last century, the development of three-dimensional (3D) microspheres have piqued the attention of researchers due to the ability to better mimic the cellular microenvironment in-vivo for regenerative medicine purposes. The traditional 3D microspheres are generally made of a single material and lacks compartmentalisation that can truly replicate the several different cells present in an organ. Herein, we attempt to fabricate core-shell microspheres made of gelatin methacryloyl (GelMA) where the outer shell layer could serve to protect the encapsulated cells while allowing for the co-culture of different cell types for different biomedical applications. GelMA with varying degree of methylacrylate substitution was first synthesized using the protocol published by our group1. The successful conjugation of methacrylamide grafts to gelatin was confirmed by 1H-NMR and rheological studies of GelMA were done to characterise the storage moduli and viscoelastic property of GelMA with different degree of substitution (DS). A nearly monodisperse 3D GelMA core-shell microspheres with a size distribution of 395 ± 25µm were successfully fabricated via co-axial electrospraying using two-fluid GelMA solutions. This facile core-shell electrospray method thus renders this system useful to encapsulate and co-culture different cells in a scalable manner for cell therapeutics and regenerative medicine purposes.

Corresponding author's email: ashiba-keisuke@ed.tmu.ac.jp

Mesenchymal stem cells (MSCs) - based therapy has been widely used for therapeutic application of various diseases. MSCs have a self-renewal ability and multiple differentiation potential. When cultured MSCs are used in clinical, cellular senescence of MSCs is progressed because MSCs are repeatedly cultured in vitro. To get many MSCs without cellular senescence, the senescence should be suppressed in culturing process. To suppress the cellular senescence, many strategies had been tried, but rejuvenation of cells was not accomplished. In senescent cells, many dysfunctional mitochondria and reactive oxygen species (ROS) occur because of dysfunction of protein quality control system such as autophagy or mitophagy and proteasome. It was reported by many publications that ROS or dysfunction of autophagy were one of a cause in cellular senescence. Especially, mitophagy in dysfunctional mitochondria is important factor in senescence because of major production source of ROS.

In this presentation, we will report that liposome nanocarrier (LNC) composed of manganese porphyrin (MnP) with SOD activity and pifithrin-alpha such as p53 inhibitor suppresses cellular senescence in MSCs by inducing mitophagy. By treating LNC for senescent MSCs, the growth ability was recovered, and senescent marker such as p21 and SA-beta-Gal decreased. In addition, mitochondria membrane potential by LNC was decreased so that parkin as the marker of mitophagy was induced. We consider that the induced mitophagy eliminates dysfunctional mitochondria in senescent MSCs, was rejuvenating MSCs. We will discuss the mechanism of LNC for rejuvenation of MSCs.

The need for research to analyze the effects of dust particles on the respiratory system has been highlighted because such damage causes serious respiratory problems. However, most studies of dust toxicity have been conducted in two-dimensional cell culture, animal models, and epidemiological investigations. To find out how dust can cause respiratory problems, researchers should investigate using a reliable three-dimensional structural model that mimics human nature alveoli. In this study, dust particles were applied to the previously developed three-dimensional alveoli barrier created by the inkjet bioprinting process. As a result, we observed dramatic cell apoptosis, reduced proliferation and lung dysfunction in inkjet bioprinted alveolar barriers exposed to dust particles. We also observed an increase in pro-inflammatory cytokines that stimulated the secretion of matrix metalloproteinase (MMP). To analyze the effect of increasing immune response from dust, dust was treated in dose- and time-dependent manner and alveolar tissue collapse was identified to induce structural collapse and reduced barrier robustness. We further investigated lung surfactant protein-related genes in dust-treated alveoli tissues and then estimate the harmful effects of dust on lung surfactant dysfunction. This study demonstrated the physiological effects of dust on cytotoxicity, alveolar barrier stiffness and surfactant secretion at gene expression level using inkjet bioprinted alveoli barriers. It has also been demonstrated that dust can have serious consequences that can lead to the collapse of the alveoli barrier. Using in vitro inkjet bio-printed 3D alveoli barriers, we expect this strategy to be a useful tool for identifying air pollutant exposure-related diseases.

MULTI-SCALE X-RAY COMPUTED TOMOGRAPHY FOR THE EVALUATION OF BONE REGENERATION IN CRITICAL-SIZED DEFECTS PROMOTED BY MAGNESIUM-BASED FIBRES

Roxane Bonithon[P][1]

[1] *Zeiss Global Centre, School of Mechanical and Design Engineering, University of Portsmouth*

Corresponding author's email: roxane.bonithon@port.ac.uk

Magnesium (Mg) alloys are of particular interest for application as degradable bone substitutes due to their appropriate mechanical properties, closer to bone than any other biomaterials (1). Once implanted, Mg implants must provide adequate mechanical support to maintain the integrity of the injured site while promoting bone ingrowth to ensure optimal tissue healing (2). The aim of this study was to employ high-resolution X-ray computed tomography (XCT) to assess the bone regeneration pattern at 4, 8 and 16 weeks following the implantation of Mg-based fibres into critical-sized defects, compared to that induced by natural bovine bone grafts (BBG) and empty controls. Mechanical characterisation was also performed on 16-weeks newly formed bone-biomaterial tissues by means of in situ XCT mechanics coupled with digital volume correlation (DVC). Mg promoted higher bone formation (0.77 ± 0.15, 0.53 ± 0.07 and 0.45± 0.06 at 16 weeks for Mg, empty and BBG, respectively) up to full restoration of critical-sized defects, with closer interaction between bone and Mg fibres, as well as adequate corrosion rate. The newly formed bone seemed to undergo mineralization (541 ± 50 mg HA.cm-3), physiological remodelling (osteocytes cavities 426 ± 221µm3) and angiogenesis after 16 weeks, enabling the Mg-bone system to gain sufficient mechanical strength (3.32 ± 0.92MPa and 152 ± 1MPa for apparent yield stress and Young's modulus, respectively). This study provides evidence that these Mg-based fibres has the ability to promote osteointegration, conduction and promotion allowing the reconstruction of critical-sized defects while maintaining the mechanical integrity of the injured site.

Epithelial-to-mesenchymal transition (EMT) is a key event in embryo development and post-natal life in which epithelial cells undergo a transdifferentiation into mesenchymal cells by acquiring a mobile state. This cell transitioning process recognizes the activation of signaling pathways which occur under controlled environments in response to factors leading stem cell epigenetic reprogramming, self-renew and production of differentiating progenitor lineage (1). The investigation of EMT processes controlling tissue patterning and organization as well as disregulating healing processes leading to fibrosis has been, indeed, addressed for enabling the advancement of bioengineering strategies.

In order to achieve control over the regenerative process, tissue engineering usually rely on isolation, expansion and transplantation of progenitor cells to repair target tissues (2-3). The underlying strategy is that committed progenitors will directionally support the regeneration of damaged tissue by avoiding dedifferentiation or transdifferentiation involving cellular transitions (EMT or MET) leading to adverse fate decisions or to the release of alternative factors.

Controlled EMT-mediated regenerative events are totally depend on the ability to generate favorable local environmental of stem cell-host tissue dialogue as well as repairing feedback loop between extracellular matrix (ECM) mechano-chemical signaling and progenitor cells (4).

Studies that probe the mechanisms underlying the relationship between stemness and EMT and EMT/ECM interactions thus represent the next steps forward in elucidating strategies for reducing fibrosis and selecting progenitor populations for tissue repair.

Liver disease is a major healthcare challenge, accounting for ~2 million deaths yearly worldwide. Liver transplantation is the best way to re-establish normal liver function and currently less than 10% of transplantation needs are met. As part of the EU Horizon 2020 OrganTrans consortium we aim to address this by developing a liver tissue printing platform for transplantation.

One critical need is a reliable source of healthy cells and liver spheroids that are used to fabricate a liver construct using bioprinting. Using robotics, microfluidics, and deep learning we have developed a novel spheroid classification and sorting platform that can image, classify, and sort 80,000 spheroids within 2 hours. This classification and sorting system is the first platform that is compatible with biosafety cabinets and any well plate design, can sort spheroids, and uses deep learning with a classification accuracy of > 98%. Images of the underrepresented unhealthy class are synthesized using generative adversarial networks for an enhanced classifier training process. The platform removes unhealthy spheroids and the healthy spheroids are then harvested and concentrated within a hydrogel precursor solution for bioprinting.

Immediately after bioprinting, the liver construct matures at physiological conditions. We are developing an automated bioreactor that enables continuous tissue perfusion via to automated fluidics while ensuring sterility. The bioreactor will incorporate sensing functions and enable the maturation of six tissues in parallel. These two research and development efforts will help to address challenges in organ engineering and begin to close the gap between patient need and transplant supply.

Hydrogels are a significant and growing segment of the drug delivery, tissue engineering, and wound care markets. Naturally-derived hydrogels have numerous benefits over synthetic hydrogels such as biocompatibility and biodegradability, but they often suffer from challenges such as batch-to-batch variability and sensitivity to preparation conditions such as mixing ratio, shear stress, temperature, pH, CO2 concentration, and humidity. These challenges pose a complex process control problem for high-throughput hydrogel manufacturers. In partnership with a pioneering hydrogel manufacturer, we have developed a novel process control strategy that incorporates in-line sensors and deep learning and can provide real-time process monitoring, predictive / adaptive decision-making, and prescribe corrective actions.

We have chosen collagen type I hydrogel manufacturing as a test case due to (1) our extensive expertise working with this material in industrial manufacturing settings, and (2) known end-user interest. Our strategy incorporates in-line temperature, pH, flow rate, pressure, and conductivity sensors to monitor mixing and preparation conditions. Additionally, we use environmental temperature, CO2, and humidity sensors to subsequently log crosslinking conditions. We have also developed a final optical quality control readout that will monitor the color and opacity of the final hydrogel. All of these variables are tracked in real-time against a known baseline, and a deep learning anomaly detection identifies any deviations from this baseline and can prescribe corrective actions.

Having successfully demonstrated applicability to collagen we hope to explore the application of this strategy to other biomaterial manufacturing processes such as gelatin.

Introduction. Poly[ε]caprolactone is one of the most suitable and desired synthetic biodegradable polymers having favourable mechanical properties and biocompatibility, however suffering from hydrophobicity. Processing of PCL by electrospinning is among the most promising routes for scaffold fabrication. Coaxial electrospinning allows the fabrication of polymer composites and blends having superior properties, such as increased hydrophilicity and controlled release of active substances.
Materials and methods. The aim of this study was to fabricate polycaprolactone (PCL)/cellulose (CEL) composite scaffold having co-axially bi-layered structure with uniform morphology and to assess the effects of attached bioactive additive on cell growth and proliferation. Cellulose acetate (CA) solution was used to fabricate shell layer of fibres, and subsequently converted to cellulose using a NaOH solution. Fibres were further coated with gelatine filled with glucosamine sulphate (GS) as an active substance to facilitate proliferation of cartilage cells. Scaffold physicochemical properties were determined by SEM, TEM, ATR-FTIR, XRD, water contact angle, chemical carboxyl group, and mechanical analysis. Biocompatibility was assessed as cell proliferation evaluated by the CCK-8 assay.
Results. Scaffold formation via coaxial electrospinning resulted in uniform PCL/CA fibers with and average diameter of ~2 µm (outer to inner ratio of 1:6). After the conversion of CA to CEL, scaffold wettability was improved, and water contact angle decreased 30-40% to ~60 degrees. The cell proliferation in the described scaffold was 20% more efficient compared to control PCL matrix without modification with CA and GS.

Each year, more than one million patients are hospitalized in the U.S. for significant skin loss due to injuries, diabetic ulcers or genetic skin diseases. The way we engineer skin grafts for these patients today follows the same principle that was first described nearly 30 years ago. The current approach generates skin layer-by-layer, as flat patches with open edges and disregards the fact that human skin is, in fact, a fully-enclosed organ with curved geometries. As a result, the conventional skin grafts (cSGs) typically fail to effectively cover irregular body parts, e.g., hands, due to their generic geometry and poor mechanical properties. In this study, we challenge this prevailing paradigm by reimagining skin grafts as fully-enclosed 3D tissues that recapitulate region-specific biomechanical properties of the skin and can be transplanted as a wearable tissue on any part of the body. We developed a method to generate wearable skin grafts (wSGs) to perfectly fit the recipient site. The method includes acquisition of biometric data with a laser scanner and 3D-printing a patient-specific scaffold on which wSGs are grown under continuous perfusion until they are ready for grafting. We found that wSGs have enhanced region-specific mechanical properties compared to cSGs and an improved organization of the basement membrane proteins. In addition, we generated wSGs tailored specifically to fit on mouse hindlimbs as skin sleeves and demonstrated their transplantation. Our study introduces wSGs as a compelling new technology that can make a transformative impact on the lives of patients with significant skin loss.

How adhesive forces are transduced and integrated into biochemical signals at focal adhesions (FAs) is poorly understood [1,2]. Using cells adhering to deformable micropillar arrays, we demonstrate that traction force and FAK localization, as well as traction force and Y397-FAK phosphorylation, are linearly coupled at individual FAs on stiff, but not soft, substrates. Similarly, FAK phosphorylation increases linearly with external forces applied to FAs using magnetic beads. This mechanosignaling coupling requires actomyosin contractility, talin-FAK binding, and full-length vinculin that binds talin and actin. Using an in vitro 3D biomimetic wound healing model, we show that force-FAK signaling coupling coordinates cell migration and tissue-scale forces to promote microtissue repair. A simple kinetic binding model of talin-FAK interactions under force can recapitulate the experimental observations. This study provides insights on how talin and vinculin convert forces into FAK signaling events regulating cell migration and tissue repair.

VASCULARIZATION OF TISSUE ENGINEERED CARTILAGE - SEQUENTIAL IN VIVO MRI DISPLAY FUNCTIONAL BLOOD CIRCULATION

Peter Apelgren[P][1]

[1] *Sahlgrenska Akademin Institutionen för Kliniska Vetenskaper Plastikkirurgiska Kliniken*

Corresponding author's email: peter.apelgren@gu.se

Establishing functional circulation in bioengineered tissue after implantation is vital for the delivery of oxygen and nutrients to the cells. Native cartilage is avascular and thrives on diffusion, which in turn depends on proximity to circulation. Here, we investigate whether a gridded three-dimensional (3D) bioprinted construct would allow ingrowth of blood vessels and thus prove a functional concept for vascularization of bioengineered tissue. Twenty 10 × 10 × 3-mm 3D-bioprinted nanocellulose constructs containing human nasal chondrocytes or cell-free controls were subcutaneously implanted in 20 nude mice. Over the next 3 months, the mice were sequentially imaged with a 7T small-animal MRI system, and the diffusion and perfusion parameters were analyzed. The chondrocytes survived and proliferated, and the shape of the constructs was well preserved. The diffusion coefficient was high and well preserved over time. The perfusion and diffusion patterns shown by MRI suggested that blood vessels develop over time in the 3D bioprinted constructs; the vessels were confirmed by histology and immunohistochemistry. We conclude that 3D bioprinted tissue with a gridded structure allows ingrowth of blood vessels and has the potential to be vascularized from the host. This is an essential step to take bioengineered tissue from the bench to clinical practice.

The rapid development of tissue engineering and regenerative medicine has provided a new strategy for ear reconstruction. Polyglycolic acid scaffold has been successfully used to regenerate auricular cartilage and achieved the first clinical breakthrough. However, due to acidic degradation products of polymer materials, the clinical effect was unsatisfied, which seriously limits its clinical application. Cartilage acellular matrix is one of the most potential biomimetic materials for cartilage regeneration because of cartilage matrix components and cartilage-specific microenvironment. Combined with 3D-printing, cast-molding, and freeze-drying, the mature auricular cartilage was successfully regenerated. However, pore structure, cell distribution, and three-dimensional morphology of freeze-dried scaffolds are difficult to be accurately controlled, which results in heterogeneous and unsatisfactory structure of regenerated cartilage. 3D bioprinting can realize the directional distribution of both cells and materials, and can complete the precise control of morphology, which provides a new direction to address this problem. In this study, the photo-crosslinkable cartilage-derived extracellular matrix hydrogel was successfully prepared by decellularized, enzyme digestion, and modified with methacrylic anhydride. The porous structure formed by polyethylene oxide (PEO) is beneficial to cell proliferation, migration, and extracellular matrix secretion. After imported the 3D digital model, the bioink consisted of chondrocytes and hydrogels was prepared into a human-ear-shaped construct by 3D-Bioplotter bioprinter. After photo-crosslinking and dissolving PEO, the auricular construct was transplanted subcutaneously in nude mice. Finally, the mature and homogeneous human-ear-shaped cartilage with satisfactory morphology and good elasticity was successfully regenerated, which provides scientific evidence and support for future clinical application in auricular tissue engineering.

HIGHLY LOADED MICROSPHERE SCAFFOLDS FOR BONE AND CARTILAGE TISSUE ENGINEERING

Stefan Lohfeld$_P$[1], Denise Iliff[1]

[1] *University of Missouri-Kansas City*

Corresponding author's email: lohfelds@umkc.edu

Microspheres are utilized to deliver factors and drugs in tissue regeneration therapies in a controlled manner. Control mechanisms for the timely release of the substances are the material's degradation time and the shell thickness of the microspheres. Gradient tissue engineering scaffolds consisting of multiple types of microspheres can release different factors at different sites of the scaffold for an enhanced influence on tissue formation. Currently, for load bearing applications, microspheres are either in bulk scaffolds, with no defined internal architecture that may supports specific tissue formation, or are embedded in other scaffold matrix materials, where the release of encapsulated matter is also depending on the prior biodegradation of the matrix material and where only limited amounts of the factors that are to be released from the microspheres.

We created a 3D Printing bioink from PLA microspheres to fabricate scaffolds from microspheres without compromising the inherent advantages, such as the high surface-to-volume ratio of spheres and the microporosity within the struts. A subsequent sintering process with subcritical CO2 allowed for stronger scaffolds, yet preserved the microsphere characteristics. Cells and bioactive factors can be present during such sintering step.

These scaffolds allow for most effective release of factors from the microspheres. Multihead printers allow selective placement of such inks within one scaffold. Future work includes cell culturing with multigradient microsphere scaffolds, with the aim of creating scaffolds for osteochondral tissue engineering and scaffolds for large bone defects, in which the grown tissues better mimic natural tissue.

Most breast cancer related deaths are not caused directly by the primary tumor, but by secondary tumors formed through metastasis to other organs [1]. Current in-vitro models rarely mimic the initial phase of metastasis: invasion. Hence, we focus on modeling breast cancer invasion and the relevant microenvironment on a chip. We develop microfluidic Cancer-on-a-Chip (CoC) devices to recapitulate essential cues in cancer microenvironment, namely (1) Extracellular Matrix (ECM) heterogeneity and (2) microvasculature. To generate the cancer niche, we use cell-embedded hydrogel encapsulation [2]. A water in oil flow-focusing device was used to encapsulate cancer cells in Matrigel beads. Next, Matrigel beads were cultured in collagen I hydrogel, mimicking the stromal ECM. This way we recapitulate the pre-invasive condition where cancer cells initially reside in a soft basement membrane before invading the fibrous and stiffer stromal ECM. Beside encapsulation method, we use alternative techniques like sugar-printing in CoC models to create the interface between two different materials. The model of ECM heterogeneity can potentially lead to better understanding of pre-invasive and invasive breast cancer.

Moreover, we use sugar-printing technology to create perfusion lumens, cast directly in ECM [3]. When seeded with endothelial cells, these form the (micro) vasculature. Combined with a neighboring channel for cancer cell culture, the process of cancer invasion, migration through ECM, and intravasation can be studied. This way we avoid using artificial materials like Polydimethylsiloxane (PDMS) which usually have drawbacks for cellular experiments.

Hallmark of the osteoarthritis (OA) disease pathophysiological process is the recuperation of OA chondrocytes towards a hypertrophic, growth plate-like morphology and signalling, leading to cartilage degeneration and mineralization. Previously, our group showed by genetics and functional studies that upregulation of thyroid signalling (T3) could be driving this process (1,2). Because the molecular pathways involved are poorly defined, we applied RNA-sequencing to our established ex vivo osteochondral age-related human explant model in which OA hypertrophy is triggered by T3. Hereto, full thickness osteochondral explants were isolated from the macroscopically preserved condyles of eight human knee-OA patients obtained after joint-replacement surgery. RNA-seq analysis was performed on cartilage isolated from the explants. VST normalization and DESEQ analysis was performed to identify differentially expressed (DE) genes in T3-treated versus matched untreated control samples. Pathway analysis was performed using Cluster Profiler. In total 247 significantly DE genes were identified, of which 182 genes were upregulated and 65 genes were downregulated. Next to the upregulation of some usual suspects, for example HIF-2alpha (EPAS1), we found that the most significantly up- and downregulated genes were CCDC80 and ANGPTL7, respectively. The main pathways involved were regulation of cartilage extracellular matrix and ossification. Comparison with OA GWAS literature identified 25 OA risk genes that were DE after T3 stimulation, giving new insights into the role of T3 in OA onset and progression. Our established human OA disease model of chondrocyte hypertrophy will be further exploited for preclinical studies on drug target discovery and efficacy testing.

Human embryonic stem cells (hESCs) can differentiate into all principal cell types in human body and this capability makes the hESCs a promising tool for cell therapy, tissue engineering and variety of other bio-industrial, bio-medical and pharmaceutical applications. However, despite the currently used, stringent protocols, there is still a substantial heterogeneity in hESCs cultures that may produce aberrant cells with unwanted properties, such as lack of functional phenotype or propensity to cancer growth. Therefore, robust, easy-to-perform and sensitive methods that would determine and confirm status of cultured hESCs and also reveal divergences from optimal differentiation trajectory are needed. Here we modelled some typical unwanted scenarios that may occur in long-term cultures of hESCs. These involve development of karyotype aberrations, culture cross-contamination, and failure of hESCs to differentiate into a functional phenotype. The cultures of hESCs and their differentiation stages were analyzed by intact cell mass spectrometry followed by advanced statistical analysis of the mass spectra. Spectral fingerprints reflecting the chemical composition of the inner cellular environment contained sufficient information to identify normal and aberrant hESCs, or to confirm correct differentiation trajectory by cluster analysis and machine learning approaches.

In summary, intact-cell mass spectrometry is a promising tool for quality control in long-term preclinical and clinical stem cells cultures. This study was supported by funds from Ministry of Health of the Czech Republic (project: NV18-08-00299) and from Faculty of Medicine of Masaryk University (project: MUNI/A/1689/2020).

Osteogenesis Imperfecta (OI) is a major connective disorder caused by type I collagen (Col I) mutations [1].To date much OI research has been performed as an ex vivo technique. Second Harmonic Generation (SHG) has recently been used to visualize the extracellular matrix (ECM) of OI tissues[2]. This project aims to create an in vitro, human-cell based model of ECM deposition using Polycaprolactone (PCL) scaffolds to understand how Col I mutations alter the early collagen formation processes in 3D. PCL mats were fabricated by electrospinning as non-aligned and aligned fibers. Primary Human Dermal Fibroblasts (HDF) were collected from human donors with OI under informed consent from Sheffield's Children Hospital and healthy HDFs (adult) from PromoCell. Cell-secreted collagen was analyzed using a laser scanning confocal microscope fitted with a Ti: sapphire laser. The results indicated that collagen secreted by healthy HDFs aligned in the direction of the electrospun PCL fibres [3].Notably, collagen secreted by OI fibroblasts cultured on aligned and nonaligned fibres also produced SHG signals. The SHG signal produced by OI fibroblasts on aligned scaffolds are stronger than nonaligned scaffolds, although the collagen produced by OI HDF is less ordered. Sirius Red Assay supported the indication that OI HDF can secrete more collagen on aligned substrates. Our results demonstrate that fibrous scaffolds can be used to create in vitro human cell-based models in 3D. This will be a tool to better understand the mechanisms behind diseases of collagen such as OI. Acknowledgement: Republic-of-Turkey-Ministry-of-National Education. ELECTROSPUN EXTRACELLULAR MATRIX SCAFFOLDS FOR NEURAL REGENERATION

Lena Mungenast$_P$[1]

[1] *FHNW*

Corresponding author's email: lena.mungenast@fhnw.ch

Decellularization of tissues, with the goal of applying extracellular matrices (ECM) based scaf-folds in regenerative medicine, requires the preservation of the complex biochemical cues specif-ic to the native microenvironment (1-4).
In this work, cell-free, spinal cord-derived ECM scaffolds were produced to support the alignment of neural progenitor cells and neurons. Decellularization of pig spinal cord was accomplished by a combination of mechanical, physical (freeze-thawing) and chemical (SDS incubation) treat-ments. The decellularized tissue was characterised via dsDNA quantification and histological staining to assess the presence of cell nuclei, proteins and glycosaminoglycans. Successfully decellularized spinal cord was lyophilized, milled and solubilised into a bioink, using hexafluoroi-sopropanol (5 % w/v ECM + 0.1 % w/v Polyethyleneglycol) and patterned into an electrospun fiber scaffold (using a 3D Bioprinter). The results show that porcine spinal cord can be success-fully decellularized leading to an ECM with less than 50 ng/mg dsDNA, and without cell nuclei. The formulated bioink enabled spinning of acellular spinal cord ECM scaffold with fibers of <10 µm diameter. The non-cytotoxic scaffolds supported the viability of a human neural cell line (SH-SY5Y) over the course of 14 days and the selective differentiation into neurons, as confirmed by immunolabeling of specific cell markers (HB9, Tubulin ß). The combination of biochemical and topographical cues in this patterned ECM-derived scaffold induced the alignment of neural cells in vitro. The strategy of combining decellularized tissues followed by specific deposition patterns to opti-mize biochemical and topographical cues opens the way for clinically relevant central nervous system scaffolding solutions.

BIOACTIVE 3D SCAFFOLDS FOR THE DELIVERY OF NEUROTROPHINS TO IMPROVE NEURITE OUTGROWTH AND INDUCE SCHWANN CELL MIGRATION

Ana M Sandoval-Castellanos[P][1], John Haycock[1], Frederik Claeyssens[1]

[1] *University of Sheffield*

Corresponding author's email: amsandovalcastellanos1@sheffield.ac.uk

Peripheral nerve injury causes disability [1-2]. The clinical standard is the use of autografts, however, their performance is limited due to donor site morbidity. The addition of neurotrophins has been studied to improve the performance of nerve guide conduits (NGCs), however, nerve regeneration is still not optimal [3-4]. Therefore, it is paramount to design a platform for the sustained delivery of neurotrophins to provide a continual stimulation to axonal outgrowth and nerve regeneration [5]. The aim of this study was to fabricate a novel bioactive surface on electrospun fibers to provide a sustained release of heparin-bound NGF or BDNF to stimulate neurite outgrowth and Schwann cell (SC) migration [6]. The bioactive surface was characterized by XPS analysis and ELISA. To study the effect of the bioactive 3D scaffold, nerve regeneration was evaluated with primary nerve tissue, specifically, DRGs explants were seeded on the scaffolds, and axon outgrowth and SC migration were measured. Our results showed significantly enhanced nerve outgrowth, with the formation of neurites of up to 3 mm, accompanied by SC. We hypothesize the combination of physical guidance provided by the fibres along the sustained delivery of relevant biological factors, NGF and BDNF, provided a stimulatory environment for nerve regeneration [7-8], where the delivery of neurotrophins was sustained for 21 days. Importantly, our results were achieved by immobilizing relatively low concentrations of neurotrophins (1 ng/mL), which provides a promising, low-cost and scalable method to improve current NGCs. Future studies will assess the performance of the bioactive scaffold in vivo.

Polyelectrolyte complexes (PEC)s are supramolecular self-assembled systems formed upon combination of oppositely charged compounds by means of electrostatic interactions [1]. The possibility of directly mixing polyelectrolytes of natural origin with inherent biocompatibility, to obtain PECs with controlled water stability, biodegradability, and mechanical properties, has attracted great interest for various biomedical applications. In particular, additive manufacturing (AM) integration with naturally-derived PEC strategies is resulting into novel layered hydrogels designed for engineering human tissues [2]. This research activity's aim was the development of additive manufactured PECs based on chitosan, the reference cationic polyelectrolyte from natural source, and designed for 3D in vitro modelling of ovarian cancer. To this purpose, either alginate or hyaluronic acid were investigated as polyanions to form PEC aqueous suspensions suitable to be processed by AM. Experimental fabrication protocols were optimized to process suspensions with different polycation/polyanion weight ratio into 3D porous hydrogels through direct extrusion into an ethanol bath. The influence of PEC composition on hydrogel's physical-chemical and mechanical properties was clearly demonstrated. Structural stability in cell culture medium of optimized PEC hydrogel prototypes was exploited for in vitro tumor tissue growth. In vitro biological characterization highlighted how the adhesion, morphology, proliferation, and migration of A2780 ovarian cancer cell line kept in culture for periods up to 3 months, were significantly affected by PEC composition. Ongoing experimental investigations are dedicated to evaluating in vitro chemotherapeutics response of the 3D tissue models as well as to assess cisplatin-resistant A2780cis cell line cultured on the developed PECs.

Human respiratory system is constantly being exposed to outside environmental factors. Continuous exposure to toxic and/or infectious agents can cause many airway diseases such as asthma, chronic obstructive pulmonary disease, obliterative bronchiolitis, and cystic fibrosis. One of the most serious environmental issues are the air pollutants. Many of the toxic effect of air pollution have been linked with polycyclic aromatic hydrocarbons (PAH). PAH are ligands of the aryl hydrocarbon receptor (AhR) that has participated in detoxification and has been also shown in immune response within the lung tissue. Nevertheless, numerous others aspect of AhR signaling within the lung epithelium still remain unclear.
To investigate the role of AhR in detoxification and biodegradation of air pollutants we are developing cell model of normal lung epithelium. We generated the cells differentiated in vitro from human embryonic stem cells (hESC) that can be propagated for long-term in culture and most likely represent equivalent of expandable lung-like epithelia (ELEP). The hESC-derived ELEP express markers of early lung epithelial lineage and display properties of cells in early stages of surfactant production. They have a high proliferative potential in vitro and are capable of differentiation into mature epithelial cells. Under 3D culture conditions, both in vitro and in vivo, ELEP arrange themselves into structures resembling normal lung tissue. To investigate the involvement of AhR in lung epithelia formation, functioning, and detoxification, we have recently developed ELEP with knocked-out AhR gene.

Background: Intimal hyperplasia (IH) is a response to endothelial cell (EC) injury which triggers uncontrolled proliferation of smooth muscle cells (SMC). IH decreases the patency of bypass graft post Coronary artery bypass graft surgery (CABG) and threatens angioplasty procedure. Antiproliferative drugs such as paclitaxel and sirolimus were inhibited IH but also impede the re-endothelisation. Hydroxytyrosol is an olive-derived polyphenol. Its effect on IH attenuation has not been extensively studied. Therefore, we aimed to study the effect of HT in EC proliferation and SMC inhibition in-vitro before its application in an ex-vivo IH model.

Methods: EC and SMC were collected from saphenous veins of patients undergoing CABG surgery at Hospital Canselor Tuanku Mukhriz (HCTM), Malaysia. Dose response curve plotted using MTT assay. Whereas HT effect on proliferation and apoptosis were examined using EdU Cell Proliferation and TUNEL Assay. VEGFR2 expression evaluated via western blotting.

Results: We found 80uM of HT significantly increases the proliferation of EC and decreases apoptosis in EC. The maximal effective concentration (EC50) is 78.1uM ($p<0.05$). VEGFR2 protein which responsible for angiogenesis was highly expressed in HT-treated EC. The half-maximal inhibitory concentration (IC50) of HT-treated SMC is 300uM. A concentration of 80uM up to 320uM of HT potentially decreases the proliferation of SMC by inducing apoptosis.

Conclusions: HT boosts EC proliferation whilst inhibit SMC proliferation in-vitro in a concentration-dependent manner. Therefore, these preliminary findings enable the study of HT combinatory effect on both EC and SMC in an ex-vivo IH model to be elucidated in the future.

Decellularized tissues are those in which extracellular matrix (ECM) – derived scaffolds are widely used as a promising material for tissue engineering and regenerative medicine. As for the mechanism of biocompatibility and functionality of decellularized tissue, several exploratory researches have been studied focusing on the ECM structure and components. Recently, the presence of matrix-bound nanovesicles (MBVs) embedded within the ECM has been reported 1), but the details are still unclear. We have previously reported that decellularized tissues prepared by high hydrostatic pressure (HHP) method show good in vivo performance 2, 3). In the present study, we focused on the MBVs and investigated the extraction method of MBVs from HHP decellularized small intestinal submucosa (SIS) and their effects on vascular endothelial cells. H-E staining and DNA quantification showed that the nuclei were removed in HHP treated SIS. With nanoparticle tracking assay and transmission electron microscope (TEM) observation, nanosized (50-200 nm) and membranous particles similar to MBVs were detected. To evaluate the effect on angiogenesis, which is important in the process of tissue reconstruction, vascular endothelial cells were exposed to isolated MBVs and cell proliferation was evaluated. Isolated MBVs-like vesicles induced endothelial cell proliferation. These results suggested that MBVs-like vesicles can be extracted from HHP decellularized tissue and have important role in angiogenesis.

Osteoarthritis (OA) is the leading cause of joint disability worldwide. Despite the growing disease burden, no disease-modifying formulation has so far entered the clinic with limited control over the spatiotemporal drug release profile being one of the main challenges[1]. Here, we report on a novel polymer-drug conjugate with specificity towards cartilage tissue, controlled release of a chondroprotective drug and lubricating activity. The polymeric backbone of the system consists of a poly(2-methacryloyloxyethyl phosphorylcholine) (PMPC) chain. Zwitterionic polymers such as PMPC have long been recognized for their excellent biocompatibility and non-fouling properties[2,3]. In addition, their biological equivalents – phosphatidylcholine lipids – are known to play an important role in joint lubrication which has inspired recent research on synthetic PMPCs to improve lubrication of defective cartilage and slow OA disease progression[4,5]. We found that these polymers penetrate well into cartilage explants and we were able to achieve greater than 80% retention by conjugating them to the cartilage-specific, collagen II-binding hexapeptide WYRGRL. Regarding the therapeutic component of the system, we performed experiments with the IκB kinase inhibitor BMS-345541[6] on chondrocytes co-treated with the inflammatory cytokine IL-1β and found near complete restoration of the untreated phenotype in 2D culture. By conjugating the drug to our zwitterionic backbone through a matrix metalloproteinase-cleavable linker a triple-functional – targeted, chondroprotective and lubricating – drug depot for the disease-modifying treatment of osteoarthritis was designed.

The kidney is a complex organ that includes around 30 cell types, of which renal proximal tubule cells (RPTEC) represent 43% [1,2]. This project aims at developing 3D kidney tissue models for the investigation of recellularization strategies to support developing tissue-engineered kidneys. Decellularization of precision-cut kidney slices (PCKS) represents a promising source of scaffolds. However, effective recellularization depends largely on the decellularization method. While decellularization of PCKS by immersion in chemicals is a standard approach, it is necessary to increase scaffolds quality. We explored the potential of reducing contact time with chemicals by treating PCKS physically before immersion, with high hydrostatic pressure (HHP) or repeated freezing-thawing cycles (FTC).

Rat PCKS were decellularized using two approaches. First: immersion of PCKS in chemicals. Second: physical treatment combined with immersion in chemicals. The combined approach consists of 3 different protocols: 1) sonication during immersion 2) HHP treatment before immersion 3) FTC treatment before immersion. Decellularization of PCKS by immersion followed a slightly modified protocol: 0.025% trypsin, 2% Triton X-100, 2% SDC and 0.1% SDS [3]. Data revealed that the combined chemical and physical approach is more effective in retaining GAGs (glycosaminoglycans) than immersion alone. While HHP retained more GAGs than ultrasound, both showed a higher GAG content than decellularization by immersion alone. However, HHP was less efficient in DNA removal than FTC. Moreover, histological analysis indicated that FTC is better in preserving the ECM. Currently, differently decellularized scaffolds are being used for recellularization with human RPTEC/TERT1 cells and will be assessed microscopically.

Damage to anterior cruciate ligament (ACL) is one of the most frequently occurring joint dysfunctions in the clinic. Due to the poor self-healing capacity, the ACL repair is a considerable challenge. It is a promising treatment to reconstruct ACL by mimicking the composite and structure of ACL via tissue engineering methods. ACLs are mainly composed of highly aligned and stiff collagen fibers surrounded by the extracellular matrix (ECM)[1].

Amino acid based poly(ester amide)s (AA-PEAs) are potential materials to simulate ACL fiber. Because PEAs combine the good mechanical, thermal and processing properties of polyamides, with the degradability of polyesters into a single system [2]. Besides, amino acids impart chemical functionality allowing further polymer modification, as well as biological functionality like cell adhesion and enzymatic degradation [3]. Specially, glycine is the most abundant amino acid in collagen, with excellent biocompatibility.

Therefore, semicrystalline glycine-PEAs with different molecular weights were synthesized by active solution polycondensation. These glycine-PEAs were thermally stable with glass temperature and melting point around 22oC and 168oC, respectively. These 3D-printed glycine-PEAs fibers were further characterized mechanically to investigate their potential use for ACL regeneration.

Introduction: Accumulating evidence supports the potential of extracellular vesicles (EVs) from mesenchymal stromal cell (MSC) as therapy for cardiac healing after myocardial infarction (MI). Nevertheless, neither their efficient administration nor their therapeutic mechanisms are fully elucidated.

Purpose: To evaluate the preclinical efficacy of a tissue engineering approach to locally deliver porcine cardiac adipose tissue MSCs-derived EV (cATMSC-EV) in an acute MI pig model.

Methods: Pigs (n=24) were blindly randomized after 30 min of MI induction to an Untreated group or treated with the implantation of a tissue engineered graft composed of a decellularized human pericardial scaffold filled with peptide hydrogel and either cATMSC-EV purified by size exclusion chromatography (EV-Treated group) or buffer (Control group), placed over the post-MI myocardium. Cardiac troponin levels and MRI revealed consistent myocardial damage and infarct size amongst groups.

Results: After 30 days, cardiac function was significantly improved by graft implantation, with maintained left ventricle ejection fraction and increased aortic flow flux. cATMSC-EV delivery improved right ventricle ejection fraction (p=0.026), prevented myocardial adverse remodelling and decreased distal fibrosis (p=0.030). cATMSC-EV-treated animals had a reduced scar size (p=0.042), concomitant with increased vascularization in the infarct core (p=0.019), less macrophage infiltration (p=0.026) and more with anti-inflammatory phenotype (%CD73+; p=0.015). Surprisingly, local delivery of cATMSC-EV also triggered a systemic effect, reducing leukocyte mobilization post-MI and modulating systemic CD73+ and CCR2+ monocytes, related to immunomodulation and fibrosis modulation.

Conclusions: These results highlight the clinical potential of cATMSC-EV in modulating key features of ischemic injury and promoting cardiac repair after MI.

HIGHLY ELASTIC SCAFFOLDS PRODUCED BY MELT ELECTROWRITING

Raquel Sanchez Diaz$_P$[1]

[1] *Queensland University of Technology*

Corresponding author's email: sanchezdiazraquel@gmail.com

Melt electrowriting (MEW) is an additive manufacturing technique with the ability to create micro- to nano-fibers and collect them in a well-defined layered structure, a process highly advantageous in tissue engineering applications.[1] There is a limited selection of polymers that can be melt electrowritten. Poly(ε-caprolactone) (PCL), with exceptional thermal properties, is the gold standard for MEW.[2] The alternative polymers often require tailored synthesis or high processing temperatures that cause degradation.[3]

In this study, we introduce a rapid and efficient method to adapt commercially available polymers for MEW. We use a controlled thermal pre-treatment to tailor the melt viscosity. An elastomeric commercial copolymer, poly(L-lactide-co-ε-caprolactone) (PLCL), was subjected to this pre-treatment and successfully melt electrowritten at low temperature for the first time. The elasticity of PLCL was maintained during the process, where scaffolds showed negligible deformation after cyclic extensions up to 50% of strain. PCL cannot currently deliver this type of elastic mechanic performance without printing complex architectures.

This overall approach can be readily adopted by any MEW user and is also generally suitable for thermally degrading polymers beyond MEW, where there is a need to reduce thermal degradation during processing.

Background: Bone is highly specialized connective tissue with unique property in bone regeneration. Hydroxyapatite due to its bioactivity has been used in osseous defect to improve osteointegration. Micro RNA 21 is a biomolecule endogenously expressed to regulate osteogenesis. Coupling of miR-21 and nHA is a potential intervention to harness greater and rapid healing of the host.

Methods: Wharton's Jelly cells obtained from umbilical cord were osteoinduced then treated with nHA and miR 21. The size and morphology of the nHA was characterized by (DLS) and (FESEM). Dose curve response and proliferation rate for the hWJMSCs treated with nHA and miR 21 was assessed by using Presto Blue assay. The expression of bone proteins was evaluated via Western Blotting. The expression of miR 21 with FAM tagged were identified by confocal imaging.

Results:
Both the FESEM and DLS showed the nano range of the nHA (10-100nm) and in spherical morphology. The dose curve response demonstrated the range of nHA 50ug/ml between 250ug/ml shows no toxicity and increased proliferation rate. The concentration of 20nM to 50nM of miR 21 evaluated show no toxicity. The western blots results expressed bone related proteins. The con-focal imaging shows the tagged miR 21 has been readily taken up by the cells.

Conclusion: hWJMSCs cells shows no toxicity after treated with nHA and miR 21 and also expresses significantly higher bone proteins. This preliminary study findings will be furthered with in vivo study to prove nHA incorporated with miR 21 will accelerate the new bone formation.

A promising way to control peri-implantitits, a bacteria-associated disease causing bone loss around dental implants, is the local administration of antimicrobial drugs or growth factors at the implant site. Recombinant human bone morphogenetic protein-2 (rh-BMP-2) can effectively promote bone regeneration and osseointegration [1]. Mesoporous materials constitute promising carriers for the delivery of various cargos and could be implemented in the local administration of rh-BMP-2. The aim of the present study was to evaluate the hemolytic properties of novel, rhBMP-2-loaded mesoporous silica and their effect on the viability of human periodontal ligament cells (hPDLCs). Mesoporous silica was synthesized via sol-gel reaction, following the co-operative self-assembly route in acidic media. Tetraethyl orthosilicate (TEOS) was used as the silica source and Pluronic P123 as the structure directing agent. The loading of rh-BMP-2 was obtained after immersion in PBS, stirring and subsequent centrifugation. The effect of rh-BMP-2-loaded mesoporous silica on cell viability was evaluated through indirect MTT test. The hemolytic activity was tested at various concentrations (12.5-500μg/ml) in contact with human red blood cells. At all concentrations low or no hemolytic activity was recorded. A higher hPDLCs proliferation rate was recorded after loading with rhBMP-2. These findings suggest the potential use of the synthesized mesoporous silica as biocompatible and effective carrier for the local delivery of rhBMP-2 in peri-implantitis treatment strategies.

Acknowledgments

In the last decay, recombinant protein-based therapies have shown great potential and achieved successful results in clinical applications. (1).

The major challenges rely on the optimization of existing delivery strategies since the required high protein concentrations are extremely cost-intensive. Furthermore, high unphysiological dosages must be prevented to avoid severe side effects. Therefore, innovative delivery techniques are needed in order to improve treatment efficacy with a simultaneous reduction of the protein being applied thus reducing costs and side effects. An immobilization of the bioactive proteins onto appropriate scaffold appears here to be a sound strategy to establish such next-generation delivery systems.

But how to maintain high protein activity and achieve reproducible coupling efficacy? To guarantee a high bioactivity a site-specific coupling mechanism is essential. Therefore, we adapted a tunable and novel coupling technique on the protein level (2). The required tools are embedded within the recombinant protein and on the surface of the corresponding scaffold structures. Already upon protein expression modifications are introduced within the protein sequence thereby maintaining a high protein bioactivity.

After protein purification the resulting protein can be covalently coupled to scaffolds being composed of polyoxazolines which already showed good biocompatibility and therefore are suitable for biomedical applications (3).

Sweat glands and salivary glands share a similar secretion mechanism. The secretion is based on ion and water currents towards the glandular lumen which are triggered by Ca2+ signaling following adrenergic or cholinergic stimulation[1,2]. Both glands fulfill crucial physiological functions (temperature homeostasis, digestion). However, disturbed glandular activity caused by disease or therapeutical side effects often leads to disorders such as hyperhidrosis or xerostomia. Currently available cell lines often lack functional markers which are required for activation of sweat and saliva formation via Ca2+ signaling and the exploration of bioactive substances. Therefore, ongoing research strives to assemble improved functional models[3-5]. In this study, new protocols for the isolation of functional glandular cells were established. In addition, it was analyzed whether three-dimensional cultivation could enhance the expression of functional markers.
First, explant cultures of epithelial sweat gland and parotid gland cells and parotid gland-derived stem cells (PDSCs) were generated. Their expression profile was characterized by qRT-PCR and acetylcholine-elicited Ca2+ signaling in epithelial cells was analyzed with Fluo-4/FuraRed by laser scanning microscopy. In Ca2+ imaging epithelial sweat gland cells revealed acetylcholine excitability and excitation dynamics on a cellular level.
To further enhance functional gene expression, PDSCs were cultivated in agarose microwells. With this technique large numbers of PDSC spheroids could easily be generated. Further studies will reveal whether three-dimensional cultivation enhances in vitro functionality.
Advancements of these models will allow testing of bioactive substances in a more physiological context and hence enabling the development of new products for antiperspiration and restoration of salivation.

Focal cartilage defects are a common knee problem with a high prevalence (20%) among people of all ages [1]. Due to its avascular nature cartilage has limited ability to self-repair and defects can lead to pain and to osteoarthritis in the long term. To repair these defects, autologous chondrocyte implantation (ACI) has been used for two decades with successful surgical outcomes, however, one of its main limitations is chondrocyte (CHs) de-differentiation during in vitro expansion [2]. Here we isolated ovine CHs and studied their de-differentiation from P1 to P4 in 2D culture. We then encapsulated dedifferentiated CHs into collagen and alginate (col/alg) hydrogels and cryogels and hypothesised that these 3D scaffolds would support the cells re-differentiation to CHs in the absence of chondrogenic inducers. From P1 to P4, CHs expanded in 2D culture lose their rounded morphology (aspect ratio of 1.5) to acquire a spindle shape with abundant stress fibres; they present progressive loss of chondrogenic markers (SOX9, SOX5, SOX6, COL2A1); and over-express hypertrophic markers (COL1A1). Dedifferentiated CHs embedded into col/alg hydrogels and cryogels remained viable up to day 14; furthermore, they started to aggregate and regain the typical rounded morphology and produce aggrecan and Coll II. Gene expression analysis revealed an increase of chondrogenic markers (SOX9, FOXO1, FOXO3A, COL2A1) in both 3D cultures suggesting that both formulations support the re-differentiation of in-vitro expanded CHs potentially enhancing the success rate of ACI procedures.

Several approaches have been explored in an attempt to develop representative tissue models to study cell biology and diseases in vitro, including culture within a hydrogel (e.g. organoid culture) and culture on decellularised tissue. Nevertheless, these models do not fully recapitulate the complex tissue architectures, have limited physical and biochemical cues normally found in tissues and reproducibility is limited. Also, translatability of decellularised tissue-based scaffolds is limited due to intrinsic variability, the requirement for donor tissue and concerns over residual biological factors. Hence, the need for wholly synthetic scaffolds that incorporate sophisticated biochemical and mechanical cues as mimics of the native extracellular matrix and can ultimately provide robust platforms for the creation of 3D tissue models.This presentation will describe our recent developments of porous polymer scaffolds using emulsion-templating process. The droplets of a polymerisable high internal phase emulsion (HIPE) become interconnected upon chemical curing/crosslinking, producing a fully interconnected porous material, known as a polyHIPE. The pore diameter and properties of these materials can be readily tailored, making them suitable for 3D cell culture, tissue engineering and regenerative medicine. Non-degradable and fully degradable polyHIPE materials prepared by photochemical thiol-ene polymerisation will be presented[1]. The resulting scaffolds are similar chemically to common clinically used polyester biomaterials (e.g. polylactide and polycaprolactone). The mechanical properties of these materials can be tuned from highly elastic to highly rigid[2]. The scaffolds are capable of supporting 3D growth of many cell types including human pluripotent stem cells[3], human haematopoietic stem cells[4] and primary human endometrial cells[5].

Organoids are three–dimensional multicellular tissue constructs that recapitulate the structure, heterogeneity, and function of their in vivo counterparts when cultured in vitro. As such, organoid production is a key technology in drug discovery and personalised medicine. A key challenge is producing organoids at scale in a reproducible manner. We are working with biotechnology company Cellesce, who develop bioprocessing systems for the expansion of organoids at scale. Part of their technology includes growing the organoids within a bioreactor, which utilises flow of culture media to enhance nutrient delivery to, and waste removal from, the organoids. Understanding how to optimise bioreactor operating conditions requires spatiotemporal information about the media flow and metabolite concentrations within the bioreactor. While it is impractical and expensive to collect this data empirically, mathematical modelling can be used to address these challenges. We present a model to investigate how mass transport of glucose and lactate within the bioreactor depends on the inlet flow rate and the cell seeding density [1]. We exploit the slender geometry of the domain to derive a long–wave approximation of the system. This reduced–order model systematically accounts for the depth–averaged flow, nutrient delivery, and waste removal, at a fraction of the computational cost of the full system. We explore the behaviour of the original and simplified models using analytical and numerical approaches and explain how our quantitative insights can be used to understand how organoid viability can be improved by varying specific bioreactor operating conditions.

DESIGN OF FREEZE-DRYING HYDROGEL DRESSING BASED ON NATURAL POLYSACCHARIDE GUM KARAYA FOR WOUND HEALING OF SKIN DEFECTS

Eva Černá[P][1], Lucy Vojtová[1]

[1] *CEITEC BUT*

Hydrogel based materials are promising candidates for effective treatment of skin defects (acute, chronic). Various materials, including synthetic and natural polymers, are widely used to produce gels, hydrogels, or thin films. This work is focused on the preparation of a cost-effective hydrogel dressing consisting of both natural and synthetic polymers. Natural polysaccharide Gum Karaya (GK) was chosen as a promising renewable resourced compound due to its low price, abundance, hydrophilicity, and potential antimicrobial properties. GK solution has been modified with hydrophilic poly(vinyl alcohol), and an emollient component to obtain a soft, transparent, and elastic dressing by freeze-drying.
The work aimed to design and production of a biocompatible hydrogel dressing suitable for long-term application to the wound site with pro-healing properties, nontoxicity, biomechanical properties, and transparency by mimicking the skin behaviour. Hydrogel dressings were characterized by a range of structural and mechanical properties including FTIR, UV/VIS, transparency, dynamic mechanical analysis, swelling behaviour, hydrolytic stability, biocompatibility, and morphology. Prepared dressings were non-toxic, transparent, flexible (elongation at break 150 % at the dry state and 380% at wet) and showed sufficient ability to swell (85% water content) with long-term hydrolytic stability (37 °C in physiological solution) for weeks, creating a suitable environment for wound healing management.

Keywords

Gum Karaya; wound dressing; skin-like

Mesenchymal stromal cells (MSC) represent a promising therapeutic tool for tendon regeneration. Their tenogenic differentiation is crucial for tissue engineering approaches and could be successfully induced by the transforming growth factor (TGF)-β, which is signalling through intracellular smad molecules. Moreover, scaffold topography or tendon matrix components mediated tenogenesis via activation of the rho/ROCK cascade, which, however, is also involved in pathological adaptations in extracellular matrix pathologies. This work investigated the interplay of rho/ROCK and TGF-β3/smad signalling in tenogenic differentiation in both human and equine MSC. Primary equine and human MSC were cultured as monolayers or on tendon-derived decellularized scaffolds to evaluate the influence of the ROCK inhibitor Y-27632 on TGF-β3-induced tenogenic differentiation. The MSC were incubated with and without TGF-β3 (10 ng/ml), Y-27632 (10 µM), or both. The signalling pathway of TGF-β and the actin cytoskeleton were visualized by smad 2/3 and phalloidin stainings, and gene expression of signalling molecules and tendon markers was assessed. ROCK inhibition was confirmed by disruption of the actin cytoskeleton. Activation of smad 2/3 with nuclear translocation was evident upon TGF-β3 stimulation. Interestingly, this effect was most pronounced with additional ROCK inhibition in both species ($p < 0.05$ in equine MSC). In line with that, the tendon marker scleraxis showed the strongest upregulation when TGF-β3 and ROCK inhibition were combined ($p < 0.05$ in human MSC). In conclusion, the results showed that ROCK inhibition promotes the TGF-β3/smad 2/3 axis, with possible implications for future MSC priming regimes in tendon therapy.

Burns are a prevalent healthcare problem, worsened by factors such as advanced age, diabetes or infections. Abnormal or delayed healing can lead to long-term sequelae and significant healthcare costs. It has been shown that skin burn damage can be ameliorated by proper diagnosis of burn severity and immediate treatment. Therefore, one of the key outstanding puzzles in the field is the molecular characterization of an early response to burns. Here, we propose a methodology for the prediction of cell fates in burned skin.

We use several models to study the early effects of burns on skin, including in vivo and ex vivo approaches on murine, porcine and human skin. Our in vivo porcine model allows us to study the immediate response to burns, with detailed histological assessment up to 6 h post-burn. Our complementary ex vivo technology opens the way for agonistic and inhibitory drug treatments to modulate the burn response. We observe a temperature-dependent multi-layered burn response, with zones of cell rupture, damage signaling and necrosis, apoptosis, DNA damage, and pro-growth signaling. We quantitatively describe a spatiotemporal response to heat injury including the depth of each molecular response and functional overlap between the various zones. The most striking change is a dramatic temperature-dependent activation of growth signaling pathways in the dermis and hypodermis. This activation represents the survival zone and is integral to the wound healing response. Our findings pave the way for the development of targeted treatments and diagnostic tools for more efficient management of burn injuries.

Willemite (Zn_2SiO_4) is a bioceramic with bone defect healing properties. The aim of this study was to evaluate biocompatibility and osteogenic activity of nanoparticulate Willemite (npW) in Willemite/polycaprolactone (npW/PCL) composites. Porosity and crystallinity of npW/PCL were measured by TEM and XRD. The npW/PCL mixtures were spin-coated on 3D printed PCL scaffolds. Coating Thickness was determined by SEM. The topochemical and topomorphological changes of the scaffold surface were analysed using FTIR and XRD. The bioactivity of the npW/PCL composite was evaluated by immersion composite in simulated body fluid. In-vitro cytocompatibility studies were carried out by culturing rat bone marrow stem cells on the npW/PCL scaffolds for 72 hours. Composite scaffolds were fabricated with a geometry equal to the femur bone defects of Wistar rats and were placed in the target bone for two months and the newly formed bone was analyzed by µCT. the presence of npW in PCL increased the crystallinity and the hydrophilic functional groups compared to the neat PCL. The bioactivity studies showed that fewer but larger hydroxyapatite nuclei were formed on the npW/PCL composite than on the neat PCL. Scaffolds containing npW showed greater cytocompatibility after 72 hours than scaffolds without. Micro-CT analysis demonstrated that the npW/PCL scaffolds had a significantly higher bone ingrowth compared to neat PCL scaffolds at 8 weeks after implantation.This study was conducted to show the potential of Willemite nanoparticles in 3D printed porous npW/PCL composite scaffolds as a versatile approach to promote bone ingrowth and regeneration of osteonecrotic focus in rat femur.

SURFACE IMMOBILIZATION OF ANTIMICROBIAL CATH-2 PEPTIDE TO PREVENT IMPLANT-RELATED INFECTION

Introduction

Implant-associated infection (IAI) results from bacteria that initially colonize on the surface of the implants, then proceed to form a biofilm. Since bacteria growing in biofilms are tolerant to antibiotics and immune cell clearance, these infections are usually treated by removing the implant in a sophisticated two-steps revision surgery which imposes a huge socioeconomic burden [1]. Host defense peptides (HDPs) are considered as an interesting broad-spectrum alternatives to antibiotics in preventing IAI [2]. In particular, CATH-2 peptide (as one of the HDPs) causes a direct disruption of the microbial membrane thanks to its strong cationic charge [3]. Here, we aim to immobilize CATH-2 on porous titanium (Ti) surfaces using a carboxylic-based coating which can be applied via an electrospraying technique.

Materials and methods

A solution of propoxylated bisphenol A fumarate polyester (65 mg/ml) and Ethanol was coated by electrospray method to apply COOH group on Ti implants. CATH-2 (RFGRFLRKIRRFRPKVTITIQGSARF-NH2) was immobilized on the coated Ti through COOH bonding of polyester to amines (–NH2) of the peptide by 1-Ethyl-3-(3-dimethylaminopropyl) carbodiimide (EDC) and N-Hydroxysuccinimide (NHS) reaction.
In vitro antibacterial activity against Staphylococcus aureus, the peptide release behavior, and cytotoxicity of the coated implants were investigated by colony-forming unit (CFU) count, BCA protein kit, and Alamar blue assay, respectively.

Results and discussion

Our materials characterization and biological assays verified that the polyester coating has improved the peptide immobilization on the Ti surface, and significantly decreased bacterial adherence as well. This surface could be potentially applied on Ti implants in post-antibiotic era.

Fluorescence-based imaging of cell proliferation or adhesion on 3D/ porous scaffolds has limitations owing to its non-specific stain entrapment or its own autofluorescence behaviour. Herein, a facile route of imaging cell proliferation on non-transparent matrices was developed using polypyrrole (PPy) incorporated electroconductive gelatin-silk fibroin (Gel/SF) hydrogel. Interfacially polymerized PPy coated Gel/SF were further impregnated with carbon nano dots (CDs), synthesized using hydrothermal method from clove buds as a precursor. PPy was chosen due to its high conductivity or cytocompatibility while CDs are known for their tailorable fluorescence and excellent water solubility. Formation of CDs was first confirmed using UV-vis, which showed band corresponding to n–π* transition of multi-conjugate C=O of the CDs. Subsequently, L929 mouse fibroblast cells were seeded on as prepared formulation of PPy-Gel/SF. After 48 h, CDs were added at predefined concentration and samples were incubated for 8 h. Fluorescence imaging was performed to visualize cells on electroconductive matrix under UV (358 nm), green (540 nm), and red (650 nm) excitations. Moreover, single cell Raman signals were acquired so as to confirm intake of CDs by L929 cells. Two Raman lines associated with D-band and G-band were investigated for approving the presence of CDs. Thus, CD incorporated PPy based Gel/SF scaffolds can be deployed for facile and continuous monitoring of live or fixed cells on non-transparent/porous scaffolds.

The directed differentiation of induced pluripotent stem cells (iPSCs) to kidney organoids has facilitated pioneering studies into processes that underpin both human kidney development and the pathogenesis of disease. Continued advances in stem cell technologies have made the provision of patient-specific, bioengineered replacement organs a realistic prospective treatment for end-stage renal disease. Synthetic biomaterials represent a promising means of generating physiologically relevant, non-xenogeneic and mechanically tuneable microenvironments conducive towards improved complexity and maturity of tissue constructs. Within this context, we differentiated iPSC-derived nephron progenitors into kidney organoids within synthetic self-assembling peptide hydrogels of variable mechanical strengths. Histological analysis of kidney organoids revealed variable self-organisation of tubular epithelia and interstitial cells by day 24 of differentiation, most notably in peptide hydrogels with Storage Moduli (G') of 1 and 14 kPa. Immunofluorescent characterisation of the organoids confirmed the formation of glomerular, proximal tubular and distal tubular structures, supported by basement membrane and interstitial cells. Single-cell RNA sequencing was subsequently used to delineate the effects of the biophysical environment on the differentiation and fate of cells. Following unsupervised clustering, 13 distinct cell types were identified. Most notably, stromal expansion was shown to vary significantly between organoids differentiated within soft vs stiffer synthetic microenvironments. To the best of our knowledge, this is the first investigation of iPSC-derived kidney organoids within fully synthetic, self-assembling peptide hydrogels. These results will further support the generation of designer matrices that will improve maturity and the translational potential of kidney organoids.

Osteocytes require 3D environment to maintain their phenotype in vitro (1). Due to the difficulty to isolate and grow these cells, most studies have so far have used cell lines (2–4). Alternatively, studies have focused on the use of collagen gel to embed the cells and differentiate primary osteoblasts (1,2,5). We demonstrate the use of a new hydrogel that supports primary osteoblasts differentiation to osteocytes. Primary human osteoblasts were embedded at a density of 300 000 cells/mL in a bioink composed of fibrinogen, gelatin and alginate polymerized by calcium and enzymatic solution. Cells remained viable during the 50 days of the experiment even in the center of the tissue and displayed characteristic features of osteocytes: no cell growth, dendrites formation and expression of PHEX, a histological marker of osteocyte (6). Unlike the collagen model which requires a high density (1.106 cells/mL) of osteoblasts to induce differentiation from osteoblasts to osteocytes (7), we managed to differentiate the cells with a lower density. As primary cells are difficult to obtain and have a very limited proliferation capacity, this is of major convenience. Moreover, this biomaterial is printable and provides high shape fidelity. Therefore it could be used to reproduce the porous trabecular bone. The polymerization step can also be adjusted to tune the mechanical properties of the hydrogel (elastic modulus from 1kPa to 80kPa), allowing to examine the response of the cells to their environment stiffness.

Cryopreservation methods for cell and tissue storage have been around since 1954, where thawed sperm samples were used for an insemination. Since then, the technology has evolved for clinicians and researchers to cryopreserve tissue, cell lines and primary cells. While cryopreserving tissues helps maintain their physiological integrity for study it does not assure the viability of the cells after thawing. Furthermore, the cells cryopreserved in suspension lose their dimensional anchors, forcing them to change their morphology. To solve this issue, tissue engineering allows researchers to create 3D culture models, such as organoids and bioprinted cell clusters, that mimic the physiological characteristics of the cells in tissue and disease. Although this culture methods present promising results, there is a lack of methodology to cryopreserve 3D cell models and patients' samples for storage and transport in a way where they remain viable after thawing. We propose a protocol that uses a carboxymethyl cellulose scaffold and precise freezing and thawing conditions for spheroid survival. The scaffold provides structure for the hepatocytes to create spheroids on their own as well as support throughout the freezing and thawing processes for optimal cell viability post-thawing. Furthermore, this method will achieve higher cell viability than transporting the cells as a cryopreserved pellet for model assembling after thawing, allowing the cells to settle and form a tissue beforehand to improve viability after cryopreservation. This technique constitutes a step forward for it will facilitate the transport of already assembled 3D models from cell lines or primary cells from patients.

Bioartificial liver remains a promising alternative to liver transplantation for acute liver failure (ALF). We have recently demonstrated that the HepaRG cells encapsulated in alginate beads hosted in a perfused dynamic bioreactor (PDB) meets the clinical needs in terms of liver functions (1,2). In this study, we aim at evaluating the PDB under near-real conditions by mimicking moderate and severe ALF with several therapy modalities.

HepaRG cells were encapsulated in alginate beads by coaxial airflow extrusion and then transferred to PDB for orbital shaking in classical culture medium. Starting from day 14, cells' performances were assessed during three successive therapies of 6 hours (one per day) or a 72h therapy in moderate and severe ALF in vitro models. Different parameters were measured such as viability, albumin synthesis and ammonia detoxification rate.

Encapsulated cells remained viable and demonstrated their capacity to maintain activities after three days of therapy. Albumin production remained stable (around 2.6 µg/6h/million cells) while ammonia detoxification was higher in a severe pathologic model than in a moderate one (respectively 213 and 112 mmol/6h/million cells).

Interestingly, when we get closer to the clinical therapy conditions, cells become more efficient. It is also very important to note that cells can be used for three successive therapies. These results will help us to launch animal experiments in accordance with clinicians needs and regulatory agencies.

The research project is funded by ANR 16-RHUS-0005 in the iLite programme. The HepaRG cell line were provided by Biopredic International.

In acute tendon lesions, the effect of mesenchymal stromal cells (MSC) is mainly attributed to immunomodulatory mechanisms. However, little is known about their mode of action in chronic disease. Therefore, we aimed to establish a cell culture model that reflects extracellular matrix alterations in chronic tendon disease. Equine limbs were obtained from an abattoir and superficial digital flexor tendons were dissected. Based on macroscopic and ultrasonographic evaluation 17 tendons were chosen to be examined in a 0.27T standing equine-dedicated low-field magnetic resonance imaging (MRI) system. Subsequently, 12 of these tendons were also examined in a 3T MRI in horizontal position as usual for the 3T MRI, and in standing position corresponding to the procedure in the equine system. Tendons were decellularized to be used as scaffolds for MSC culture. Tendon disease was detected with both MRI systems, with differences in lesion discrimination and signal intensities between horizontal and standing positions. N=6 tendons with increased signal in T1 sequences and normal signal in T2 sequences were chosen to model chronic tendon disease in vitro. N=6 healthy tendons served as controls. Cultivation of MSC on tendon scaffolds altered their extracellular matrix gene expression. Based on preliminary data, we also expect adaptations to the diseased matrix environment.

To overcome global graft shortage, researchers try tackling the issue by developing human-designed organs (as opposed to native ones): devices/methods aiming to temporally assist or permanently replace the liver. To understand how they were conceived, we undertook a philosophical analysis of the field. According to findings, designers start from what they know. The first source of inspiration is nature, in this case the native liver, or, more exactly, the conception that they have of it: is the organ defined by its structure (lobule, sinusoid…)? Its functions (detoxification, metabolization…)? Both or neither? The second source of inspiration is pre-existing technologies/methods, such as dialysis or cellular culture. From those two inspirations, researchers develop design strategies: for example, conceiving purely artificial devices in order to avoid all the constraints posed by cells, or on the contrary, using cells by betting that, even if we do not completely understand their functioning, they will act as they do in vivo. Questioning current scientific methodologies could allow burgeoning of further inclusive design approaches by incorporating other inspirations and strategies. Integrating this momentum, is accepting that technique is not neutral, that technical objects carry the conceptions and values of those who created them(1) and, thus, they shape humans and the world.

MULTIFUNCTIONAL COLLAGEN MIMETIC MATERIALS FOR BOTTOM-UP CONTROL OF CELLULAR MICROENVIRONMENTS

April M. Kloxin[P][1]

[1] *University of Delaware*

Corresponding author's email: akloxin@udel.edu

Characteristics of tissues throughout the body vary based on tissue type and function, for example, from the collagen-rich compliant, loose connective tissues of the lung to the stiff, regular connective tissues of the tendon and ligament. The physical properties of these tissues arise in part from the assembly and hierarchical organization of large structural proteins and glycosaminoglycans. In particular, collagen-rich tissues rely heavily on the self-assembly of smaller collagen subunits to form multiscale structures of fibrils and fibers that are further organized and modified by cells. This bottom-up (e.g., assembly) and top-down (e.g., cellular remodeling) organization of the extracellular matrix allows adaptation of tissue properties in response to stimuli in reversible (e.g., strain hardening) or directional (e.g., fibrotic stiffening) manners. These complex systems provide inspiration for the design of engineered materials with hierarchical structures and tunable and adaptable mechanical properties, presenting opportunities for creating improved tissues mimics of relevance for studying and directing cellular responses in vitro and in vivo. Specifically, in this talk, I report on our recent efforts in the design and application of multifunctional collagen mimetic peptide (mfCMP) based materials. These mfCMP materials systems integrate collagen mimetic peptides with different reactive handles for crosslinking, modification, and dynamic modulation of the properties of hydrogel-based synthetic extracellular matrices in response to light and temperature. Further, the biophysical and biochemical properties of these materials can be tailored to promote cell spreading and motility and to stabilize injured collagen-rich tissues.

Research into the development of therapeutic strategies is based mainly on animal models and cell cultures. The ability to extrapolate data from them is limited, and research on new drugs cannot be performed efficiently. This is especially dramatic in rare diseases, which are intrinsically very heterogeneous. The generation of advanced models using tissue engineering and patient-derived cells allows fabricating new platforms for studying pathological processes and discovering new potential drugs. Here, we developed a patient-derived 3D functional skeletal muscle for Duchenne muscular dystrophy (DMD). DMD is the most prevalent neuromuscular disease diagnosed during childhood. The disease is characterized by progressive degeneration of skeletal and cardiac muscle caused by the lack of dystrophin protein. Although there are several molecules in drug development for DMD, there is no treatment available for patients to date. By using a 3D-printed casting mold, we encapsulated patient-derived myogenic precursor cells in a fibrin-composite matrix. This platform incorporated two flexible T-shaped pillars that provided continuous tension to the tissue, thus allowing the orientation of the muscle fibers. Our 3D muscle model expressed mature muscle markers and responded to electric pulse stimulation (EPS). Besides, contraction dynamics between DMD and control tissues were shown to be different. Moreover, an increase of damage markers after EPS was observed in DMD but not in healthy tissues. Finally, the tissues will be integrated into a microfluidic device to monitor drug administration. Eventually, the microfluidic system will be connected to a biosensors system for the real-time detection of biomarkers.

The ideal biomaterial for brain tissue engineering (TE) should provide versatile features which together play a synergistic role in the regeneration of the damaged brain matter. A successful candidate should not only mimic the architecture and composition of the native tissue but also protect the surroundings from excitotoxicity and oxidative stress, which are critical factors in brain injuries. Here, we address these features by exploiting the multi-active role of magnesium ions to improve both physico-chemical and biological properties of alginate biopolymer and finally develop an alginate-based biosystem for brain TE. For the first time, the calcium-driven inner gelation of magnesium alginate (MA) provided soft and homogeneous alginate-based hydrogels. 3D cultures of rat embryonic primary neurons demonstrated that MA is cytocompatible, supporting neuronal network formation. Already after 7 days in vitro (DIV), cells encapsulated in the MA hydrogels showed a higher number of total neurite length and branch points compared to commonly used sodium alginate (SA). Moreover, neurons in MA manifested a higher level of functionality after 28 DIV in terms of spontaneous neuronal activity evaluated by calcium imaging. Further, we explored the anti-oxidant and neuroprotective role of the MA in a 2D system using rat embryonic neural stem cells. These experiments showed that MA protects the cells against oxidative stress reducing cell mortality, biomarker degradation and reactive oxygen species production. Taken together, these results indicate that the MA ion-responsive polymer exhibits multiple bioactive roles in both 2D and 3D cellular systems, supporting its use for brain tissue bioengineering.

Due to rapid developments in Additive Manufacturing (AM), 3D (bio)printing (especially extrusion bio-printing) is increasingly used for tissue engineering and regenerative medicine. Extrusion bio-printing requires the shear thinning hydrogels to reliably print certain geometry. Hydrogels are versatile molecules for 3D tissue engineering, however, when they are utilized as bio-inks, the rheological and mechanical properties are challenging to print with high shape and geometry fidelity and usually require additional crosslinking.

Peptide self-assembly is a novel way of forming stable hydrogels for scaffold manufacturing, 3D bio-printing and drug delivery applications. Among these peptides, Fmoc-diphenylalanine (Fmoc-FF) is highly investigated as a scaffold material due to its biocompatibility and interesting mechanical properties, which have been shown to positively influence osteogenesis and chondrogenesis. However, although Fmoc-FF is a very promising peptide, printability and bio-ink characteristics have not been well elucidated.

In this study, we use Fmoc-FF as a bio-ink material to investigate its' printability in an extrusion printing set-up as well as the use of these peptide hydrogels in bone tissue engineering. The peptide was blended with alginate in various concentrations to create a printable material allowing for high cell viability. Alginate/Fmoc-FF bio-inks were successfully printed into various geometries. Printability of the bio-inks was calculated with respect to feed and flow rate. Surface characterization was performed using atomic force microscopy (AFM), scanning electron microscopy (SEM) and Fourier-transform infrared spectroscopy (FTIR). Mechanical characteristics and rheological properties of the bio-inks are being evaluated. Taken together, we conclude that Alginate/Fmoc-FF hydrogels are versatile bio-inks for 3D bio-printing application.

Diphenylalanine (FF) has been shown to function as a piezoelectric material with significant mechanical stiffness. The piezoelectricity of the diphenylalanine is arising from the π-π stacking in between the aromatic residues. Currently, due to high piezoelectricity, Fmoc-FF (chemical synthesis with Fmoc protecting group) is utilized for creating micro-nanogenerators and bio-organic conduits for energy harvesting purposes.

Bone is a piezoelectric tissue due to the collagen assemblies in extracellular matrix (ECM) environment. According to Wolff's law, bone adapts its architecture to the mechanical loading it is subjected to. Although the role of the mechanical loading is not fully explained, it is known that piezoregulation is one of the factors active in bone homeostasis. Piezoelectric materials create an environment for mechanical-electrical coupling, which contributes to the bone remodeling process. Fmoc-FF as material for 3D tissue engineering, has been shown to aid osteoblastic differentiation. However, the effect of its piezoelectricity on osteogenesis has never been addressed.

To understand the role of piezoelectric effects of Fmoc-FF on osteogenesis, a nanofibrous Fmoc-FF network has been created using electrospinning. Fmoc-FF has successfully electrospun into nanofibers (80-150 nm). The morphology, mechanical properties, piezoelectricity and chemical characteristics of the Fmoc-FF sheets were assessed by scanning electron microscopy (SEM), , piezoresponse force microscopy (PFM), water contact angle measurements and Fourier-transform infrared spectroscopy (FTIR), respectively. Biological tests are ongoing. In conclusion, Fmoc-FF electrospun in sheets is a potentially interesting material to design novel scaffolds with proper mechanical and electrical properties for bone tissue engineering.

ADVANCED IN VITRO MANAGEMENT OF 3D CELL CULTURES AND TISSUES

Sebastian Kress$_P$[1], Dominik Egger[1], Cornelia Kasper[1]

[1] *University for Natural Resources and Life Sciences, Vienna*

Corresponding author's email: Sebastian.kress@boku.ac.at

3D In vitro tissue and organ models gain increasing importance due to the 3R rules and to deliver more relevant results mimicing the human cellular pathways and interactions for a clinical translation.
However, there is currently no bioreactor or monitoring system commercially available, which facilitates a non-destructive long-term repetitive insight within the core of a 3D model.
The combination of open flow microperfusion (OFM) with a custom designed perfusion bioreactor and implemented sensors, enables a direct time resolved insight within the metabolic processes of a 3D tissue model. Furthermore, the setup serves as a minimally invasive sampling technology to yield highly concentrated metabolome and secretome equivalent to the interstitial fluid within the tissue. This facilitates the verification of metabolic and secretory processes, which are diluted below the detection limit when relying on analyzing the media supernatant. Moreover, the system is designed as a platform technology and by 3D printing customizable to various tissue geometries, sizes, and requirements allowing the models to be cultured mimicking physiologic conditions.

PROCESS PARAMETERS FOR CELL FREE THERAPY USING AUTOLOGOUS EVS

Sebastian Kress$_P$[1], Ciarra Almeria[1]

[1] *University of Natural Resources and Life Sciences, Vienna*

Corresponding author's email: Sebastian.kress@boku.ac.at

The use of extracellular vesicles (EVs) for cell free therapy present various advantages over cell based therapies. Many regenerative mechanisms are transmitted via secreted signals than direct cell-cell contact making the use of cell transplantion obsolete and thereby avoiding the respective risks. Nevertheless, the cellular production of EVs depends on the environmental conditions of the cells. Hence, the production of biologically active and therapeutically potent EVs requires culture conditions for the producing cells to induce and stimulate the desired functionality.
In a first study we evaluated various culture conditions for primary isolated MSCs upon their impact on EVs production, size distribution, cargo, and biological functionality.

In tissue engineering, it is important to recapitulate the microstructural organization of native tissues that is critical to their function[1]. Scaffold-based techniques have focused on achieving this via contact guidance principle wherein topographical cues offered by scaffold fibers direct migration and orientation of cells to govern subsequent cell-secreted extracellular matrix organization[2]. In contrast, this work describes a new ultrasound-assisted biofabrication (UAB) process that utilizes radiation forces generated by superimposing ultrasonic bulk acoustic waves to preferentially organize cellular arrays within single and multi-layered hydrogel constructs[3,4]. Specifically, we investigated the UAB of anisotropic cartilage constructs with patterned human adipose-derived stem cells or chondrocytes encapsulated within GelMA matrices. The cells organized in parallel arrays remained 100% viable post-UAB ($p < 0.0001$), and the metabolic activity was not affected compared to the groups without ultrasound exposure. The inter-cellular array spacing was also closely correlated with the theoretical estimate of half the ultrasound wavelength ($p < 0.001$). In addition to cells, we patterned collagen microaggregates and polycaprolactone microfibers within the GelMA matrix, which enhanced the mechanical stiffness, stretchability, and strength ($p < 0.05$) of the hydrogels while providing additional adhesion cues for cell proliferation and aligned ECM production. The results of long-term maturation of cell-laden constructs under the relevant chondrogenic culture medium clearly demonstrated that the hybrid constructs were superior to pure GelMA counterparts in maintaining construct stability and promoting cell alignment and anisotropic collagen-II deposition, and biomimicking the native organization of cells and collagen within cartilaginous tissues such as the annulus fibrosus and meniscus.

The algal polysaccharide sodium alginate represents a highly biocompatible and low immunogenic biomaterial offering a broad range of biomedical applications[1]. In brain tissue engineering, it has been employed to generate very soft hydrogels promoting neural stem cell differentiation and maturation of functional neuronal networks[2-5]. However, sodium alginate gelation, mediated by bivalent cations like calcium, is rather rapid and it leads to uneven and unstable hydrogels limiting their in vivo injectability. To overcome these issues, we carried out an ion substitution process to exchange monovalent sodium ions with bivalent non-gelling magnesium ions and we characterized, via rotational rheology and microrheology, the polymer physico-mechanical properties. Magnesium ions reduced the intrachain repulsion and increased the intramolecular interactions, in turn influencing alginate conformation and behaviour. Magnesium alginate was less viscous than sodium alginate and, in the presence of calcium, it led to slower gelation kinetics providing more homogenous and stable hydrogels. The improved resistance to deformation made magnesium alginate especially suitable for in vivo injection in the rat brain, through small infusion needles (26-28 gauge) allowing less invasive neurosurgery. In addition, being magnesium neuroprotective[6], we sought whether it could augment alginate anti-inflammatory action in brain tissue. To this aim, we performed immunohistochemistry of reactive gliosis biomarkers, upon either sodium or magnesium alginate treatment, in pathological conditions such as temporal lobe epilepsy and cytotoxic brain lesion induced in rats. Overall, this study demonstrated that magnesium alginate can provide both structural and trophic support to neural cells and revealed its potential for brain tissue repair.

Artemisinin (ART) and its derivatives, artemisinins (ARTs), are the most useful antimalarial drugs presenting no side effects1. They probably activate the endoperoxide bridge by producing radicals via mechanisms associated with iron-activation, having half-live ranging between 2 to 5 hours2. The encapsulation of ARTs in mesoporous silica (MSNs) for sustained release represents a non-investigated way to improve the pharmaceutical properties of ARTs. Mesoporous calcium-silicate MSNs doped with cerium (1, 2.5, 5%) were synthesized via sol-gel (Ce-MSNs). ART-loaded (12.5–500μg/ml) Ce-MSNs were investigated in terms of biocompatibility with human periodontal ligament cells (hPDLs) and hemocompatibility with red blood cells. ART-loaded Ce-MSNs didn't present hemolytic activity at concentrations up to 1 mg/ml, while ART concentrations ranging from 100 nM to 1 mM were hemocompatible too. The MTT assay revealed that ART-loaded Ce-MSNs enhanced hPDLCs' proliferation, while 1 and 2.5% Ce-MSNs significantly promoted mitochondrial activity. ART is a promising candidate for the treatment of patients with dental-related microorganisms causing pulpitis, periodontitis, and peri-implantitis3. In the light of previous results for the role of artemisinin in osteogenesis3 and the enhancement of osteogenic differentiation in human mesenchymal stem cells4, our study provides the first link between loading of ART in MSNs and hPDLCs proliferation and sheds novel light on developing ART-cerium doped MSNs as promising candidates for bone regeneration in patients affected by peri-implantitis.

Fetal bovine serum (FBS), which is the current gold standard as a basal medium supplement for the cultivation of many cell types, including equine MSC, is afflicted with several problems. Different alternatives are being tested, with promising results using platelet lysate in human MSC culture. The aim of this study was to establish a standardized protocol for equine platelet lysate (ePL) production and to test the ePL in equine MSC culture. Whole blood collected from 20 healthy horses was processed into platelet concentrates using a buffy coat method. In these concentrates, the cells were lysed by freeze/thaw cycles. The pooled ePL from all donors was evaluated as culture medium supplement in comparison with FBS, using equine adipose-derived MSC. Platelet, platelet-derived growth factor BB and transforming growth factor β1 concentrations were increased in the processed concentrates compared with whole blood or serum ($p < 0.05$), while white blood cells were reduced ($p < 0.05$). When the ePL obtained was used at the same concentration (10%) as FBS, MSC expansion and adipogenic and osteogenic differentiation were supported similarly. In passage 5 MSC, karyotype analyses by GTG-banding suggested a higher genetic stability in the MSC cultured with ePL.

Hydrogels have been widely used to engineer the microenvironment of cells in the field of tissue engineering and regenerative medicine. The properties of the microenvironment, such as stiffness, plasticity, degradability, and bioadhesion, will among others affect cell morphology, migration, and proliferation. However, controlling cell morphology and behavior in a defined manner by an engineered microenvironment is still challenging. Using a matrix metalloprotease (MMP)-sensitive crosslinker and polyethylene glycol-based crosslinkers with different topologies we engineered hydrogels with possibilities to control the properties of the cellular microenvironment. Hydrogels were prepared by conjugating the cyclooctyne bicyclo[6.1.0]nonyne (BCN) to hyaluronic acid and crosslinked utilizing degradable and non-degradable crosslinkers in the presence and absence of cyclic RGD (cRGD) as cell-adhesive ligand. Primary fibroblasts were cultured in hydrogels with different stiffness, plasticity, degradability, and amount of cRGD. We identified that cells encapsulated in stiffer hydrogels (G´ ≈ 0.7 kPa) in the presence of cell-adhesive ligand showed an extended morphology, irrespectively of degradability. However, cellular extensions were longer and more defined in degradable compared to non-degradable hydrogels. This effect was further pronounced in hydrogels with shorter relaxation time. In softer hydrogels (G´≈ 0.3 kPa) the extensions were less pronounced. In addition, cells cultured in hydrogels in the absence of cRGD showed a rounded morphology in both soft and stiff conditions. In conclusion, these modular and tunable hydrogels are promising candidates for design of microenvironments to control cell behavior and morphology.

Cell expansion processes are essential to acquire the high amount of cells needed to do clinical research towards cell-based regenerative applications[1]. These bioprocesses are highly variable, risking to overfeed cells when standard protocols are followed[2]. This work proposes novel, individual feeding strategies for bioprocesses in tissue flasks, using lactate values measured during the culture process as an indication for cell growth. The feeding strategies are generated by a model-based predictive controller in MATLAB R2019b. As a reference, human progenitor cells were cultured for 8 days using 4 different, fixed medium replacement strategies, each performed twice. Dynamic regression models were fit with an average accuracy of 94.43% ± 0.04%. The controller was tested by performing simulations with this reference data, resulting in an average accuracy of 97.35% between measured and predicted lactate values. Next, the controller was implemented in real-time during new culture experiments. The amount of medium replaced was based on what the controller predicted, using data from the reference experiments as a trajectory. A first experimental run used the exact lactate values from the reference experiment as a trajectory, resulting in an average accuracy of 10.41% ± 0.08% between reference data and real-time lactate measurements. A second run used rates with which the lactate values increased during the reference experiment as a trajectory, giving an accuracy of 92.78% ± 0.04% between real-time lactate measurements and reference. Using rates of lactate as a reference is therefore a promising way to control cell growth in real-time through predicted, individualized feed strategies.

Decoding the complex biological network within the tumor microenvironment (TME), which consist of spatiotemporally-regulated cell-cell and cell-matrix interactions, is crucial in advancing our understanding of tumor progression and metastasis. Furthermore, the TME secretome remains a key determinant in metastatic organotropism by priming the pre-metastatic niche via signaling proteins and extracellular vesicles (EVs). Thus, an intricate 3D co-culturing system enabling precise tissue localization of multiple cell types while allowing discrete sampling without disturbing the system's biochemical gradients is needed to recapitulate the dynamic interactions within the TME.

We developed an organ-on-a-chip device for co-culturing spheroids of MDA-MB-231 triple-negative breast cancer cell line, or its brain-, bone-, lung-, and liver-organotropic subpopulations, with up to four relevant TME stromal cell types. Organ-native fibroblast, endothelial, and immune cell types were seeded in the side chambers surrounding the spheroid chamber, mimicking cancer-stromal configurations observed in vivo. Conditioned media were sampled from chamber-specific open wells and profiled for secreted proteins and EVs throughout the experimental time-course using antibody microarrays. Our preliminary data suggested that secretomic crosstalk between breast cancer spheroids and stromal cells differed depending on metastatic organotropism. Notably, various integrin expressions in breast cancer-derived EVs were unique among lung-, brain- and bone-organotropic populations. Additionally, confocal live-cell imaging suggested that migration patterns of the spheroid varied depending on its organotropism and the presence of co-cultured stromal cell types.

In conclusion, our platform opens up potential avenues for bridging our understanding of the highly dynamic TME secretome and its heterogenous effects on tumor-stromal migration and metastatic organotropism.

Type 1 Diabetes Mellitus is an autoimmune disease characterized by an insulin deficiency caused by pancreatic β-cell destruction, which leads to persistent high blood glucose levels [1]. There is an urgent need for more efficient and cost-effective strategies to ensure physiological insulin production that responds to blood glucose levels. This study has developed a high-throughput and low-cost 3D bioprinting methodology for producing insulin-secreting spheroids through encapsulation of β-cells in a single-step procedure. The reduced spheroid volume and the increment of surface-area-to-volume ratio could improve the diffusion distance compared to large volumes and decrease time response to blood glucose changes. We used collagen as a biocompatible encapsulation material which provides a physiological environment for β-cells. To improve the mechanical stability, we crosslinked the collagen hydrogel with Tannic Acid (TA), which interacts with the collagen chain-forming hydrogen bonds [2]. Additionally, TA possesses pleiotropic effects, such as anti-inflammatory and anticancer properties [3].

This protocol allows customizing the size of the spheroids with extremely low variability, minimizing cell damage during the encapsulation process. Specifically, we show that collagen crosslinked with TA hydrogels present easier handling and far more resistance to collagenase degradation. Furthermore, the stiffness increases in time and dose-dependent manners. Importantly, encapsulated β-cells do not escape from the collagen hydrogels crosslinked with TA, and insulin secretory function is sustained over time.

In conclusion, the present study provides a foundation toolset to generate cell-laden spheroids by 3D bioprinting, which can be helpful for future advanced functional studies.

The gut microbiota has been increasingly recognized in its role for human health and disease(1). In vitro fermentation systems that model various parts of human GI tract allow for the investigation of microbial communities with precise control of various physiological parameters while decoupling interference from the human host. Current systems, such as the Simulator for Human Intestinal Microbial Ecosystem (SHIME)(2) and Robogut(3), while effective at propagating and stabilizing complex microbiota communities, are large in footprint, lack multiplexing and of low experimental throughput. Alternatives which address these shortcomings are often reliant on expensive and delicate lab equipment which hinders lab replication, such as the Mini Bioreactor Arrays (MBRA) system(4). Here, we present GITbox, a low-cost, miniaturized multi-bioreactor system that simulates the human colon microbiome environment with physiologically relevant conditions simultaneously in triplicate bioreactors. The bioreactors had 30ml working volume, were independent of anaerobic chamber and equipped with automated pH, temperature, gas, and fluidic control. We found that from 14-day experiments, GITbox was able to support a stable complex microbiota community from individual fecal samples after only 3-5 days of initial adaptation period. We further characterized GITbox-grown microbiota and found that GITbox retained inter-sample microbiota differences by developing closely related communities distinctive to each donor. GITbox also maintained both minimal variations between replicate reactors and day-to-day variations after stabilization similar to other existing systems and mouse model. Together, we demonstrate that GITbox is an accessible system for studying effect of various xenobiotics and perturbation on gut microbiota with high throughput and multiplex.

Intrafusal skeletal muscle fibres (Bag and chain) are a specialised population found within the muscle spindle and have a mechano-sensory capacity, forming a key component of proprioceptive function. Dysfunction of intrafusal fibres is linked with many neuromuscular diseases and injury. To-date, progress towards generating de novo intrafusal fibres for studies of development, function and disease are limited to basic two-dimensional cultures. Neuregulin isoform 1 (Nrg-1) initiates differentiation in vivo and has been the focus of in vitro literature. C2C12s in 2D respond to Nrg-1, with some prominent features of intrafusal skeletal muscle, but with limited expression of putative intrafusal specific proteins. The capacity for C2C12 Intrafusal specific differentiation in a 3D tissue engineered model is undetermined, forming the rationale for this study.

Collagen I, Matrigel and cell mixtures cast into 3D printed moulds, were supplemented every 48hrs with +/-Nrg-1 (100ng/mL) during differentiation. Intrafusal bag myotubes were morphologically assigned from fluorescent micrographs. To elucidate mechanisms underpinning morphological differences, gene (RT-qPCR) expression of key transcription factors, myogenic regulatory factors, and myosin heavy chains (MyHCs) were analysed. Maximal twitch and tetanic forces were measured following electrical field stimulation using a force transducer system.

Ongoing results indicate Nrg-1 supplementation increases intrafusal bag myotube differentiation. MyHC expression was altered in nearly all isoforms, suggesting specificity towards a distinct phenotype comparable to that observed in 2D, but with a shift towards mature isoforms. There were no identifiable increases in putative intrafusal specific genes as characterised in vivo. Functional assessments and metabolic assays are currently being undertaken.

Recently, macrophage polarization, which expresses pro-inflammatory (M1) and anti-inflammatory (M2) phenotypes, is focused because it strongly related to chronic disease and biomaterial compatibility. In order to evaluate an immunological property of biomaterial, macrophage polarization is assessed in vivo and in vitro. Generally, for in vitro evaluation of macrophage polarization, macrophage was detached from culture dish enzymatically and physically and subjected to macrophage polarization analysis. However, it has been reported that these treatments strongly affect the macrophage polarization ability due to the cell membrane damage. Therefore, in this study, we proposed a new method of macrophage polarization evaluation, which is utilization of macrophage adhering macroparticles, without the cell detachment process. THP-1 cell was used as a model of macrophage. Polystyrene macroparticles were used. THP-1 adhering particle was prepared by rotation culture of mixture of THP-1 and particle stimulating with phorbor-myristate-acetate. The THP-1 cells were adhered on particle uniformly with 30-40 cells/particle. The macrophage polarization ability on particle stimulating with LPS/IFNγ and IL-4/IL-13 was investigated by using RT-PCR analysis of IL-1β and MRC1, which were markers of M1 and M2, respectively. The high expressing of IL-1β and MRC1 on particle was showed compared to macrophage treated with detachment process. From these results, we have successfully developed a new method of macrophage polarization using the macrophage adhering particles.

With no available treatments for brain tissue repair and functional recovery in patients with lost or impaired neurological functions, stroke therapy remains an important unmet clinical need. The lack of structural support in the stroke cavity and insufficient endogenous tissue repair dramatically limit brain functional recovery after stroke. Novel regenerative therapies aim to use soft hydrogels that can offer structural support and deliver pro-regenerative therapeutic agents whilst improving their half-life [1,2]. We propose a novel combination therapy based on a self-assembling peptide hydrogel (SAPH), the anti-inflammatory and microglial modulator tumor necrosis factor-alpha stimulated protein-6 (TSG-6) [3], and the angiogenic and neurotrophic vascular endothelial growth factor (VEGF). Here, we show that following intra-cerebral injection in healthy mice, RGD/IKVAV-PeptiGel-Alpha2 hydrogel did not induce microglial activation or astrocytic scarring, suggesting its biocompatibility with the brain tissue. Furthermore, the hydrogel released VEGF in a sustained manner in vitro. These findings support the use of RGD/IKVAV-PeptiGel-Alpha2 as a temporary scaffold for brain repair and VEGF release system for angiogenic applications following brain injury. In parallel, we have tested the reparative properties of TSG-6 administered sub-acutely into the stroke infarct. Results have shown a trend toward improved wellbeing and decreased microglial activation, as well as signs of angiogenesis at 28d post-stroke. Ongoing work is testing the efficacy of TSG-6 and VEGF combination assisted by the RGD/IKVAV-PeptiGel-Alpha2 delivery system to enhance tissue repair and promote functional recovery after stroke.

EFFECT OF ELECTRICAL AND MECHANICAL STIMULATIONS ON CONTRACTILITY AND MYOKINE SECRETION OF TISSUE-ENGINEERED SKELETAL MUSCLE

Toshia FUJISATO$_P$[1]

[1] *Osaka Institute of Technology, Osaka, JAPAN*

Corresponding author's email: toshiya.fujisato@oit.ac.jp

Tissue engineering can be applied to three-dimensional skeletal muscle model for physical exercise. In this study, the tissue-engineered skeletal muscle was cultured under various electrical and mechanical stimulations and examined its contractility and myokine secretion.

Two artificial tendons were introduced at both ends of our engineered muscle. The two tendons were hold with stainless steel pins placed 12 mm apart before cell seeding. The C2C12 myoblasts embedded in collagen gel was added between and on the surface of the two tendons. After gelation of the cell suspension, the constructs were cultured in growth medium of high-glucose DMEM with 10% FBS for 2 days. Then, they were cultured in differentiation medium of high-glucose DMEM with 7% horse serum with various electrical pulse stimulation or passive mechanical stretch movements. After the stimulation, the contractile force was measured by micro load cell and the amount of secreted IL-6 in the culture medium was determined by ELISA.

The isometric twitch force of the tissue-engineered skeletal muscle cultured with electrical pulse of 5V, 2msec, and 0.5Hz was remarkably higher than that of without stimulation up to 7 days. However, there was no difference when the constructs were cultured more than 14 day with electrical stimulation. In addition, the amount of IL-6 secreted from stimulated skeletal muscle was larger than that of without stimulation.

These results suggest that tissue-engineered skeletal muscle may be applied to physical exercise model in vitro.

Corresponding author's email: gianni.pecorini@phd.unipi.it

Bone tissue lesions are among the most common injuries of the human body. The increased need for bone replacement becomes a key scientific, socio-economic, and clinical challenge. Tissue Engineering-based strategies are providing reliable therapeutic tools for healing damaged bone tissue [1]. Polyhydroxyalkanoates are bio-polyesters whose biocompatibility, biodegradability, sustainability, good processing versatility and mechanical properties make them unique scaffolding polymer candidates for Tissue Engineering [2]. The development of new materials suitable for advanced biofabrication techniques, such as Additive Manufacturing (AM), are of primary importance for the advancement of Tissue Engineering. The formation of polymeric blends represents a useful strategy to develop new scaffolds that can mimic the properties of the target tissue [3]. In this contribution scaffolds from polymeric blends consisting of poly(3-hydroxybutyrate-co-3-hydroxyvalerate) (PHBV) and poly(D,L-lactide-co-glycolide) (PLGA) have been fabricated employing a solution-extrusion AM technique, referred to as Computer-Aided Wet-Spinning. Scaffold's fibers were constituted by a biphasic system formed by a continuous PHBV matrix and a dispersed PLGA phase which assumed a microfibrillar morphology. The influence of blend composition on morphological, physical-chemical and biological properties of the scaffolds was evaluated. In particular, increasing the content of PLGA in the starting solution resulted in an increase of the pore size, the wettability, and the thermal stability of the scaffolds. Overall, the biological evaluation indicated the suitability of the scaffolds to support murine preosteoblast cells colonization as well as their capability to promote cell differentiation towards an osteoblastic phenotype, highlighting better results for scaffolds richer in PLGA.

Treating deep-second degree burns, and third-degree burns requires debridement of nonviable tissue, attainment of homeostasis followed by skin graft application to assist wound closure. The severity of burns wounds impairs blood supply, giving rise to poor wound bed vascularization resulting in impaired regeneration and diminished grafting. To address this issue, the wound bed is prepared using a dermal substitute to re-vascularize the dermis layer prior to graft application [1]. While existing products such as Integra® prepare the wound bed for skin grafting, a relatively long period of 15 to 20 days is required for neodermis formation and wound bed re-vascularization [2]. Reducing the time taken for re-vascularization and neodermis formation results in better wound healing outcomes.Within the 'additive manufacturing for biological materials' (AMBM) program that seeks to biomanufacture the next-generation of burns wound healing technology, we are developing processes for producing novel biomimetic dermal templates which improve wound healing via incorporation of pro-vascularization and pro-regenerative additives.Herein, we demonstrated that collagen scaffold produced via manual fabrication have pore sizes matching the target range (20-125µm) and attain 32% crosslinking following glutaraldehyde (GA) treatment. Successful incorporation of bio-additives into scaffolds was demonstrated and further shown to be biocompatible with variable degradation rates during validation in the Chick Chorioallantoic Membrane (CAM) assays. Following manual fabrication, scaled-up manufacturing techniques were used to produce multiple 2.5cmx2.5cm scaffolds to demonstrate scale-up production potential. These collaborative efforts by the program show promising results in developing novel dermal template that improve healing in severe burn wounds.

In Spondyloarthritis (SpA)-associated Achilles tendon enthesitis, IL-23 receptor (IL-23R) expressing γδ-T-cells that secrete cytokines of the IL-17 family were described to play a driving pathogenic role.[1] We investigated whether the IL-23R/IL-17 signaling cascade also contributes to the development of non-SpA-associated tendon pathologies.

Achilles tendon biopsies from acute ruptures (n=39) and chronic tendinopathies (n=17) were analyzed immunohistologically and by flow cytometry to prove the presence and identify the cellular source of IL-23R, IL-17A, IL-17F, IL-22. Moreover, hematoma aspirate was harvested from the Achilles tendon rupture side and analyzed for IL-23R/IL-17 signaling mediators on protein level.
Immunohistology revealed the presence of IL-23R+ and IL-17A/F+ cells in acute ruptures and chronic Achilles tendinopathies. Interestingly, 100% of the chronic specimens contained IL-23R+ cells, whereas only 42.9% of acute ruptures showed IL-23R+ cells. Furthermore, a higher percentage of the chronic specimens showed IL-17A/F+ cells (46.7%) compared to the acute ruptures (20%). Preliminary flow cytometry data identified tenocytes as possible source of IL-17F and IL-22, but not of IL-17A expression. The analysis of hematoma aspirate revealed elevated concentrations of IL-23, IL-17F and IL-22 in 4 of 24 patients with acute Achilles tendon rupture.

We demonstrate the presence of mediators of the IL-23R/IL-17 signaling axis in non-SpA-associated Achilles tendon pathologies with differences between acute ruptures and chronic tendinopathies. Compared to IL-17A as trigger in the SpA-associated enthesitis model, we propose that IL-17F might drive non-SpA Achilles tendon pathologies.[1] The results of the project contribute to a better understanding of underlying pathomechanisms of acute ruptures and chronic tendinopathies.

Tissue-engineered scaffolds fabricated through conventional techniques such as lithography, and stamping are limited in their geometrical complexity, fabrication speed, and automation capacity [1, 2]. To overcome these limitations, 3D printing based on Digital Light Processing (DLP) technology has been gaining popularity, however, there is a lack of suitable photo-biopolymers to exploit the potential of light-based 3D printers [3, 4]. This study optimizes a photo-crosslinkable, biocompatible and biodegradable elastomer - poly(octamethylene maleate (anhydride) citrate) (POMaC) [1, 5, 6, 7] for DLP 3D printing through careful consideration of the interplay between printing parameters, and ink formulation, such as monomer ratio and the use of an appropriate photoinitiator. The POMAC prepolymer was premixed with the Irgacure-819 photoinitiator, and polyethylene glycol dimethyl ether (PEGDM), a material with viscosity as low as 57 cPa, serving both to reduce the viscosity and enable the formation of nanopores. POMaC was successfully fabricated into intricate free-form lattices with a sub-millimetre resolution, as well as semi-embedded features down to a width of 70 µm. The use of the multi-exposure mode presented here allows rapid selection of an appropriate exposure time. The optimized exposure time for a 20 µm layer of premixed polymer is 55s, which is considerably faster than the 4-minute crosslinking time required in manual stamping of the same material [1]. By combining the previously demonstrated biocompatibility, biodegradability and mechanical versatility [1, 5, 7, 8, 9] with the printability achieved in this study, POMaC serves as a paradigm for biomaterial design in soft organ-on-a-chip engineering.

Cartilage regeneration remains a formidable challenge because of its harsh physiological environments, such as avascularity and aneurality. Piezoelectric biomaterials emerged as a promising source of scaffolds for cartilage repair and regeneration. We fabricated a piezoelectric smart electrospun scaffold from biologically originated Poly(3-hydroxybutyrate-co-3-hydroxy valerate) (PHBV) polymer reinforcement with carbon-based nano-material such as Graphene oxide (GO) and Amino-graphene (AG). The bead-free and smooth nanofibers were fabricated by electrospinning technique and characterized with FE-SEM and AFM techniques. The spectroscopic and thermal studies reveal that there is no significant interaction between reinforcing agent (GO and AG) and polymer. The scaffolds with GO and AG demonstrated improved mechanical and piezoelectric properties against the pristine PHBV. The polarised scaffolds in presence of GO and AG evident for better ECM production and chondrogenic marker expression as compare to PHBV. The developed piezoelectric scaffold will also be characterized under dynamic loading conditions to demonstrate the effect of piezoelectricity in tissue formation. The developed scaffold was also characterized in vivo rat osteochondral defect model where PHBV-AG showed excellent cartilage tissue integration and regeneration compared to PHBV and PHBV-GO. The developed piezoelectric scaffold will also be characterized under dynamic loading conditions to demonstrate the effect of piezoelectricity in tissue formation. The developed scaffold will also be characterized in vivo rat osteochondral defect model. Keywords: Piezoelectricity, Cartilage regeneration, Poly(3-hydroxybutyrate-co-3-hydroxy valerate), Graphene, Electrospinning, polarisation.

Background: 2D Preclinical assays have largely failed to effectively predict the efficacy of anticancer drugs. Moving to 3D models, one of the challenges is how to assess drug efficacy. Viability assays are typically used in low cell density 2D cultures and may not produce the same results in 3D cultures.

Aim: Our aim is to validate the common viability assays in three different models: conventional 2D culture, matrigel-based 3D culture and an organ-specific 3D brain tumour model recently developed by us.

Methods: Identical U251 cell numbers were plated in 2D and were mixed with matrigel to form a 3D culture model. Organ-specific 3D scaffolds were developed by decellularizing animal brain tissue followed by seeding with U251 cells. We tested the performance of four different viability assays (MTT, Alamar Blue, ATP, LDH) on three different culture models and calibrated the assay output versus known cell numbers by counting and DNA quantification.

Results: In all of our selected cell viability assays, the assay output was higher in 2D samples compared with matrigel samples containing the same number of cells. In MTT assay by increasing the reagent concentration the difference between assay reading in 2D and matrigel samples became less which might indicate that there is a decreased reagent availability to the cells grown in Matrigel.

Conclusions: Most protocols for viability assays that are validated for 2D cell culture are not (directly) applicable to 3D models, however, optimization and calibration can make them relevant for 3D cell culture.

Inability of neurons to spontaneously proliferate and prevalence of neuro-inflammation at the site of injury are the major barrier for spinal cord injury treatment. To overcome this issues, we have fabricated an electroconductive and immunomodulatory graphene-crosslinked-collagen cryogels. The fabricated cryogels showed an electro-conductivity of 3.8±0.2 m Siemens/cm, and supports the growth and proliferation of bone marrow derived mesenchymal stem cells. Besides this, the fabricated graphene collagen cryogels had well interconnected porous structure, as evident by FESEM and Cryo-FESEM analysis. The incorporation of graphene has increase the mechanical strength of cryogels, and also have resulted in increase of collagen fiber alignment as analyzed using Raman spectroscopy. Further, ex vivo culture of spinal cord slice culture study demonstrated the cryogel potentials in controlling astrocytes reactivity and promoting neuronal development upon external electric stimulus. Additionally, in vivo implantation in rat's hemi-sectioned model at thoracic level T9-T11 demonstrated the animals with cryogels showed faster recovery from paralysis within 7-10 days of implantation. The cryogels has also shown the capability in polarization of microglia into M2 phenotype and showed higher neuronal network formation after 28 days of implantation as evident by higher expression of β-tubulin III and neurofilament 200. Upon investigating the possible mechanism, we found the role of STAT3, and increased extra-cellular matrix development in controlling the neuro-inflammation and fostering the axonal development at the site of injury respectively.

A vascularized and perfusable in vitro model of human skin would facilitate skin aging and tissue injury research. A critical player in both processes is cellular senescence, a state of irreversible cell cycle arrest. Senescent cells arise in injured tissues and have been found causally involved in accelerating the healing of acute wounds but impeding chronic wound closure. Current experimental dermatology models investigating the impact of senescence on tissues mainly involve animal models due to the skin's cellular heterogeneity, complex anatomy, and a lack of suitable in vitro models. However, ethical concerns, long experimental times, and restricted experimental flexibility limit the applicability of these in vivo models for wound-healing associated senescence studies. As a solution, we engineered a vascularized 3D full-thickness in vitro skin model including epidermis, dermis, and microvasculature (vascuSKIN) to create an accessible and standardized in vitro skin model. Our approach mimics human skin in vitro, allowing us to gain knowledge on cellular-level wound healing processes impossible to acquire in animal models. Our model uses a customized vascuSKIN device that enables (a) the connection of the vasculature to external pumps and (b) the elevation of the cultures to the air-liquid interface to form a stratified epithelium. The vascuSKIN recreates skin by including a dermis and an epidermis cultivated at the air-liquid interface that consists of the essential cell types associated with senescence-associated processes in wound healing. We will apply the developed full-thickness vascularized skin equivalents to study wound healing and the role of associated senescent cells in vitro.

Dental implant failures arise from poor integration of the implant with surrounding soft and hard tissues. Osseointegration and periointegration are crucial to their prevention. A persistent challenge is the inconsistency between tissue surrounding an implant and natural periodontal tissue around natural teeth. This increases vulnerability to peri-implant diseases, affecting soft and hard tissue integration and highlighting the need for implants with improved osseointegration and periointegration potential. Implant surface nanostructures promote osseointegration; however, designs which improve the soft tissue response have yet to be identified.

We present novel nanoparticle coatings applied to surfaces in a single step technique driven by liquid-feed flame spray pyrolysis, which uniquely permits the construction of bespoke nanoparticle architectures from a breadth of inorganic precursors. This highly scalable technique has the potential to create multi-layer nanostructures of differing thicknesses, diverse patterns, and pore sizes – qualities as diverse as the inorganic building blocks of which these nanoparticle layers are composed.

Novel nanoparticle-based coatings with bioactive inorganic architectures can enhance osseointegration, reduce the inflammatory response, and possess exemplary process versatility and stability, permitting precise control over the synthesis process, and so too, evaluation of the concomitant soft tissue bioresponse.

Tissue engineering is one of the most recent studies to make modeling in order to optimize the tissues that cannot be adequately structurally and functionally.

In this study, gelatin methacryloyl (GelMA) synthesis was performed. GelMA polymerization was performed with ultraviolet ray (UV) using photomask with the device designed by our team. Polymerized hydrogel human umbilical vein endothelial (HUVEC) and neuroblastoma (SH-SY5Y) cells were encapsulated. The effects of marine-derived 'Citreohybridonol' molecule doped into GelMA in different ratios on the co-cultured cells were investigated.

Fourier transform infrared spectroscopy (FTIR), scanning electron microscopy (SEM), atomic force microscopy (AFM) analyzes were performed to characterize the synthesized GelMA polymer. Cell viability was observed by methylthiazole diphenyl tetrazolium (MTT) and hydrogen peroxide (H2O2) for 14 days. Numerical data obtained from viability analysis were analyzed by GraphPad Prism 8 two-way ANOVA and Tukey test as post hoc. Immunohistochemical staining was performed by using Angiopoietin 1 polyclonal antibody for HUVEC cell line and Nestin antibody for SH-SY5Y cell line in order to observe the molecular effect.The obtained images were found to support cell viability analysis.

In all analyzes, the marine-induced "Citreohybridonol" molecule did not have a negative effect on the HUVEC cell line. In SH-SY5Y cell line, it was found to have a negative effect on cell viability.

In this study, type-I bovine collagen solved in diluted acidic solutions (acidic acid and formic acid) and fed into the centrifugal spinning device to obtain nanofiber formation. The centrifugal spinning device is providing submicron fibers thanks to its rotational movement during the solution feeding. Different feeding ratios and rotational speeds are studied to optimize the process. Obtained nanofiber webs were observed via scanning electron microscopy (SEM). Structural characterization of samples was investigated via FTIR. Fabricated collagen-based nanofibers filtration performance was evaluated in terms of filtration efficiency and air permeability tests. Tests results are pointed that fabricated gelatin nanofibers can be an efficient alternative biomaterial design against Covid-19.

One of the most rapidly emerging tools of nanoscience and nanotechnology is microfluidic chips. With the increase of alternative production techniques and improved capacity of manufacturing devices, it became possible to create microfluidic chips with high resolution and excellent accuracy which can be used for many different fields. In this research, to create a three dimensional cell culture environment, a microfluidic chip was used. To create the three dimensional scaffold structure, Gelatin Methacrylate (GelMA) was synthesized. With using ultraviolet light and photoinitiator a three dimensional hydrogel structure was built. With this method, an alternative and easier strategy, compared to other techniques used to create hydrogels inside of microfluidicchips was proposed.

Chemical compounds of synthesized GelMA was identified with fourier transform infrared spectophotometry (FITR), surface morphology was observed with field emission electronmicroscopy (FESEM), and structural properties was analyzed with atomic force microscopy (AFM). Inside of the produced GelMA hydrogel structure, a neurovascular co-culture was created, and cellular viability of the hydrogel created inside of microfluidic chip was compared with the hydrogel created outside of the chip. Swelling performance of the hydrogel inside of microfluidic chip was observed visually and permeability of this hydrogel was examined with a migration study as a proof of concept.

Results show that synthesized GelMA has desired biomechanical properties with more than 80% cellular viability while being structurally stable, and it was shown that even if its produced inside of microchip, it still has the same biomechanical properties.

Latest advances in three-dimensional (3D) cell culture technologies have shown outstanding assembling and self-organizing properties of embryonic and adult mammalian stem cells into organoids that replicate key structural and functional properties of organs such as the lungs, hence, becoming an indispensable tool for basic and translational research(1) . Current protocols to generate lung organoids rely on gel-like basement membrane matrices, in which cells assemble and self-organize into multiple randomly “floating” organoids(2). However, these culture methods present some challenges for downstream analysis and are not easily compatible with translational research.

Herein, we propose a platform that consists of an array of micro-wells thermoformed on a polycarbonate film(3), where, in a single film, 289 organoids can be generated. Additionally, the platform enables long-term culture and (real-time) monitoring of lung organoids. This platform surpasses conventional culture methods with a superior observability, traceability and possibility of controlled manipulation of single organoids. Our findings showed that the lung organoids were successfully cultured in the arrayed micro-well platform using established culture protocols and with reduced matrix content for up to two months, and maintained their phenotypical and functional properties. Furthermore, we monitored the development of individual organoids and the fusion of multiple organoids, forming one functional spherical luminal structure. Finally, we demonstrated the individual manipulation of organoids on this platform by luminal microinjection of a dye. These results highlight the potential of the film-based microarray culture platform for gaining in-depth understanding of organoid development in fundamental studies and for employing organoid models in translational research.

Skin is the largest tissue of the human body and represents our daily barrier against the external environment. Nowadays, mimicking the complex skin structure with high spatial resolution is one of the most important challenges of tissue engineering, for skin replacement in transplantations, drug testing and disease modelling (1,2). Here we present a novel approach based on visible-light 3D bio-printing to produce skin tissue models as faithful as possible to the in-vivo structure. Hydrogels scaffolds are the best choice to echo the perfect cell microenvironment due to their biocompatibility and their tunable properties. A Direct Laser Writing system (DLW), equipped with a 405 nm wavelength laser diode and automated translational stages, is used to print photo-polymerizable hydrogels, based on Norbornene thiol-based reactions (3), preserving both mechanical and biochemical properties of cell microenvironment and reproducing skin heterogenous architecture. Different polymer compositions were evaluated in terms of printing morphology and stability. Cell-laden scaffolds with embedded human skin fibroblasts were fabricated and kept in standard culture conditions for several days, showing cell spreading and migration, resulting in high cell viability values. Co-culture systems studies, including both fibroblasts and keratinocytes, containing RGD cell-friendly motifs to promote cell attachment on the scaffolds' surface, have been performed showing cellular compatibility. Furthermore, immunostaining results revealed an enhanced production of extracellular matrix (ECM) proteins compared to single fibroblasts cultures, proving that the combination of photo-crosslinkable hydrogels based on thiol-Norbornene chemistry and co-culture systems provides promising skin-like models.

Silk fibroin is an eligible biomaterial for the development of small-caliber vascular grafts for reconstruction of blood vessels [1]. A new multi-layered SF tubular scaffold for vascular grafting (SilkGraft) has been designed and tested in vitro and in vivo. The wall architecture consists of two electrospun layers (inner and outer) and an intermediate textile layer. The latter confers high mechanical performance, while the electrospun layers allow enhancing the biomimicry properties and host's tissues integration of the device. In vitro cell interaction studies demonstrated the biocompatibility of the graft, while in vivo preliminary pilot trials on minipig and sheep allowed assessing the functional behavior of the implanted SF-based vascular graft and to identify the sheep as the more apt animal model for medium-to-long term preclinical trials.
In this study, SilkGraft was used to replace carotid artery in a sheep model (internal diameter = 4.5mm, length = 80mm). Acute performance of the implant was evaluated by Doppler ultrasound and angiography. Chronic performance was evaluated by Doppler ultrasound and/or angiography at Week 4, 26, and 52. Degradation, local tissue effects, and distant systemic effects were evaluated 52 weeks following implantation.
The SilkGraft implantation was successful. After 52 weeks patency of the graft was demonstrated by Doppler ultrasound, angiography, and histopathology. Degradation was moderate and mechanical resistance was guaranteed by the effective integration of SilkGraft by the new endogenous tissues showing also a good endothelialization.
These results demonstrated the opportunity for SilkGraft to be an "off-the-shelf" device for small blood vessel reconstruction.

Mesenchymal condensation is one of the earliest stages of bone tissue development and its a critical step for the resulting biological structure. Many attempts have been made to replicate the condensation process in vitro in order to produce high quality engineered bone tissue. Condensation is not only regulated through chemical signaling but also through mechanical cues. Hence, mechanical stimulation has been suggested as a way to control condensation. Indeed, micro-aggregate experiments show how compression, tension, shear stress and substrate stiffness influence condensation and consequently in vitro tissue quality [1]. Unfortunately, little is known about the origin and type of these mechanical cues during in vivo condensations and how they should be mimicked.

In this work, the developing chick limb is studied as a model-system for mesenchymal condensation. The mechanical cues that influence the condensation are a direct result of the mechanisms that drive outgrowth the limb bud. Therefor a better understanding of limb bud outgrowth is needed. We propose an individual cell-based model where mesenchymal cells are represented as individual agents. Interactions between the cells are modeled using two types of forces. Passive attraction-repulsion forces are used to represent cell-cell adhesion and cortical tension. The effect of active cell protrusions is represented as a directed migratory force. The ectoderm surrounding the mesenchyme functions as a boundary condition, and is modeled as a visco-elastic material. Our simulations indicate that graded proliferation mediated by FGF and directed intercalations directed by a WNT3a gradient are needed to ensure limb bud elongation.

Human-derived bone organoids are emerging alternatives to investigate disease treatments. However, non-destructive methods to monitor mechanical properties and extracellular matrix (ECM) within these organoids are lacking. ECM mineralization has been successfully used for tissue mineral density to modulus conversions in native bone. This study aims to create an automated approach to non-destructively assess ECM mineral density and corresponding mechanical properties of organoids from micro-computed tomography (micro-CT) images.3D-bioprinted graphene oxide-incorporated cell-laden scaffolds[1] were cultured over 56 days in compression bioreactors, monitored using weekly micro-CT and endpoint compressive stiffness. Images were divided into 27 subsets. Density histograms of each subset were fit with two Gaussian curves to differentiate between background and ECM (R2=0.996), enabling regional and global assessment of mineralization. Tissue density was converted to Young's modulus using several exponential functions for FE analysis.Mechanical loading (ML) resulted in higher weekly mineral density increases (9.8mgHA/week) and greater stiffness than static culture (CN) (5.8mgHA/week). The top third of the ML organoids showed significantly higher mineral density compared to the middle and bottom thirds. Regional mineral density from the bottom third correlated highly with organoid mineral density (0.92) and experimental stiffness (0.98). This allowed using representative subsets, reducing boundary condition errors and computing time. The function:E[kPa] = 62.53×10^6×ρ^7.4[gHA/cm3]+3resulted in a high correlation (R2=0.94) between FE- and experimental stiffness.In this study, we created an automated approach to non-destructively assess ECM density and corresponding mechanical properties of organoids. This will facilitate future research into organoid development, especially regarding mechanical properties and mechano-regulation.

Galactic cosmic radiation (GCR) contains high energy ions that pose significant health risks to humans. Exposure to GCR promotes degenerative tissue effects1, decreases cardiovascular function, and increases the risk of negative cardiovascular events in astronauts 2. With the increasing interest in interplanetary and long duration spaceflight missions, methods to mitigate GCR need to be developed. Despite decades of research, little is known about the effects of GCR at the cell and tissue scale due to use of other radiation species in previous studies. Recently, the NASA Space Radiation Laboratory (NSRL) has developed methods to simulate GCR in a more realistic manner3. However, dysfunction of cardiac contractility can be difficult to model in vitro. To enable assessment of the effects of GCR on cardiac tissue function, we designed, optimized, and validated a method to fabricate and simultaneously measure the contractility of 24 3D human engineered muscle tissues fabricated from induced pluripotent stem cell-derived cardiomyocytes. The substrate features an embedded magnet; as tissues contract, the magnet's displacement is quantitatively detected in a highly parallel manner using specialized sensors to measure contractile function and kinetics. Using this platform, we are exposing hundreds of these tissues to 3 different doses of simulated GCR at NSRL and, for the first time, elucidating its negative impacts on cardiac tissue function and integrity, cell viability, mitochondrial function, genetic stability, and proteostasis. Using this data, we are developing methods to mitigate these effects.

Spaceflight has a negative impact on the heart and the cardiovascular system1, but the cell and tissue scale effectors of this negative impact remain poorly understood. To address this, we developed a high-throughput microphysiological model of human cardiac tissue, derived from human induced pluripotent stem cells (hiPSCs). To generate engineered heart tissues (EHTs) that are physiologically-representative of human myocardium, we used a biocompatible and cardiac-specific decellularized extracellular matrix (dECM)-based electroconductive composite scaffold. These dECM hydrogels contain tissue-specific ECM proteins, obtained through decellularization, and when combined with reduced graphene oxide, they recapitulate native cardiac tissue-like stiffness and electroconductivity2. The EHTs were successfully launched to the International Space Station (ISS) where they remained for 28 days while cardiac contractile function was measured in real time using a magnetic force sensor system before being returned to Earth. Analysis of flight sample data revealed a degradation of contractile function in EHTs, including reduced twitch forces and an increase in arrhythmias. Transmission electron microscopy results indicate changes in sarcomeric structure, lipid accumulations, and mitochondrial defects in spaceflight samples. This correlates with previous studies showing that mitochondrial dysfunction acts as a central hub for spaceflight-induced damage3. Using a random positioning machine to simulate microgravity, we compare the effects of simulated microgravity to actual spaceflight. Finally, using simulated microgravity, we show the effects of various mitigation strategies, such as increased resistance to contraction and small molecule therapeutics.

The regenerative process guided by bone scaffolds depends on how they alter the interaction between immune and tissue-specific cells, which defines their osteoimmunomodulatory properties [1]. Despite the growing interest on additive manufacturing for orthopedic regenerative medicine, osteoimmunomodulatory properties of 3D printed bone scaffolds have not been widely assessed. In this study, we investigated the effect of 3D printed titanium (Ti) scaffolds on macrophages and skeletal progenitor cells in vitro. Human monocytes were seeded on 3D printed Ti scaffolds and differentiated to unpolarized macrophages. Simultaneously, human periosteum-derived cells (hPDCs) were seeded in separate wells. After 5 days, condition media from macrophages was applied to hPDCs and vice versa. Osteoimmunomodulation was evaluated in terms of metabolite concentration in macrophage cell culture media and gene expression analysis of both cell types. Results showed that Ti scaffolds inhibit the reduction in glucose consumption and lactate secretion, associated to an anti-inflammatory state and induced by hPDC-derived conditioned medium. Moreover, Ti scaffolds also upregulated macrophage pro-inflammatory genes both in the presence and absence of hPDCs conditioning. Conversely, macrophages cultured without Ti scaffold upregulated pro-regenerative genes when conditioned with hPDCs-derived media. Importantly, hPDCs did not upregulate osteogenic genes when conditioned with media from macrophages seeded on Ti scaffolds. Overall, these data suggest that 3D printed Ti scaffolds might have a negative influence on the regenerative response, by inducing an inflammatory state that inhibits the immunomodulation from skeletal progenitors as well as osteogenesis. Research aiming at functionalizing Ti scaffolds should address both effects.

This was a Phase 2, prospective, multicenter, open-label, single-arm study. The primary objective of this study is to evaluate the safety, efficacy and immunogenicity over 3 months after implantation of human acellular vessels (HAVs) manufactured using the commercial manufacturing system LUNA. At Month 3, primary patency and primary assisted patency were maintained in 29 of 30 subjects, and all subjects showed secondary graft patency. HAV infections and indications of mechanical failure or weakness of the HAV were not observed. The percentage of subjects who exhibited elevation from Baseline in Class I PRA levels at Month 2 (7%) is consistent with previous clinical studies of Aura- or Terra-produced HAVs in patients requiring hemodialysis (6%). Overall, the results of the LUNA-produced HAV to date do not indicate any particular safety or immunogenicity issues. A follow-up 12-month assessment is currently ongoing and results may show similar outcomes.

MESOPOROUS BIOACTIVE GLASSES DOPED WITH HYPOXIA-MIMICKING ELEMENTS

Mesoporous bioactive glasses (MBGs) are characterised by outstanding surface area and high porosity. These textural properties lead to significantly enhanced bioactivity compared with other glasses. Furthermore, this provides the possibility to use MBGs as local drug delivery systems, which combined with the release of therapeutic ions (e.g. Cu2+ and Co2+) gives opportunity for the development of multifunctional biomaterials. Cu2+ and Co2+ ions released from bioactive glasses have been shown to induce formation of new blood vessels by mimicking hypoxia (low oxygen concentration).

The aim of this work was to explore bioactivity and dissolution profiles of hypoxia-mimicking elements (Cu2+ and Co2+ ions) from MBGs and also to investigate the effect of these ions on the textural properties of MBGs. The Cu- and Co-doped MBGs with composition of 80SiO2–16CaO–4P2O5 (mol%) were produced using sol-gel technique coupled with evaporation-induced self-assembly process. CuO and CoO was substituted for CaO in the amounts of 1-5 mol%. MBGs were analysed using TEM, SAXS, and BET. MBGs were incubated in simulated body fluid (SBF) for 14 days. Changes in ion concentration in SBF were monitored using ICP-OES. FTIR and SEM/EDX were used to evaluate structural, morphological, and chemical changes of MBGs during incubation in SBF.

The results indicated that Cu2+ and Co2+ ions affect bioactivity and dissolution of MBGs to a great extent. Furthermore, the presence of hypoxia-mimicking elements altered their textural properties (surface area, porosity, pore size and structure).

Due to the dynamic development of regenerative medicine, materials for bone tissue regeneration should exhibit bioactive, anti-inflammatory, antibacterial, antioxidant and anticancer properties. Extending the functionality of biomaterials is possible thanks to the enrichment of biomaterials with drugs or active substances. However, due to the contact of biomaterials with the patient's body, the materials are subjected to various sterilization techniques. Therefore, the aim of the research was to investigate the influence of various sterilization techniques on the properties of biomaterials.

The solvent casting method was used to produce polymer films (PCL) and composites modified with bioactive glass (BG). The materials were modified with polyphenolic compounds (PPh) extracted from sage (4.5 wt.%). Melt-derived and sol-gel-derived BG particles (d50 - 2 µm) with the composition (mol%) 40SiO2-54CaO - 6P2O5 (30% by weight) were used as the modifying phase. After ethylene oxide, gas plasma sterilization and UV-C sterilization, wettability and surface energy, the in vitro release of polyphenols and the antioxidant activity (ABTS) of the film were measured.

The influence of sterilization processes on the tested films turned out to be varied and dependent on the composition of materials. Moreover, for each of the materials, different sterilization methods showed different effects on the properties of the materials. Therefore, for the materials we test, the target type of sterilization should be selected individually. The possibility of changing the parameters of individual sterilization processes may constitute an important direction for further research.

This work was supported by the National Science Centre, Poland Grant no. 2017/27/B/ST8/00195 (KCK).

Despite the high prevalence and devastating outcome, only a few treatment options for cerebral ischemic stroke exist. Previously, our group demonstrated that 'extremely low frequency electromagnetic stimulation' (ELF-EMS)' increased survival, reduced infarct size and improved neurological outcome in a rat model of global ischemia. The beneficial effects of ELF-EMS were inhibited by a general nitric oxide synthase inhibitor L-NMMA, indicating that nitric oxide (NO) is key in the actions of ELF-MF1. Since NO is a known vasodilator, we examined whether ELF-EMS was able to stimulate cerebral blood flow and investigated the activated intracellular pathways.

We demonstrated that ELF-EMS increased NO production in a human microvascular endothelial cells (HMEC-1), which was accompanied by enhanced phosphorylation of Akt and endothelial NOS (eNOS). Laser Speckle Contrast imaging (LSCI) proved that ELF-EMS increased the perfusion of the cerebral vasculature in both control and ischemic stroke mice. Moreover, application of ELF-EMS reduced lesion volume following ischemic stroke in collateral-rich C57BL/6 mice, but not in collateral-scarce BALB/c mice. These findings suggest that decreased lesion sizes in response to ELF-EMS results from improved cerebral collateral blood flow. Furthermore, ELF-EMS induced angiogenesis in the chicken chorioallantoic membrane assay and it enhanced key steps of the angiogenic cascade in vitro (endothelial cell proliferation, migration and tube formation).

In conclusion, we showed that ELF-EMS is a promising strategy to treat ischemic stroke by enhancing cerebral perfusion. In addition, because of its potential to induce angiogenesis it can also be an attractive strategy for other tissue regeneration purposes.

Chemotherapy and radiation used for cancer and other treatment can cause depletion of the ovarian reserve, or primordial follicles, resulting in premature ovarian insufficiency (POI). Our goal is understanding the physical and biochemical properties of the ovarian microenvironment and their roles in folliculogenesis to inform a bioprosthetic ovary design that restores fertility and hormone function.

We mapped the rigidity (via Young's Modulus) of the ovary using atomic force microscopy (AFM) finding a significant decrease in rigidity from the cortex (8.87±0.80 kPa) to the medulla compartments (1.04±0.14 kPa). In order to associate these differences with specific ovarian features, we performed higher resolution (100µm) mapping across 3 zones (cortex, intermediate and deep medulla) in a 25X10 grids. Data was superimposed over H&E stained tissue to correlate information with specific follicles, vessels and other features. We have further assessed the specific contribution of matrisome proteins to these physical properties using compartment-derived decellularized ECM hydrogels. Additional investigation on how proteins of interest, such as EMILIN1 and AGRN, influence primordial follicle activation is ongoing using specifically designed hydrogels.

This work defines the physical properties of the ovarian microenvironment and develops tools to further investigate the role of specific proteins on folliculogenesis. This feeds our underlying knowledge towards creating an affective bioprosthetic ovary.

Macrophages play a pivotal role in the initiation and regulation of inflammatory processes in the joint. Hence it is suggested that they are involved in the initiation and development of degenerative joint diseases such as osteoarthritis. Pro- and anti-inflammatory macrophage subpopulations are already described humans. To promote the use of synovial explants from horses for further in-vitro studies and to describe the role of macrophages, species specific markers have to be established. Therefore, macrophages isolated from synovial tissue by digestion and migration were characterized. Further, immuno-characteristics of macrophages in paraffine embedded tissue samples were compared to frozen sections of synovial samples from premature, juvenile, affected and non-affected adult horses to develop a distinct marker panel for equine synovial macrophages.

STRUCTURED SOFT SOLIDS FOR TISSUE REGENERATION

Liam M Grover[P][1]

[1] *University of Birmingham*

Corresponding author's email: l.m.grover@bham.ac.uk

Soft solids have found a plethora of applications in biomaterials and tissue regeneration, due to their similarity in structure to the extracellular matrix and high water-content. A major factor that limits their practical use is their low viscosity prior to gelation and poor mechanical properties after gelling has occurred. Our research has focussed on ways that the structure of hydrogels can be modified, without significant chemical modification, to enable the production of materials that exhibit shear-thinning properties with rapid elastic recovery once shear has been removed. Such materials have a range of practical uses including: minimally invasive delivery by injection; spraying; and delivery to the ocular surface. In addition to this, the materials can be used as a supporting medium into which other materials can be extruded. This presentation will discuss how we have generated processes to manufacture such materials and how we have adapted them for use as supporting beds in additive layer manufacturing. We will discuss how we have used this approach to manufacture and maintain complex cultures containing multiple cell types as analogues of cartilage, skin and bone

Bone exhibit great capacities to regenerate due to tissue-specific stem cells, i.e. skeletal stem/progenitor cells from periosteum and bone marrow. However, bone fails to heal properly in 10% of bone injuries and delayed healing is increased to 40% in patients with soft tissue damage associated with bone fracture. The role of skeletal muscle in bone repair is well recognized clinically but the underlying cellular and molecular mechanisms are poorly understood.

We show that mesenchymal progenitors residing in skeletal muscle adjacent to bone also participate in cartilage and bone formation during bone regeneration. We used single cell RNAseq analyses to characterize the periosteum and skeletal muscle mesenchymal progenitors, their response to bone injury and the impact of musculoskeletal trauma on the cellular response to injury. The results elucidate the diversity of skeletal stem/progenitors during bone repair and the role of skeletal muscle mesenchymal progenitors as a source of persistent fibrosis in musculoskeletal trauma. The findings suggest that new pharmacological and cell-based approaches can be developed to improve musculoskeletal regeneration by targeting skeletal muscle adjacent to bone.

We apply polymeric molecular and nano- to micron-scale building blocks to assemble soft 3D biomaterials with anisotropic and dynamic properties. Microgels and fibers are produced by technologies based on fiber spinning, microfluidics, and in-mold polymerization. To arrange the building blocks in a spatially controlled manner, self-assembly mechanisms and alignemnt by external magnetic fields are employed. Reactive rod-shaped microgels interlink and form macroporous constructs supporting 3D cell growth. On the other hand, the Anisogel technology offers a solution to regenerate sensitive tissues with an oriented architecture, which requires a low invasive therapy. It can be injected as a liquid and structured in situ in a controlled manner with defined biochemical, mechanical, and structural parameters. Magnetoceptive, anisometric microgels or short fibers are incorporated to create a unidirectional structure. Cells and nerves grow in a linear manner and the fibronectin produced by fibroblasts is aligned. Regenerated nerves are functional with spontaneous activity and electrical signals propagating along the anisotropy axis of the material. Another developed platform is a thermoresponsive hydrogel system, encapsulated with plasmonic gold-nanorods, which actuates by oscillating light. This system elucidates how rapid hydrogel beating leads to a reduction in cell migration, while enhancing focal adhesions, native production of extracellular matrix, and nuclear translocation of mechanosensitive proteins, depending on the amplitude and frequency of actuation.

A CLINICIAN'S PERSPECTIVE ON ADDITIVE MANUFACTURING IN OTOLOGY

Aaron Remenschneider$_P$[1]

[1] *Massachusetts Eye and Ear Infirmary*

Corresponding author's email: AARON_REMENSCHNEIDER@MEEI.HARVARD.EDU

The care of patients with otologic disorders is challenging given the intricate anatomy of the ear and the fragile nature of the auditory pathway. Patient outcomes following middle and inner ear procedures could stand to benefit from novel approaches to tissue, bone and cellular implants. The field of additive manufacturing has made significant recent progress in refining the resolution and biocompatibility of implantable materials, many of which are applicable to otologic applications. Furthermore, the ability to customize patient specific implants permits a tailored, personalized approach to patient care. This presentation will provide a state-of-the-art review of how additive manufacturing will impact the management of otologic disease. Specifically, we will discuss how 3D printed implant form affects is post-implant function. This talk will also explore the impact of advances in additive manufacturing on preoperative surgical planning, surgical simulation, biomimetic and patient specific implants and drug delivery in the treatment of ear disorders. We will explore 21st century approaches to solve persistent problems in otologic patients with a focus on late-stage translational science.

Current options for treatment of bone metastases are only temporarily effective because metastatic disease is ultimately an incurable conditions. Consequently, current treatments are only palliative. Therefore, new modalities for the treatment of bone metastases are urgently required. This presentation focuses on treatment of bone metastases by exploiting the potential of systemically or locally delivered Pt-based anticancer drugs. With respect to systemic delivery of these anticancer drugs, a novel radioactive bisphosphonate-functionalized platinum-based drug (195mPt-BP) was successfully synthesized to combine the diagnostic, radio- and chemotherapeutic properties of 195mPt with the bone-targeting characteristics of bisphosphonates. We confirmed for the first time that targeted delivery of these bone tumor-seeking radioisotopes induces killing of cancer cells in bone tumors due to the effects of Auger therapy. In the second part of this presentation, novel local delivery strategies are presented to deliver Pt-based anticancer drugs from hydroxyapatite nanoparticles into bone defects created by resection of bone tumors. These platinum-functionalized hydroxyapatite nanoparticles effectively killed breast cancer cells in zebrafish models. Furthermore, local co-delivery of platinum and selenium anticancer drugs from hydroxyapatite nanoparticles facilitated effective killing of cancer cells without harming co-cultured stem cells. Overall, this presentation shows how bisphosphonate-functionalized Pt-based anticancer drugs can be used to eradicate cancer cells in metastatic bone, thereby opening new avenues of research on treatment of metastatic bone disease.

BIOINSPIRED HYDROGELS FOR REGENERATIVE MEDICINE: TWO APPLICATIONS

Christophe Marquette[P][1]

[1] *3d.FAB - Université Lyon1*

Corresponding author's email: christophe.marquette@univ-lyon1.fr

Producing in vitro large pieces of tissue or organ is already within reach of few bioprinting laboratories. Advances in 3D printing, 3D bioprinting, but also complex tissue engineering and 3D tissue maturation are some of the key technologies that will make this happen.

Nevertheless, nothing will happen without informed strategies for biomaterial formulation. Here we will present a bioinspired approach for hydrogel formulations (1, 2) and their use as bioinks for regenerative medicine. In this approach, the lesson learned from the human tissue properties such as water content, biomolecules and mechanical properties, were used to design and validate proliferative and regenerative bioinks.

Two example of translational applications of the bioinspired hydrogel will be use to illustrate the approach: breast cancer reconstruction and skin regeneration (3).

DEVELOPMENT OF A PEO-PROCESS TO GENERATE A MICRO-POROUS SURFACE STRUCTURE ON TI6AL4V-IMPLANTS

Thomas Derra$_P$[1]

[1] *Meotec GmbH*

Corresponding author's email: thomas.derra@meotec.eu

During the last decades, the development of orthopaedic implants has made great progress in adjusting the used materials to individual defect-related requirements. In the case of metallic implants new materials are still tested and alloys are optimized regarding biocompatibility and mechanical properties. In addition to shape and material of implants, the surface conditions have recently moved into focus of research. Interactions between implant surface and surrounding tissue can be influenced concerning osseointegration and soft tissue reactions. Furthermore, bioactive modifications can support bone growth and reduce risks of autoimmune and inflammatory diseases.

A promising surface modification for Ti6Al4V-implants is the Plasma Electrolytic Oxidation (PEO). PEO is an electrochemical technology that induces the transformation of a metal surface into a porous oxide ceramics surface. The resulting surface layer can be adjusted in thickness, porosity and chemical composition.

Meotec, as partner of the EVPRO-consortium, aims to use the PEO-technology to produce an implant surface on Ti6Al4V that supports the incorporation of MSC-EV loaded hydrogels into revision endoprosthesis. To reach better incorporation properties, the porosity and stability of the surface layer are focused, while the biocompatibility must be maintained. Only selected electrolytes are candidates for the PEO-process since their chemical elements migrate into the surface layer and support the resulting titanium oxide ceramics. Meotec conducted parameter studies with different electrolytes and found a process window for an electrolyte containing NH4H2PO4 and H2SO4. The resulting surface layer has a sufficient porosity and stability. Further tests will show the reproducibility and the interaction with hydrogel.

Abstract **#2212**

INJECTABLE AND 3D PRINTABLE GELATIN HYDROGELS RELEASING NITRIC OXIDE OR HYDROGEN PEROXIDE FOR TISSUE REGENERATION

Ki Dong Park$_P$[1]

[1] *Ajou University*

Corresponding author's email: kdp@ajou.ac.kr

Injectable hydrogels have been widely used as bioactive materials for tissue regeneration, owing to their extracellular matrix mimicking properties and minimally invasive surgical procedures. However, the inadequate vascularization of 3D injectable constructs limits their success after implantation. Currently, hydrogen peroxide (H2O2) nitric oxide (NO) are reactive molecules that are involved in many physiological processes such as immune responses, apoptosis, inflammation, etc. In particular, the angiogenic activities of H2O2 and NO were widely applied in the wound healing process and tissue repair/regeneration. In our lab, we developed injectable gelatin hydrogels that can control H2O2 / NO release to induce angiogenesis. In our approach, phenol moieties were conjugated onto the gelatin backbone to enable crosslinking of them for hydrogel formation via enzymatic crosslinking reaction of horseradish peroxidase (HRP). The gelation time, mechanical properties, and degradation of hydrogels were easily controlled by varying concentrations of HRP and H2O2. In vitro release studies demonstrated ed that the release behavior of H2O2 and NO from the hydrogel matrices can be precisely controlled by varying the concentrations of encapsulated glucose oxidase and copper ions, respectively. The hydrogels with optimal conditions enhanced the cellular activities of endothelial cells (proliferation, migration, and tube formation) in vitro and facilitated neovascularization in ovo. Our results suggest that H2O2/NO-releasing gelatin hydrogels can be utilized as advanced materials for tissue regenerative medicine and 3D bioprinting applications.

CONTROL OF THE ADAPTIVE IMMUNITY BY LYMPH NODE STROMAL CELLS

Reina Mebius[P][1]

[1] *Amsterdam UMC location VUmc*

Corresponding author's email: r.mebius@amsterdamumc.nl

Lymph nodes are strategically located throughout the body in order to drain the tissues. They greatly enhance the odds that rare antigen-specific T cells encounter dendritic cells that present the antigen derived from the tissues. Stromal cells are crucially involved in the formation of lymph nodes through interacting with hematopoietic lymphoid tissue inducer cells (LTi cells). Once these structures are formed, lymph node stromal cells differentiate into the different stromal cell subsets, which are critical for organizing specialized microenvironments within lymph nodes, providing survival signals, guidance to immune cells leading to efficient cellular interactions.

One additional function of lymph node stromal cell is their capacity to present antigens, by which they shape immunity through inducing MHC-I-dependent deletion of self-reactive CD8+ T cells and MHC-II-dependent anergy of CD4+ T cells. We have shown that MHC-II expression by lymph node stromal cells is additionally required for homeostatic maintenance of regulatory T (TREG) cells and that in the absence of MHC-II expression on lymph node stromal cells, CD4+ as well as CD8+ T cells become activated. We now show that presentation of self-antigen in MHC-II by lymph node stromal cells resulted in the conversion of naive CD4+ T cells towards TREG cells.

In order to allow the study of human lymph node functioning we are currently creating a 3D organotypic in vitro model containing at first lymph node stromal cells and antigen presenting cells.

CELL-BASED THERAPIES - A SET OF BOTH PROMISES AND CHALLENGES

Malgorzata Lewndowska-Szumiel[1,2]

[1] *Laboratory for Cell Research and Application, Medical University of Warsaw*

[2] *Department of Histology and Embryology, Medical University of Warsaw*

Corresponding author's email: malgorzata.lewandowska-szumiel@wum.edu.pl

Regardless of having several approved ATMPs, with a 30% representation of tissue engineered products, and about 5,000 registered clinical trials of cell-containing products (excluding T cells), our knowledge about the principles of cell-based therapies in regenerative medicine is still very limited. The fundamental questions still remains: Do cells survive after being delivered? For how long? Are the cells, with multipotency confirmed in vitro, still multipotent in host tissues? Which is the predominant therapeutic mode of action: delivery of components to restore tissue in situ or providing trophic and/or immunomodulatory agents? It is not surprising, as we look at it. Unlike traditional medicines, the seemingly identical ATMPs can vary radically in terms of cell number, detailed manner and number of applications, medium/scaffold used for cell delivery, details of in vitro manipulations prior to application - just to mention the most important variables that characterize each individual treatment.

At the same time cell-based therapies are extremely demanding in terms of scientific, technical, regulatory and financial challenges, which explains much pressure put on the breakthrough success and the establishment of new directions. A critical review of those issues, based on the available data and our own experience, shows that the last two decades have not been a waste of time, and the further directions toward development of effective cell-based therapies can be identified. Nevertheless, the current situation is like a race - shall we manage to implement effective tissue engineered products before their development is strangled due to over-regulation and dramatically high costs?

CELLULAR AND MOLECULAR FORCES AT THE MATERIAL INTERFACE

E. Ada Cavalcanti-Adam[P][1]

[1] *Max Planck Institute for Medical Research*

Corresponding author's email: eacavalcanti@mr.mpg.de

Mechanical and chemical properties of the extracellular environment regulate cell adhesion and migration. Designing materials and tools which allow the local control of cell-matrix and cell-cell adhesion is of great interest to address how specific receptor-ligand interactions affect cell mechanotransduction. In this work, we report on the development of surface functionalization strategies to control integrin clustering for the generation of molecular and cellular forces at the interface during adhesion. We will also present some examples on the crosstalk between integrins and growth factors in the regulation of cell adhesion and mechanotransduction signaling.

INNOVATIONS TO MAXIMIZE THE GIFT OF ORGAN AND TISSUE DONATION

Prakash Rao$_P$[1], Dayanand Deo[1], Misty Marchioni[1]

[1] *Personalized Transplant Medicine Institute at NJ Sharing Network*

Corresponding author's email: prao@njsharingnetwork.org

Stem cells can be isolated from various human tissues including bone marrow (BM) and adipose tissue (AT). Our studies outline the processes to isolate adult stem cells from research-consented deceased donors. We have found that deceased donor stem cells are a viable alternative to living donor stem cells and may help meet the current demand for cellular products. As a transplant organization, our goal is to save and enhance lives. Our efforts have resulted in the creation of functioning cardiomyocytes, hepatocytes, chondrocytes, adipocytes, osteocytes, and islet cells from otherwise unusable donated tissue. Our results demonstrate the structural and functional integrity of these cells. These differentiated cell types may be used as bridges to transplant. These cells may be utilized in immunomodulation, cellular therapy, starting material for 3-D bioprinting, and organoids. The secreted proteins from these cells, secretome, may provide cues for cell attachment, migration, proliferation, and special organization, and me be involved in regulation of immune responses. We have further observed in a preclinical model of acute kidney injury (AKI), the administration of a mixture of stem cells and secretome appeared to reverse AKI. Maximizing the gift of donation is a priority for the Personalized Transplant Medicine Institute. Procurement and processing of stem cells from deceased donors could be a routine practice and will offer increased accessibility for patients awaiting stem cell therapies.

ORGAN AND TISSUE MODELS BY DESIGN: A NEW FRONTIER FOR TISSUE ENGINEERING DEDICATED MATERIALS

Gianluca Ciardelli[1]

[1] *Politecnico di Torino*

Corresponding author's email: gianluca.ciardelli@polito.it

Despite its being around for more than 50 years, Tissue Engineering has brought little commercial translation, with only few products having achieved market success. However, the increased understanding of human biology and our capacity to replicate it through sophisticated technologies and tailor-made materials has stimulated optimistic market forecasts. The design of 3D replicas of living tissues is expected to gain increasing attention considering their potential in personalized medicine and in high-throughput testing of cosmetics, drugs and chemicals, where they contribute to reduce animal experiments. It is worth considering e.g. that ~75% of drugs approved for liver and cardiac pathologies are withdrawn from the market due to safety concerns which were not highlighted in pre-clinical testing. Moreover, bioengineered models represent a more realistic scenario in testing implantable devices (e.g., prostheses testing in bone models).Ad-hoc designed materials are expected to play a strategic role in this arena, since they recapitulate the multicomponent composition and complex hierarchical architecture of the native extracellular matrix (ECM). Despite this potential, new biomaterials are still under-exploited: for instance, polyesterurethanes are extremely promising as cardiac patches but their difficult pathway to FDA approval negatively affected their translation. The talk will focus on novel trends in materials design, functionalization, and processing into biomimetic structures for the development of experimental models that respond to current challenges in the testing and evaluation of chemicals, drugs, and implantable devices.This work has received funding from the European Union's Horizon 2020 research and innovation action under grant agreement No. 814495-EVPRO (www.evpro-implant.eu).

TRENDS IN MATERIALS-DRIVEN IN-SITU REGENERATION

Carlijn Bouten[P][1]

[1] *Eindhoven University of Technology*

Corresponding author's email: c.v.c.bouten@tue.nl

Material-driven in-situ regeneration is emerging as an approach to regenerate tissues or organs directly at their functional site inside the human body using cell-free scaffolds or hydrogels. The approach requires the design of intelligent, 'life-like' biomaterials and fundamental understanding of how such materials guide functional neo-tissue formation by interacting with the host's endogenous regenerative processes and immune responses under (patho)physiological conditions. Within the Materials-Driven-Regeneration (consortium, Dutch researchers from various disciplines have joined forces to address the research challenges of in-situ regeneration and educate the next generation of regmed scientists in this new area. Together, they address the dynamic reciprocity between materials and the biological processes of regeneration at the cellular, tissue and organ level; and investigate the roles of chemical, physical and bioactive modifications of materials for this purpose. Enabling Technologies, Clinical Translation and Talent platforms are established for acceleration, cross-fertilization and translation of research outcomes.

As an example of the program I will concentrate on in-situ tissue engineering of heart valves and vessels. Here, the challenge is to design scaffolds that function upon implantation and during the process of tissue formation and scaffold degradation; and provide the necessary cues for a stable and organized load-bearing extracellular matrix under harsh hemodynamic conditions. I will describe how biomimetic in-vitro models and computational analyses are used in direct comparison with in-vivo animal experiments to provide handles for the optimization of scaffold immunomodulatory and degradation properties, where immunomodulation is introduced via biophysical or bioactive properties of the scaffold.

CELL-ASSEMBLED EXTRACELLULAR MATRIX PRODUCED IN VITRO AS A TRUE BIOMATERIAL

Nicolas L'Heureux[P][1]

[1] *BIOTIS - University of Bordeaux / Inserm*

Corresponding author's email: nico4cells@gmail.com

Tissue engineering was, and still is, often simplified to the basic recipe: scaffold + cells = replacement tissue. In this equation, the scaffold is so often a synthetic polymer that the two concepts have become synonyms in the minds of many. Unfortunately, even the most inert synthetic polymers are recognized by the innate immune system as a foreign body to be destroyed. In many applications, this foreign body reaction will cause complications like obstructive fibrosis, thrombosis, and chronic inflammation. An alternative approach is to use biological materials to provide a scaffold that the body can recognize and work with. However, this means that the body's adaptive and innate immune system will also recognize and destroy xenogeneic proteins or extracellular matrix (ECM) proteins that have been denatured (i.e., damaged). This is why animal-derived implants are treated with powerful crosslinking agents, making them unrecognizable to the cells (and a sort of foreign material). This also explains why extracellular matrix proteins that have been chemically solubilized and re-assembled are rapidly degraded after implantation. Another alternative is to have human cells assemble an ECM in vitro that can be used as a strong, unprocessed, completely biological, human scaffold for tissue engineering and/or surgical repair. This talk will present how Cell-Assembled extracellular Matrix (CAM) can be produced as a sheet, as a thread, and as particles to provide a new toolbox to address various regenerative medicine challenges. Past, present, and future applications will be discussed with a special emphasis on the development of human textiles.

ADVANCED HUMAN STEM CELL-BASED MODELS FOR MIMICKING CARDIOVASCULAR DISEASE. TOWARDS PERSONALIZED MEDICINE

Robert Passier[P][1]

[1] *University of Twente*

Corresponding author's email: robert.passier@utwente.nl

Cardiovascular disease is the leading cause of death globally, representing approximately 30 percent of all death. Although in the last decades researchers have focused on the treatment of heart disease, there is currently no cure for this disease. In addition to genetic and environmental factors, which are considered to be key determinants of cardiac disease, impaired cardiac function may be exhibited by unexpected drug-induced side effects, called cardiotoxicity. Besides the safety concerns, unpredicted cardiotoxic side effects leading to late-stage drug attrition or withdrawal of drugs from the market is a financial catastrophe for the pharmaceutical industry. One major problem is the limited ability to accurately mimic human heart disease and to predict the effects of potential heart drugs on patients using the current in vitro assays and experimental animal models. Human pluripotent stem cell (hPSC)-derived cardiac cells can be used to set up human-relevant, patient-specific cell-based assays for biomedical and pharmacological research. Here, I will discuss the application of hPSC-derived cardiomyocytes to more accurately mimic human heart function in vitro and their potential for tissue engineering and regenerative medicine. Moreover, the use of patient-derived cells will allow personalized medicine (also called precision medicine), enabling accurate assessment of the disease phenotype and underlying mechanisms, drug discovery and drug toxicity testing, leading to better and safer drugs.

FRONTIERS IN CELL MODELLING

Manuela T. Raimondi[P][1]

[1] *Polytechnic University in Milano*

Corresponding author's email: manuela.raimondi@polimi.it

This talk provides the fundamental concepts behind the design of frontier cell models that I have invented in the last two decades. One concept is miniaturisation associated to full-thickness optical accessibility(1) to recreate and monitor in real time and in long term culture, the interstitial perfusion process of 3D natural tissues such as brain, bone marrow and lymph node tissues. Cell models based on this concept proved able to recapitulate in vitro several slowly-developing biological processes, such as the formation of a bone metastasis by breast cancer cells(2), the instruction of adaptive immune cells in a lymphnode(3) and the neuroprotective effect of mesenchymal stem cell secretome on pathological neurons. I have then connected these models to recapitulate mechanisms involving multiple body compartments, such as the microbiota-gut-brain axis in neurodegeneration(4) and the bone marrow-lymphnode axis in leukemic transformation. Another concept is miniaturisation of the 3D cell scaffold. In the aim to better control and monitor stem cell function, I miniaturised the culture substrates in my models by applying a microfabrication technique called two-photon laser polymerization(5). Using these 3D micro scaffolds, I was able to condition mesenchymal stem cells, neural precursor cells and embryonic stem cells towards maintenance of a greater stemness and multipotency/pluripotency, compared to conventional 3D scaffold culture. Finally, I have recently invented a revolutionary concept of implanting the cell model in a living organism to regenerate a micro vascular network anastomosed to the host, allowing for studies involving interactions of the cell model with the host immune system.

A BIOMIMETIC APPROACH TO MECHANICAL LOADBEARING IN HYDROGELS FOR CARTILAGE IMPLANTS

Corrinus C van Donkelaar$_P$[1], Rienk H Schuiringa[1], Maria Pastrama[1], Keita Ito[1]

[1] *Eindhoven University of Technology*

Corresponding author's email: c.c.v.donkelaar@tue.nl

Hydrogels are commonly used in cartilage tissue engineering, as they provide suitable environments for chondrogenesis. However, hydrogels have the general *limitation* that they are mechanically inferior to natural cartilage, and cannot withstand the loads in a joint after implantation. We developed an approach to address this, in which the loadbearing functionality originates from osmotic pressure, generated by the swelling potential of a charged hydrogel that is restricted from swelling by a textile mesh. This is very similar to the mechanism by which natural cartilage physiologically functions. This presentation will demonstrate the performance of such a construct, with quantitative relations between swelling potential of the hydrogel and compressive stiffness of the final construct. For this purpose, hydrogels with a variation of fixed charges are used, which are swollen and mechanically restricted with or without the presence of a textile spacer fabric.

Further, initial results of cell cultures within these constructs are shown, to illustrate the potential of these load-bearing, reinforced hydrogels for creating cartilage implants.

STEM CELL ENCOUNTERS WITH STRESSFUL SITUATIONS: SURVIVAL OF THE FITTEST

Elaine Fuchs[P][1,2]

[1] *Howard Hughes Medical Institute*

[2] *The Rockefeller University*

Corresponding author's email: fuchs@rockefeller.edu

Barrier epithelial tissues such as the skin, lung and gut are the first line of defense between our body and the external environment. As such, their stem cells must take on multifaceted tasks, self-renewing, protecting themselves, rejuvenating and repairing their tissues and calling for help from the immune system when their barrier has been breached. These stem cells reside in protected niches and together they undergo complex crosstalk to coordinate the stem cells' behavior and tasks. When the tissue is challenged by environmental stresses, such as allergens, pathogens, wounding or oncogenic stress, the stem cells must be poised to cope. We use high throughput genetic and genomic approaches to learn at a molecular level how the stem cells' differentiation programs are primed to operate under environmental stresses and how stem cell interactions with their niches differ in homeostasis, wound repair and inflammation. Our global objective is to apply our knowledge of the basic science of epithelial stem cells to unfold new avenues for therapeutics.

BIOENGINEERING ORGANOID PATTERNING

Adrian Ranga[P][1]

[1] *KU Leuven*

Corresponding author's email: adrian.ranga@kuleuven.be

Organoids serve as increasingly widespread model systems for understanding the complex interplay between biochemical and physical signals which govern in vivo fate specification, patterning and morphogenesis. While some elements of these complex biological processes can now be recreated in vitro, the current reliance on reductionist culture conditions largely overlooks the extracellular factors which promote multicellular growth and reorganization, leading to stochastic and poorly controllable outcomes. We tackle the challenge of reconstructing the multifactorial in-vivo microenvironment by deploying synthetic matrices in combination with customized devices which allow us to spatiotemporally control and manipulate mechanical forces to study early development events, as well as to microvascularize these tissue constructs at increasingly large scale. Our work with organoid-based models of neural tube morphogenesis suggests that the way forward towards engineering reproducible and scalable patterned tissue constructs may involve harnessing cells' inherent capacities for self-organization by providing mechanically active and highly perfused microenvironments.

TAMING CELLULAR SELF-ORGANIZATION IN MICROENGINEERED SYSTEMS

Stefan Giselbrecht$_P$[1]

[1] *MERLN Institute for Technology-Inspired Regenerative Medicine, Maastricht University*

Corresponding author's email: s.giselbrecht@maastrichtuniversity.nl

Stem cell-based organoids, mimicking the development, physiology or disease of various organs, have become an important tool in understanding fundamental biological mechanisms. However, tools facilitating a faithful recapitulation and precise manipulation of such multicellular systems are still lacking. More advanced in vitro systems embracing the geometric and dynamic complexity are required to gain an improved understanding of tissue patterning and separation, long-term maintenance of tissue architectures and organogenesis. Microfluidic systems, allowing for a controlled decoupling of biological compartments, will play a key role in decoding spatial and temporal characteristics of signaling cues and mechanisms of cell-cell and tissue-tissue interactions. To recapitulate morphogenetic processes in vitro, we are developing techniques to engineer spatiotemporally controlled environments to orchestrate self-organization of pluripotent stem cells. Here, we present tailored microengineered cell culture systems, e.g. for blastoids and gastrointestinal organoids, to study early embryonic development and organogenesis. The development of more sophisticated 3D cell culture systems will also be a vital step forward in addressing specific questions in the field of organoids related to maturation, reduction of off-target phenotypes and the development of higher-order tissue architectures in the future.

YOU ARE WHAT YOU EAT: MODULATING METABOLISM TO DIRECT STEM CELL FATE

Nick van Gastel[P][1]

[1] *De Duve Institute, UCLouvain, Brussels, Belgium*

Corresponding author's email: nick.vangastel@uclouvain.be

Unraveling the molecular regulation of stem cells is critical to understand the functioning of these cells in health and disease, and to leverage their potential for regenerative medicine. Once thought to be a mere consequence of the state of a cell, intermediary metabolism is now known to play a key role in dictating whether a stem cell proliferates, differentiates or remains quiescent. In this presentation, I will highlight the recent methodological advances that allow us to investigate stem cell metabolism. I will further discuss our findings on the role of cellular metabolism in skeletal stem cells during bone fracture healing, and the potential of targeting metabolic pathways in bone tissue engineering approaches.

Vessel adapt to flow through a process of vascular remodelling. We have limited understanding of the direct relationship between changes in flow and the consequence on the network morphology. Some techniques, such as ultrasound biomicroscopy and optical coherence tomography, can follow flow over time, but due to resolution limits, they can only assess changes to larger vessels. Our group has developed a time-lapse imaging technique that allows us to measure flow patterns with micron resolution and concurrently image the blood vessel morphology. We use developmental avian models as our vascular bed. We combine the flow imaging with computational fluid dynamics (CFD) to extract shear stress levels and other forces. We follow both flow and vascular morphology over a period of 10 to 12 hours. In this way, we can calculate the force that are present and image how the vasculature reacts in real time. We have also combined our time-lapse imaging technique with computational modelling to understand how these forces induce the observed changes. Our results have shown that sprouts form at shear stress minimum. Interstitial flow also plays a role, limiting sprout formation to the side of an avascular region that is at lower pressure. Lastly, we use all this insight to develop self-propelled particle (SPP) model to model how endothelial cells move in response to flow and use this to predict final vascular morphologies based on our measured flow patterns.

COMPUTATIONAL MODEL OF CELL FATE DECISION IN THE EARLY MOUSE EMBRYO

Geneviève Dupont$_P$[1]

[1] *Université Libre de Bruxelles*

Corresponding author's email: genevieve.dupont@ulb.be

Embryonic development is a self-organised process during which cells divide, interact and change fate according to a complex gene regulatory network. In the early mouse embryo, the lineage specification of inner cell mass (ICM) cells into epiblast (Epi) and primitive endoderm (PrE) cells is tightly regulated by a gene regulatory network (GRN) and by extracellular signalling. We developed a realistic computational model of this GRN, which was shown to exhibit tri-stability and to account for the self-organized process of specification observed in vivo. The model also sheds light on various observations performed on wild-type or mutant embryos submitted to exogenous treatments that interfere with extracellular signalling. Models of increasing complexity, starting from the single cell level to a population of dividing cells interacting via extracellular signalling, are used to investigate the mechanistic origin of the experimentally observed spatial arrangement of the Epi/PrE cells in a salt-and-pepper pattern. The possible sources of noise, responsible for the initial symmetry breaking in murine early development, will also be discussed.

BIOENGINEERING CELLULAR MICRONICHES WITH PHOTOPOLYMERIZED HYDROGELS TO STUDY CURVATURE-INDUCED TISSUE REORGANIZATION

Marie Versaevel[P][1], Marine Luciano[1], Sylvain Gabriele[1]

[1] *University of Mons*

Corresponding author's email: marie.versaevel@umons.ac.be

Conventional 2D cell culture techniques have provided fundamental insights into key biochemical and biophysical mechanisms, however they do not fully capture the physical and chemical properties of the native cell microenvironment. Indeed, many tissues and organs present complex 3D environments with specific topographies, stiffness and biochemical patterns. These biochemical and mechanical properties of the cellular environment are related to the physiological function of the cells and tissues. The development of innovative cell culture substrates that reproduce the complexity of the 3D cell microenvironment is essential for physiologically-relevant in vitro studies and testing.

Here, we present an easy and robust method to produce hydrogel microniches in a wide range of stiffness, covering the whole physiological range (from 1 kPa to 250 kPa). We use the Irgacure 2959 photoinitiator to photopolymerize hydroxy-polyacrylamide (hydroxy-PAAm) hydrogels with ultraviolet illumination. By illuminating the hydrogel solution through an optical photomask with micrometer-scale patterns, we form 3D hydrogel microniches of varying geometries like corrugations, hemispheric and star-shaped bowls or villis.

In this work, these bioengineered microniches are used to study how matrix curvature impacts cell fate. By culturing epithelial tissues within bowl-shaped microniches of different diamaters and depth, we show that substrate curvature alters tissue morphology that results in nuclear deformation and orientation. This particular organization of cells within epithelial tissue generates numerous cellular exchanges between the niche and its surrounding environment. We envision that our 3D microniches will have potential applications in understanding how multicellular architectures organize and adapt to well-defined 3D structures.

TRANSCRIPTOMICS OF HEPATIC CELLS IN 3D ORGANOID SYSTEMS

Padma Rajagopalan[P][1]

[1] *Virginia Tech, Department of Chemical Engineering*

Corresponding author's email: padmar@vt.edu

Liver homeostasis requires the presence of both parenchymal and non-parenchymal cells (NPCs). However, systems biology studies of the liver have primarily focused on hepatocytes. Using an organotypic three-dimensional (3D) hepatic culture, we report the first transcriptomic study of liver sinusoidal endothelial cells (LSECs) and Kupffer cells (KCs) cultured with hepatocytes. Through computational pathway and interaction network analyses, we demonstrate that hepatocytes, LSECs and KCs have distinct expression profiles and functional characteristics. Our results show that LSECs in the presence of KCs exhibit decreased expression of focal adhesion kinase (FAK) signaling, a pathway linked to LSEC dedifferentiation. We report the novel result that peroxisome proliferator activated receptor alpha (PPARα) is transcribed in LSECs. The expression of downstream processes corroborates active PPARα signaling in LSECs. We uncover transcriptional evidence in LSECs for a feedback mechanism between PPARα and farnesoid X-activated receptor (FXR) that maintains bile acid homeostasis. We demonstrate that KCs in 3D liver models display expression patterns consistent with an anti-inflammatory phenotype when compared to monocultures. These results highlight the distinct roles of LSECs and KCs in maintaining liver function and emphasize the need for additional mechanistic studies of NPCs in addition to hepatocytes in liver-mimetic microenvironments.

RETINAL CELL THERAPY USING IPS CELLS

Masayo Takahashi[P][1,2]

[1] *Vision Care Inc.*

[2] *Kobe City Eye Hospital*

Corresponding author's email: takahashisec@vision-care.jp

Our aim is to develop outer retinal cell therapy using iPS cells. The first in man application of iPS cells started in 2013 for age-related macular degeneration. At first autologous iPS-derived retinal pigment epithelial (RPE) cell transplantation was done and then we proceeded to clinical research using HLA matched allogeneic iPSC-derived RPE cells from 2017. Immune responses to transplanted allogeneic cells could be controlled with topical steroids without systemic immunosuppressants. These clinical studies have confirmed the safety of iPS-derived RPE.

The next challenge is photoreceptor replacement. iPSC-retinal organoid transplantation is a promising treatment to restore visual function in degenerated retinas. We proved that (1) grafted immature retinal sheets maturated after transplantation in the eye, and (2) grafted photoreceptor cells could form synapses with host secondary neurons in adult mice with photoreceptor degeneration. (3) MEA (multi-electrode array) recordings showed that the grafted cells could elicit light responses in host ganglion cells. (4) The blinded mice could response to light stimuli in the behavior test after transplantation. With those findings as POC, we conducted a clinical study using retinal organoids for retinitis pigmentosa in two patients.

Based on these experiences, we are developing therapies for each case of outer retinal diseases. Our company regards regenerative medicine not only as the manufacture of final products but also as therapies. I will talk about the current status and future vision of retinal cell therapy.

SUPPORTING MODELLING IN TOXICOLOGY WITH NATURAL LANGUAGE PROCESSING

Marc Teunis[P][1], Marie Corradi[1]

[1] *HU - University of Applied Sciences*

Corresponding author's email: marc.teunis@hu.nl

Extracting information from text is a challenging task. Due to the increasing volumes of data, previously used paradigms such as systematic reviews are becoming impractical. The advancement of machine learning provides alternative solutions to this challenge. Qualitative and quantitative Information about effects of chemicals, chemical properties, molecular pathways, key-initiating events, in vitro assays, and dosage are contained within scientific literature, in-house testing reports and chemical and toxicological databases such as those of ECHA and ToxBank. To extract and organize relevant information from these sources, it seems valuable to employ deep learning Natural Language Processing techniques. This approach has already shown its value in some areas of toxicology, such as nanotoxicology and drug-induced liver injury. To support the data extraction for building toxicological models we propose the following approach. 1) Named Entity Recognition: We trained an NLP model using deep learning, that can recognize a number of entities relevant for the toxicological context. 2) Semantic relationships (linguistic dependencies) will allow to add qualitative (biological) and quantitative meaning to the entities. 3) Building semantic networks and relational graph visualizations will help provide context to chemical-organism interactions. 4) Connecting molecular ontologies and pathways aims to use existing ontologies to provide further insight in pathways and genes, related to effects of chemicals. With this data we can map underlying mechanisms that lead to toxicological effects and start building quantitative models for hazard and risk assessment.

WHY TERMIS

Jöns Hilborn[P][1]

[1] *Upsala University*

Corresponding author's email: hilborn@kemi.uu.se

Isn´t it exciting when you get your first proof-of-concept that your idea works? This is especially true when dealing with concepts that could help people with medical problems like lack of tissue or selecting the right combination of drugs for cancer treatment. When translating findings from bench to clinic, however, we reach the roadblocks of reality. We find that our source of scaffold materials varies between batches, our cells are too expensive to produce, our regulatory agency requests too much, and surgeons think that the procedure is complicated. Finally, the cost to bring our solution to the patient is too high for the small market we had in mind.

Could you have planned for this?

Much of the knowledge we are looking for we may find among colleagues in TERMIS. Before TERMIS was founded in the year of 2005 there were (competing) societies scattered over the world. To benefit from global knowledge, the idea was born to create ONE Society providing the best meeting in the field. We now have meetings that gather all competencies for our planning. Many of us, also would like to advance beyond the state-of-the-art and we are exploring new technologies, like 3D printing, IPSC, and extracellular vesicles with the hope that it will provide a breakthrough – but will it?

Here I would like to cite a Danish proverb: “It is very hard to predict, especially the future.”

HYALURONIC ACID BASED HYDROGELS FOR ANTIBODY DELIVERY AND 3D-BIOPRINTING

Tina Vermonden[P][1], Blessing Ilochonwu[1], Carl Schuurmans[1], Wim Hennink[1], Yu Shrike Zhang[2]

[1] *Utrecht University*

[2] *Harvard Medical School*

Corresponding author's email: t.vermonden@uu.nl

Hyaluronic acid (HA) is a highly negatively charged polysaccharide abundantly present in the body including in the vitreous of the eye. Injectable hydrogels based on hyaluronic acid therefore have high potential for delivery of therapeutic biomolecules for ocular diseases. Crosslinking HA by using dynamic bonds is an interesting approach to prepare these in situ gelling systems. On the other hand, covalent crosslinking leads to mechanically stable materials suitable for preparation of scaffolds by 3D printing.

Diels-Alder chemistry based hydrogels were prepared by mixing Furan-modified Hyaluronic acid (HAFU) with 4 arm-PEG10kDa-maleimide (4APM). The potential of this system for the treatment of ocular diseases was shown by testing the injectability into the vitreous body of an ex vivo porcine eye through a 29G needle. Importantly, 4APM-HAFU hydrogels were able to sustain delivery of bevacizumab for more than 90 days in vitro.

3D-printable hydrogels were prepared by photopolymerization of methacrylated hyaluronan. Complexing the negatively charged HA network with cationic polymers resulted in significant shrinking of the printed hydrogels due to electrostatic interactions. We showed that the use of opposite charges to shrink hydrogels is broadly applicable using different polycations. This shrinking effect was exploited to enhance the printing resolution.

QUANTIFYING CELLULAR FORCES IN 3D: TOOLS AND APPLICATION TO ANGIOGENESIS

Hans Van Oosterwyck[P][1]

[1] *KU Leuven*

Corresponding author's email: hans.vanoosterwyck@kuleuven.be

Cellular forces play a crucial role in tissue and organ formation. In order for cells to organize into 3D multicellular entities they need to apply forces to neighbouring cells and their extracellular matrix. In addition, forces are modulators of molecular signaling, as they can influence molecular activity and interactions in a process that is known as mechanotransduction. As such, cellular forces are important for development, growth, regeneration and disease and assessing them can enhance our understanding of governing mechanisms, complementary to information stemming from cell and molecular biology assays.

In this talk I will give an overview of the tools we have developed in quantifying cellular forces in 3D in vitro systems. Having added the third dimension makes those tools more relevant for tissue engineering and regenerative medicine, but also comes with a price in terms of complexity. I will highlight some of the pitfalls related to the use of 3D Traction Force Microscopy (TFM), and the solutions we have developed in order to ensure a sufficiently accurate and efficient workflow (1). We have developed a stand-alone software called TFMLAB (2), that is freely available and that has the ambition to also be used by non-expert users, so that cellular force data becomes more accessible to different fields in life sciences. Finally, I will illustrate the applicability of these tools to the study of angiogenesis (3) and the role of cellular forces in microvascular disease.

4D PRINTING: A FOREFRONT MANUFACTURING APPROACH FOR SMART DEVICES.

Giovanni Vozzi[1], Irene Chiesa[1], Carmelo De Maria[1], Amedeo Franco Bonatti[1]

[1] *University of Pisa - Research Center "E. Piaggio" & Department of Information Engineering*

Corresponding author's email: giovanni.vozzi@unipi.it

In 2013, the term “four-dimensional (4D) printing” was introduced to denote the fabrication via additive manufacturing (AM) of structures capable of shape transform over time, under a predefined stimulus. Thus, 4D printed constructs are no longer static objects but programmable active structures that accomplish their function through a change, over time, in their physical and/or chemical properties when exposed to a predefined stimulus [1,2]. The key points of 4D printing are AM technologies, smart materials or combination of different materials, and external stimuli. Since 2013, the 4D printing approach has been in rapid expansion in several biomedical fields, including tissue engineering, and biomedical devices. Indeed, native tissues exhibit unique functions that are achieved through dynamic changes in tissue conformation. Thus, 4D printing may produce biologically active constructs that can alter their shapes upon desired stimulation, mimicking the native tissue movements, adapting to the 3D complex shapes of the human body, or providing appropriate stimuli to promote cell differentiation and activities [3]. Similarly, 4D printing has the potential to drive a significant transformation in the medical devices field, manufacturing customized implants able to grow up with the patient, devices that allow the use of minimally invasive surgical procedure, or perform their action without the need of electrical energy [4]. Here, we present the implementation of the 4D printing paradigm in practical applications of biomedical interest, such as bio-based medical devices for abdominal surgery and bioengineered platforms for neural tissue engineering, developed by the Biofabrication Group of the University of Pisa.

Most current applications of biofabrication are for the production of devices that are aimed at modeling disease processes, screening drugs, or producing a device to be used in therapy, most often regenerative therapy. However, one of the most significant problems facing all cell-based therapies is the expansion of the relatively small numbers of donated by consented patients to the number of cells needed for therapeutic interventions. A single donor may contribute millions of cells. With or without the pooling of cells donated from multiple individuals, the therapeutic need for hundreds of millions to billions cells is a significant challenge. An example of the type of cell expansion that is needed for therapeutic interventions is the use of Bone Marrow-derived human Mesenchymal Stem Cells (BM-hMSCs) in leukemia therapies and, potentially, in regenerative medicine. Our group has recently demonstrated the ability to create layers within biofabricated filaments at nanometer to micrometer resolution with a novel technique, Chaotic Printing (CP). An ongoing study shows that CP offers promise as a technique for the proliferation of BM-hMSCs as it overcomes the limits on surface area to volume (SAV) seen in current cell expansion bioreactors. As SAV increases, a second challenge arises is the ability to provide sufficient nutrients and remove rapidly accumulating waste products. Our use of CP to intercalate fugitive and cell-bearing layers shows promise for this second challenge. Based on our recent results using this technology we anticipate that CP can be used to significantly improve BM-hMSC expansion over current bioreactor strategies.

USE OF ADVERSE OUTCOME PATHWAYS FOR THE IN VITRO PREDICTION OF LIVER TOXICITY

Mathieu Vinken[P][1]

[1] *Vrije Universiteit Brussel*

Corresponding author's email: mathieu.vinken@vub.be

Adverse outcome pathways (AOPs) are pragmatic tools in toxicology and human risk assessment with broad potential. AOPs are designed to provide a clear-cut mechanistic representation of toxicological effects that span over different layers of biological organization. Because of its unique location and function in the organism, the liver is a frequent target for systemic toxicity. Not surprisingly, several AOPs related to liver toxicity have been introduced over the fast few years. Focus will be put in this presentation on liver toxicity triggered by bile acid accumulation. This so-called cholestatic hepatotoxicity underlies many drug-induced liver injury cases and has also been associated with various other types of chemicals, including food additives, cosmetics and biocides. The present presentation will give an overview of the validation of this AOP on cholestatic liver injury. In particular, testing of the specificity and applicability domain will be presented along with its potential to predict cholestatic liver toxicity in vitro.

COLLABORATIVE ANALYSIS OF WHOLE-SLIDE TISSUE IMAGES WITH CYTOMINE OPEN-SOURCE RICH INTERNET APPLICATION

Raphaël Marée[P][1]

[1] *University of Liège*

Corresponding author's email: raphael.maree@uliege.Be

The Cytomine project (https://www.cytomine.org/) started in 2010 at University of Liège (https://uliege.cytomine.org) to build a rich web environment for the analysis of multi-gigapixel imaging data. This open-source software tool has been designed with the following objectives in mind: provide remote and collaborative principles, rely on data models that allow to easily organize and semantically annotate imaging datasets in a standardized way, efficiently support high-resolution multi-gigapixel images (e.g. whole-slide images in digital pathology), and provide mechanisms to readily proofread and share through the web image quantifications produced by machine/deep learning-based image recognition algorithms. By emphasizing collaborative principles, our aim with Cytomine is to accelerate scientific progress and to significantly promote image data and algorithm accessibility and reusability. Cytomine collaborative principles allow to break common practices where imaging datasets, quantification results, and associated knowledge are still often stored and analyzed within the restricted circle of a specific laboratory.

In this talk, we will summarize its main features [1] and applications in various domains, and give an overview of recent results and its extension to perform image analysis benchmarking (Rubens et al., 2020).

LIGHT-ADDRESSABLE CELLULAR MATRICES WITH IN SITU SENSING AND ACTUATION FUNCTIONALITIES

Carmen Bartic[P][1]

[1] *KU Leuven*

Corresponding author's email: carmen.bartic@kuleuven.be

In order to decipher cellular functions, understand disease mechanisms and develop regenerative strategies, we need methods allowing modulating and detecting cellular activity with high spatio-temporal resolution, in 3D cell preparations. In this contribution, a multifunctional platform will be discussed where nanoparticle sensors and actuators are incorporated in a hydrogel supporting cell encapsulation. This system functions as a light-addressable cellular matrix, where 3D temperature gradients are produced locally and dynamically using the localized surface plasmon resonance (LSPR) of gold nanorods (AuNRs) under near infrared (NIR) laser illumination. At the same time, the temperature changes are probed locally by monitoring the temperature induced changes on fluorescent nanothermometers. Plasmonic heating also deforms the hydrogel controllably and reversibly, allowing to apply mechanical and thermal stimuli in a 3D cell preparation. The hydrogel deformation is quantified by means of inline holographic microscopy and in principle it can be to probe cellular mechanical properties. Combining the environment-sensitive and size-dependent optical properties of nanoparticles with soft hydrogels and light-patterning strategies allows tuning the properties of the cellular environment with sub-cellular resolution and can provide an efficient method for remote, highly localized cell stimulation with in situ parameter monitoring.

BIOPRINTING IN SPACE

Vladimir Mironov[P][1]

[1] 3D B

Corresponding author's email: vladimir.mironov54@gmail.com

Magnetic levitational bioassembly of three-dimensional (3D) tissue constructs represents a rapidly emerging scaffold- and label-free approach and alternative conceptual advance in tissue engineering. The magnetic bioassembler has been designed, developed, and certified for life space research. To the best of our knowledge, 3D tissue constructs have been biofabricated for the first time in space under microgravity from tissue spheroids consisting of human chondrocytes. Bioassembly and sequential tissue spheroid fusion presented a good agreement with developed predictive mathematical models and computer simulations. Tissue constructs demonstrated good viability and advanced stages of tissue spheroid fusion process. Thus, our data strongly suggest that scaffold-free formative biofabrication using magnetic fields is a feasible alternative to traditional scaffold-based approaches, hinting a new perspective avenue of research that could significantly advance tissue engineering. Magnetic levitational bioassembly in space can also advance space life science and space regenerative medicine.

PATIENT-SPECIFIC MODELLING FOR OPTIMISING HEART VALVE IMPLANT DESIGN AND INTERVENTION

Sotirios Korossis[P][1,2]

[1] *Loughborough University*

[2] *Hannover Medical School*

Corresponding author's email: s.korossis@lboro.ac.uk

Understanding healthy and diseased tissue behaviour is of paramount importance in designing implants and surgical interventions for the clinical setting. However, the biomechanical and, for the case of cardiovascular tissues, haemodynamic behaviours of tissues are difficult to be assessed in vivo. In addition, tissue behaviour and function are specific to the individual patient and this needs to be accounted for in order to appropriately tailor patient-specific implants and/or interventions. In contrast to the practice of one-size-fits-all, tailoring the implant and/or intervention to the individual patient is considered to significantly improve implant survival and reduce risky and costly reoperations. Recent advancements in medical imaging offer important solutions for such patient-specific assessment of tissue behaviour and function. However, medical imaging is still limited to predominantly qualitative assessment. To this end, experimental and computational simulations have the potential to generate quantitative information of tissue behaviour and function, by complementing medical imaging and providing patient-specific assessments. This talk will present and discuss a number of experimental and patient-specific computational models that were developed at Loughborough University and Hannover Medical School with a view to assessing heart valve function in health and disease and optimise surgical intervention.

PLACENTAL CELL THERAPY FOR MUSCLE TRAUMA IN HIP FRACTURE PATIENTS: FROM PRECLINICAL TO CLINICAL PHASE III

Tobias Winkler$_P$[1]

[1] *Charité - Universitätsmedizin Berlin*

Corresponding author's email: tobias.winkler@charite.de

Mobility after hip fracture arthroplasty is critical but difficult to achieve. This can be related to the general condition of the patients and the additional muscle injury needed for joint exposition in these frail patients. Our studies have explored therapy with mesenchymal stromal cells (MSC) for skeletal muscle injuries and transferred this therapy from preclinical tests to clinics.

In a muscle injury model, we tested autologous and allogeneic MSC transplantation, using placenta-derived cells (PLX-PAD) for the latter. We translated this therapy by using iatrogenic muscle damage after total hip arthroplasty (THA) as a model system and conducted a prospective, randomized, double blind, placebo-controlled phase I/II study randomizing 20 THA patients (lateral approach) to transplantation with 300x106 (300M), 150x106 (150M) PLX-PAD or placebo into the injured gluteus medius muscles (GM).

Preclinical experiments showed improved functional muscle healing. Patients of the phase I/II study showed safety and an increase of GM strength and volume in the 150M group (p=0.0067) after 6 months accompanied by faster histological healing and a reduction of postoperative immunological stress.

Based on these results we conduct a phase III study (The HIPGEN study) treating hip fracture arthroplasty patients (N=240) with PLX-PAD (EU Horizon 2020 No 779293) currently enrolling in 20 international sites. Patients are followed for function, biomechanics, quality of life, muscle volume and immunological biomarkers.

Treatment with allogeneic cells could be a game changer not only in the treatment of hip fracture patients but also for other traumatic or iatrogenically induced muscle injuries.

CLINICAL APPLICATION OF TISSUE ENGINEERED VASCULAR GRAFT IN CONGENITAL HEART SURGERY

Toshiharu Shinoka$_P$[1]

[1] *Nationwide Children's Hospital*

Corresponding author's email: toshiharu.shinoka@nationwidechildrens.org

In 2001, we developed the first tissue engineered vascular graft (TEVG) for use in congenital heart surgery and confirmed its significant potential via an initial clinical trial. Between September 2001 and December 2004, 25 patients underwent an extracardiac Fontan using tissue engineered vascular graft (TEVG) in Tokyo. There was no graft-related mortality occurred. There was no evidence of aneurysmal formation, graft rupture, graft infection, or calcification. Ten patients had asymptomatic graft stenosis. Six of 10 patients underwent successful balloon angioplasty. Angiographical assessment shows the growth of grafts. Based on our animal experimental data, we figured out that higher dose cell seeding on the graft could reduce the stenosis rate. We had applied new protocol to FDA for the second generation of TEVG, including a rapid cell seeding technique in 30 patients as Fontan conduits. The rational design of improved, second-generation TEVGs will be predicated on our understanding of the cellular and molecular mechanisms underlying the formation of TEVG stenosis. The feasibility of tissue engineering large caliber, autologous vascular conduits for use as venous interposition grafts for congenital heart surgery has been demonstrated in both large animal and in a human clinical trial. The carefully designed second clinical trial under the supervision of the FDA is underway in the United States.

DEVELOPMENT OF CELL-ASSEMBLED 3D MAGNETICALLY RESPONSIVE TENDON CONSTRUCTS OFFERING THE PROSPECT OF EFFECTIVE TISSUE REGENERATION

Manuela E. Gomes$_P$[1]

[1] *3B's Research Group - I3Bs Research Institute-University of Minho*

Corresponding author's email: megomes@i3bs.uminho.pt

The limitations of currently used therapies together with the limited regenerative ability of tendons have motivated tissue engineering (TE) strategies to develop living tendon substitutes. However, the limited knowledge on tendon development and healing processes has hindered the design of TE procedures that more closely recapitulate tendon morphogenesis. Our lab has been exploring the development of unique cell-laden 3D magnetically responsive systems that recapitulate key features of the native tissue and that can be further remotely modulated both in vitro and in vivo by the application of external magnetic stimuli. We are exploring conventional and innovative tools such as multimaterial 3D bioprinting to design magnetic responsive systems mimicking specific aspects of tendon tissue architecture, composition and biomechanical properties, which, combined with adequate stem cells, shall render appropriate behavioural instructions to stimulate the regeneration of tendon tissue.

Despite the limited knowledge on tendon development and healing processes, it is known that inflammation plays a key role in tendon tissue healing. Persistently increased inflammatory cytokine levels have been associated to tendon degeneration and/or scar tissue formation upon injury and therefore may provide a target for assisting new therapeutic strategies. Therefore, we have been also focusing efforts on understanding possible uses of magnetic stimulus, in combination with magnetic responsive materials, to modulate inflammation in tendon/tendon cells, which can provide an additional valuable tool to trigger tissue regeneration instead of simple repair.

Abstract **#2246**

HUMAN PLURIPOTENT STEM CELL-DERIVED GASTROINTESTINAL ORGANOIDS AS NEW MODELS TO STUDY HUMAN ORGAN DEVELOPMENT, DIGESTIVE DISEASES AND DIABETES

James Wells$_P$[1]

[1] *Cincinnati Children't Research Foundation*

Corresponding author's email: james.wells@cchmc.org

Successful efforts to direct the differentiation of human embryonic and induced pluripotent stem cells (PSCs) into specific organ cell types in vitro have largely been guided by studies of embryonic organ development. Based on this, we can now direct the differentiation of human PSCs into gastrointestinal (GI) organoids including esophageal, gastric fundus, gastric antrum, small intestinal and colonic organoids. GI organoids contain complex epithelial structures and diverse cell types that are unique to their representative organ; esophageal organoids develop a stratified squamous epithelium, gastric organoids have a glandular epithelium that secrete digestive enzymes, and acid, and intestinal organoids secrete mucins and hormones and absorb nutrients. While the first generation of GI organoids were lacking important cell types and functions, we are now able to engineer additional complexity at will. For example we have engineered gastric, intestinal and colonic organoids to have functionally innervated smooth muscle generated colonic organoids with functional immune cells capable of triggering an inflammatory cascade in response to pathogenic bacteria. We have used PSC-derived organoids to identify the underlying mechanisms behind human GI diseases ranging from infections to malabsorption. We are further using organoids to uncover the molecular basis of congenital malformations including Hirschsprung's disease and esophageal atresia and to identify new pathologies in patients with complex GI diseases.

FABRICATION OF ENGINEERED VASCULATURE TO MODEL PATHOLOGICAL PROCESSES

John H Slater$_P$[1,2]

[1] *University of Delaware*

[2] *Department of Biomedical Engineering*

Corresponding author's email: jhslater@udel.edu

Many diseases either directly affect the cardiovascular system, hypertension and inflammation for example, or utilize the cardio and/or lymphatic vasculature during disease progression, cancer metastasis for example. While diseases that affect or utilize cardiovasculature can be studied in both human and animal models, high-resolution temporal imaging of cellular and subcellular events during these processes is often challenging due to the resolution limitations of existing in vivo imaging modalities. Accordingly, the ability to model these processes using engineered vasculature in fluidized, in vitro devices offers the opportunity to begin forming a better understanding of the cellular and molecular mechanisms occurring. Toward this goal, I will discuss various biofabrication techniques (sacrificial molding, laser-induced hydrogel degradation) to generate simplified, three-dimensional microvascular systems embedded in synthetic (poly(ethylene glycol)) or natural (collagen, fibrin) hydrogels. I will also discuss the implementation of these devices to form a better understanding of the cellular and molecular mechanisms that facilitate extravasation of circulating tumor cells during breast cancer metastasis and the potential role of pathological hemodynamics in dementia.

BIOHYBRID CARDIOVASCULAR IMPLANTS: A BRIDGE BETWEEN THE ARTIFICIAL AND THE NATURAL

Alicia Fernández Colino[P][1]

[1] *Department of Biohybrid & Medical Textiles (BioTex), AME-Institute of Applied Medical Engineering, Helmholtz Institute, RWTH Aachen University, Aachen, Germany*

Corresponding author's email: fernandez@ame.rwth-aachen.de

Biological systems in general, and native tissues in particular, display astonishing designs that have been defined and redefined by the process of evolution. While native organs are able to function in the majority of individuals through a lifetime, the reality is that current bioengineered cardiovascular substitutes are far from reaching the native performance. Therefore, the principles of bioinspiration and biomimicry should be embraced in order to develop functional implants. The transfer of the designs found in Nature to the lab represents a promising avenue to develop replacements able to cover the gap between the suboptimal performance of currently available replacements and patients in need of a life-saving implant. Here we propose the use of advanced materials together with innovative bioprocessing techniques to develop biohybrid implants that mimic the complexity of native tissues. The developed cardiovascular replacements combine the elasticity and hemocompatibility of novel genetically engineered polymers with the superior strength of fibrous components.

MAPPING AND PERTURBING CELL-INTRINSIC GENE AND PROTEIN REGULATORY NETWORKS IN EMBRYONAL CELLS: LESSONS FOR CELL-BASED TERM APPLICATIONS

Danny Huylebroeck$_P$[1,2]

[1] *Dept. Cell Biology, Erasmus University Medical Center (Rotterdam, NL)*

[2] *Dept. Development and Regeneration KU Leuven (Leuven, BE))*

Corresponding author's email: d.huylebroeck@erasmusmc.nl

Developmental signaling is repeated during tissue/organ regeneration and used to expand cells with regenerative potential. The multipotent BMP-system has many components, which are studied in lab animals and cell culture, often by loss-of-function or other perturbations. Such studies encompass single intracellular signaling effectors and transcription factors determining cell fate, maturation and behavior. This large set of BMP components is exquisitely connected via autoregulation, synexpression and feedback control at the transcriptional level of all component genes. Hence, modulation of one component has consequences for other ones in cell transitions. We have started to map such consequences, including within single cells and at various time points and cell states, using BMP component perturbations (n=96; esiRNA, CRISPR/Cas), and combine profiling of temporal transcriptional changes, single-cell heterogeneity, and gene-to-gene interactions. One lesson is that 85% of significant gene-to-gene interactions are restricted to one specific cell transition or stage/state, are driven by few transcription factors and, within such system, there exist low vs. high perturbation-sensitive genes. Therefore, interpretation of the consequences of single-gene perturbation in cell lineage progression should occur with caution and consider cell stage and transition. Our results also have consequences for many of the CRISPR-KO based proposed improvements of tailored stem cells.

Abstract **#2251**

Lorenzo Piemonti[P][1,2]
[1] *Diabetes Research Institute, IRCCS OSpedale San Raffaele, Milan, Italy*
[2] *Vita-Salute San Raffaele University, Milan, Italy*

Corresponding author's email: piemonti.lorenzo@hsr.it

In patients with type 1 diabetes, pancreatic β cells are destroyed by a selective autoimmune attack and their replacement with functional insulin-producing cells is the only possible cure for this disease. As of now, intrahepatic islet transplantation is the gold standard cell therapy for β cells replacement. The main limitations, however, remain the insufficient supply of human tissue and the need for lifelong immunosuppression therapy. Great effort is then invested in finding innovative sources of insulin-producing β cells. One old alternative with new recent perspectives is the use of non-human donor cells, in particular porcine β cells. Yet, large-scale production of human insulin-producing cells from stem cells is the most recent and promising alternative. Among the common unsolved problem, the lack of tissue engraftmet represents a relevant obstacle for a wide application of all these approaches in humans. We proposed, for the first time, the use of organ decellularization as a tool for the beta cell replacement strategy with the final goal to engineer a functional Vascularized Islet Organ (VIO). This approach demonstrated that the ex vivo combination of specific ECM native structure composition, geometry and the engraftment of the endocrine side of the pancreas in a dedicated vascular bed dramatically improved β cell survival, function and in vivo performance. This approach suggest a paradigm shift in the field: moving from an in vivo to an ex vivo engraftment strategy.

RECOMBINANT HUMAN BMP6 (RHBMP6) DELIVERED IN AUTOLOGOUS BLOOD COAGULUM IS A NOVEL THERAPY FOR BONE REGENERATION

Slobodan Vukicevic[P][1]

[1] *Laboratory for Mineralized Tissues, Center of Excellence for Regenerative Medicine, Center for Translational and Clinical Research, University of Zagreb School of Medicine*

Corresponding author's email: slobodan.vukicevic@mef.hr

We developed a novel autologous bone graft substitute (ABGS) implant composed of recombinant human BMP6 (rhBMP6) delivered in autologous blood coagulum (ABC). ABGS contains low doses of BMP6 as compared to BMP2 (InFuse®) and BMP7 (Ossigraft®) and is free of animal sourced collagen, not causing inflammation and immune responses. Safety and efficacy preclinical studies using rabbit ulna segmental defect model and posterolateral lumbar spine fusion models in rabbits and sheep have been conducted. ABGS was examined alone and in combination with allograft or synthetic ceramics as compression resistance matrices (CRM) in spine fusion models. ABGS induced a robust bone formation resulting in restoration of segmental defects and complete ectopic bone fusion with adjacent transverse processes at bilateral lumbar spine sites.

The safety and efficacy of ABGS was tested in Phase I/II randomized, double blind, placebo controlled trials in patients with a distal radius fracture (DRF) and high tibial osteotomy (HTO). ABGS was formulated to render a flexible and injectable implant. In the DRF study, three groups of patients were enrolled: standard of care, ABC alone and ABGS (ABC+rhBMP6). The HTO trial was conducted in 20 patients treated with 10 ml ABC containing placebo or 1 mg rhBMP6. Evaluation of ABGS with allograft is in progress following recruitment of 143 patients with degenerative disc disease to a randomized Phase II posterolateral lumbar interbody fusion (PLIF) study. Phase III trials will include patients with weight bearing long bone non-unions and transforaminal lumbar interbody fusion (TLIF) in patients with degenerative disc disease.

SCAFFOLDS FOR CARDIOVASCULAR TISSUE ENGINEERING VIA MELT ELECTROWRITING

Petra Mela[P][1]
[1] *Chair of Medical Materials and Implants, Department of Mechanical Engineering and Munich Institute of Biomedical Engineering, Technical University of Munich*

Corresponding author's email: petra.mela@tum.de

Introduction
Melt Electrowriting (MEW) is an advanced fiber forming additive manufacturing technology that has gained increasing attention for tissue engineering applications. Following a bioinspired approach for in situ cardiovascular tissue engineering, we developed fabrication strategies to obtain functional scaffolds with heterogenous architectures, controlled mechanical anisotropy and porosity.
Methods
A G-code generator was developed to output toolpath commands for the MEW machine based on user defined scaffold parameters. Different scaffold architectures were fabricated and investigated by scanning electron microscopy (SEM). Hybrid constructs could be obtained in combination with biologically favorable materials such as elastin and fibrin. Mechanical properties were determined by tensile testing, infiltration of human umbilical artery smooth muscle cells was verified after 1, 3, and 7 days of culture via SEM and (immuno)histology. Finally, tubular scaffolds were used for heart valves and were tested in a mock circulation system.
Results
MEW resulted in highly reproducible 3D scaffolds that closely matched the morphologies from the G-code generator. Complex heterogenous architectures were obtained, with fiber orientation and patterns defined by the user to tune the mechanical properties and anisotropy in a region-specific way. The scaffolds were fully infiltrated in vitro after 3 and 7 days. The functionality of heart valves based on the developed scaffolds was successfully verified according to the 5840 ISO requirements.
Conclusions
The versatile MEW platform enables the fabrication of highly tunable cardiovascular scaffolds with control on the architecture, heterogeneity, mechanical properties and porosity.

TARGETING SKELETAL CELL METABOLISM AS TISSUE ENGINEERING APPROACH

Geert Carmeliet[P][1]
[1] *KU Leuven*
Corresponding author's email: geert.carmeliet@kuleuven.be

Cell-based tissue engineering is a promising approach to treat large bone defects, but skeletal stem and progenitor cells are often lost during ex vivo expansion, resulting in reduced bone forming capacity. In addition, many cells do not survive after implantation because of insufficient supply of nutrients and oxygen, reducing thus the efficacy of this strategy. However, by targeting cell metabolism stem and progenitor properties can be preserved during ex vivo expansion and cells can be preconditioned to the nutrient-poor environment before implantation. Targeting cell metabolism during in vitro culture may thus improve the in vivo outcome of bone regeneration strategies.

MULTISCALE FRACTAL SHAPE CUES SUPPORT HIERARCHICAL ASSEMBLY AND MATURATION OF PODOCYTES VIA CURVATURE-INDUCED EXTRACELLULAR MATRIX PATTERNING

Anastasia Koroljₚ[1], Milica Radisic[1]
[1] *University of Toronto*
Corresponding author's email: anastasia.korolj@gmail.com

Nature efficiently self-organizes cells and tissues into complex fractal forms. Whether fractal patterning contributes functionally to maturation, and how cells sense and interpret such shape cues, is not well understood. Using kidney podocytes as a model system, bioinspired templating of glomerular histology was leveraged to design controlled fractal 2½ - D surfaces for cell culture. Microcurvature was associated with charge density gradients in space, found to direct extracellular matrix protein organization resulting in hierarchical assembly of cell structures and fractally-branching podocyte morphology in vitro, outlined with a novel fluorescent assaying technique. Shape simulation was uniquely associated with mature-like foot processes on an organized ECM. In applications of drug testing, coronavirus infection, and a cells-as-sensors approach to patient serum diagnostics, fractally stimulated cells were more responsive than flat cultures. Fractal frameworks may thus provide a functional role in podocyte maturation and could serve to advance other bioengineered systems.

UNRAVELLING METABOLIC DEPENDENCIES IN CANCER AND AUTOIMMUNITY

Celia Berkers[P][1,2]
[1] *Division Cell Biology, Metabolism & Cancer, Department Biomolecular Health Sciences, Faculty of Veterinary Medicine, Utrecht University*
[2] *Biomolecular Mass Spectrometry and Proteomics group, Bijvoet Center for Biomolecular Research, Utrecht University*
Corresponding author's email: c.r.berkers@uu.nl

Dysregulation of metabolism contributes to many serious health problems, ranging from diabetes to cardiovascular disease and cancer. Changes in cellular metabolism are widely recognized as a hallmark of cancer cells and the rewiring of metabolism is considered essential for rapid tumour growth and proliferation. Because metabolic alterations aid in the cellular adaptation to pharmacologically changed environments, metabolic changes also play an important role in the development of drug resistance in cancer. In turn, cancer metabolism is intimately linked to immunity and immunometabolism. Upon activation, immune cells undergo a metabolic switch that is comparable to the metabolic rewiring observed in cancer cells. In the tumour microenvironment, immune cells compete with tumour cells for the same resources, further linker cancer and immuno-metabolism.
Interestingly, cells can become reliant on their metabolic reprogramming, a vulnerability that can be exploited for therapy. Research in the Berkers group aims to gain mechanistic insight in cancer and immuno-metabolism to ultimately identify novel metabolic targets for therapeutic intervention. In this talk, I will explain how we employ metabolomics and multi-omics strategies to study the role of metabolic pathways. I will showcase how metabolic inhibitors can be combined with chemotherapy to increase therapy responses. I will also highlight how omics methodologies can be used to shed light on T-cell metabolism.

Abstract **#2257**

IN TRANSITION TOWARDS SAFETY ASSESSMENT OF COMPOUNDS COMPLETELY BASED ON HUMAN DATA

Cyrille Krulp[1], Anne Kienhuis[2]
[1] *University of Applied Sciences Utrecht*
[2] *National Institute for Public Health and the Environment*
Corresponding author's email: cyrille.krul@hu.nl

Safety and efficacy testing of compounds is traditionally performed in laboratory animals, with limitations regarding translatability to humans. For the development of better translational methods we need advanced in vitro models that closely mimic the human situation. Such (organ-specific) models based on human cells are preferred over animals and immortalized cell lines. Recent scientific developments in tissue engineering, microfluids and material science have led to the development of promising advanced in vitro models, such as organ-on-a-chip and organoids. An advantage of using these type of models is that they provide more mechanistic information on chemical-induced adverse effects on biological pathways. For applications in toxicology, especially in the regulatory context and the acceptance and use by industry, performance and acceptance criteria need to be defined. These criteria include requirements with respect to the validity (relevance, robustness, reproducibility, reliability), transparency and accessibility. Furthermore, the context-of-use of advanced in vitro models need to be defined for complex technology such as organ-on-a-chip. 'As simple as possible and as complex as necessary', seems to be a good starting point. Recently we started with the development of a 'Virtual Human Platform': a new approach integrating existing human data, data obtained from in vitro models, and exposure assessment with AI/machine learning. We aim to design a new framework for safety assessment of chemicals. This should be a combined effort of all stakeholders, researchers, industry, regulators, NGO's and patients to address the emerging challenge to accelerate the transition towards animal-free safety assessment completely based on human data.

THE FABRIC OF LIFE: HOW FIBRE SYSTEMS WITH UNIQUE PROPERTIES DETERMINE TISSUE MECHANICS AND FUNCTION

Rudolf E. Leube[P][1]
[1] *RWTH Aachen University*
Corresponding author's email: rleube@ukaachen.de

The most abundant polypeptides produced by the organism form elongated polymer chains, which assemble into complex fibre systems. Their diversity and plasticity support all of life's functions and are essential for tissue morphogenesis and maintenance. An important aspect is the physical connectivity between the different intra- and extracellular fibre systems defining tissue mechanics.
We study the cytoplasmic keratin intermediate filament-based epithelial cytoskeleton as a paradigm to examine these relationships. The more than 50 keratins form highly heterogeneous filaments with an epithelial cell type- and context-dependent composition. The compositionally unique filaments assemble into different types of cytoplasmic networks, which reflect and determine the cross talk between epithelial differentiation and function. The keratin cytoskeleton is linked to the nuclear cytoskeleton and to the extracellular matrix through different types of protein assemblies. Together, these fibre systems co-ordinate cell and tissue behaviour controlling homeostasis at different length and time scales.

BIOMEDICAL APPLICATIONS OF MAGNETIC NANOPARTICLES: REMOTE CONTROL OF CELLS

Jon Dobson[P][1]
[1] *University of Florida*
Corresponding author's email: jdobson@ufl.edu

The use of magnetic micro and nanoparticles for biomedical applications was first proposed in the 1920s as a way to measure the rheological properties of the cytoplasm. Since that time, particle synthesis techniques and functionality have advanced significantly. Magnetic micro and nanoparticles are now used in a variety of biomedical applications. More recently, magnetic micro and nanoparticles have been used to investigate and manipulate cellular processes both in vitro and in vivo.

This talk will focus on our work developing Magnetically Activated Receptor Signaling (MARS) – a magnetic nanoparticle–based technique for activating cell surface receptors and controlling the activity of biomolecules such as growth factors. The basic principles involve surface functionalization of magnetic nanoparticles (MNPs) with molecules targeting specific cell surface receptors. We have investigated antibodies targeting specific ion channels (e.g. TREK1), surface receptors (e.g. PDGFRα & β) and peptides (e.g. RGD) targeting integrins. The particles bind to the receptors and, upon the application of a highgradient external magnetic field, energy is transferred to the particles. The energy delivery induces a conformation change in the receptor, activating the specific biochemical signaling pathway associated with that receptor. By targeting specific receptors, we have been able to control ion channel activity, activate bone and cartilage matrix formation, and control the differentiation of human mesenchymal stem cells both in vitro and in vivo. We have developed this technology for applications in cell engineering/regenerative medicine and stem cell therapy. The MARS technology has applications in regenerative medicine, drug screening and cell engineering.

Keywords
magnetic; nanoparticles; regenerative medicine

Unlike seasonal coronaviruses, SARS-CoV-2 has a profound tropism for the heart. Estimates indicate 78% of individuals infected with SARS-CoV-2 experience cardiac side effects, with asymptomatic individuals still at risk of viral-induced heart failure, yet the mechanisms and consequences of such effects remain unclear. [1] Thus, therapeutics targeting SARS-CoV-2-induced heart failure remain elusive. The organ-on-a-chip industry has emerged at the intersection of microfluidics and tissue engineering, combining cells and biomaterials in arrangements that mimic organ processes, facilitating investigation of human physiology in a controlled and accessible environment. [2],[3] Recent studies indicate that cell signalling in the heart plays an integral role in tissue physiology and phenotype. [4],[5] For instance, it has been suggested that extracellular vesicles (EVs) released and taken up by cells in the heart are critical to regulating cardiac function and cellular responses to stress, disease, and injury. [6],[7] The “Biowire” model of cardiac tissue-on-a-chip was used to study the cardiac side effects of coronavirus infection in the heart and to screen EV therapeutics for mitigating such effects. EVs sourced from induced pluripotent stem cells (iPSCs) facilitated the recovery of infected cardiac tissue function to baseline levels. miRNA sequencing and gene ontology analyses suggested several stress responsive pathways are targeted by iPSC-EV miRNA that may alleviate some detrimental effects of coronavirus infection. Limited knowledge regarding SARS-CoV-2 side effects in the heart make tissue-on-a-chip models a novel tool to better understand the mechanisms of viral-induced heart failure and to study the potential for cell signalling-based therapeutics to improve patient outcomes.

MUSCLE AND FAT CELL MATURATION ON EDIBLE 3D-PRINTABLE SCAFFOLDS FOR CULTURED MEAT DEVELOPMENT

Shulamit Levenberg[P][1]
[1] *Technion-Israel Institute of Technology*
Corresponding author's email: Shulamit@bm.technion.ac.il

Cultivated meat is a promising technology that could generate meat without the need for animal agriculture. Generating a tissue requires a 3D scaffold to provide support to the cells and mimic the extra cellular matrix. The scaffolding materials must meet key requirements to enable cell growth and maturation, and should preferably have nutritional values. In our research we developed nutritious scaffolding compositions which enable flexible fabrication processes of edible bovine muscle and fat tissue. The biomaterials were assessed both for 3D-printing capabilities and for their support of growth and maturation of muscle-fibers and fat cells. The suggested 3D-printable compositions enable a cell-friendly fabrication of nutritious scaffolds in well defined geometries, capable of supporting cell growth and maturation, as a step towards an edible engineered steak.

CULTURED MEAT: HYPE AND REALITY

Gabor Forgacs$_P$[1,2]
[1] *University of Missouri-Columbia*
[2] *Fork & Goode, Inc.*
Corresponding author's email: gabor@forkngoode.com

Any attempt of making cultured meat needs to deal with three fundamental issues: choice of cells, nutrient medium needed to grow the cells and the bioprocess, the particular way to grow cells. The good news is that the scientific and technical methods to tackle these issues are known; no new rocket science is needed. The sobering news is that none of these methods have been tested at the scale where the cultured meat industry needs to operate. To put things in perspective: 1 kg biomass (~10 hamburgers) contains about quarter trillion cells and requires liters of medium to culture, in massive bioreactors. Furthermore, estimating the cost associated with the running of such operation and comparing it with the Walmart price of about $6/kg of ground meat evidence that significant practical challenges exist for the marketing of cultured meat. Academics never deal with scale issues, whereas this nascent industry is all about scale. Commercial cultured meat activity started in 2011 and by now there are more than 100 companies in the space. Investment is growing at an impressive pace. When early progress is so spectacular, it is tempting to make statements that unavoidably fuel hype. The aim of this talk is to draw attention to the existing challenges, emphasize that they are solvable and call all the interested parties to participate in solving the challenges. This might be particularly appropriate at this forum, with many tissue engineers who are dealing with many of the same challenges as the cultured meat community.

IMMUNOBIOLOGY AS A DETERMINANT OF SUCCESSFUL REGENERATIVE MEDICINE

Stephen Badylak[P][1,2]
[1] *University of Pittsburgh*
[2] *McGowan Institute for Regenerative Medicine*
Corresponding author's email: badylaks@upmc.edu

Whereas the primary function of the immune system was long considered to be defense against potential pathogens, discoveries during the past twenty years have established the critical role that the immune system plays in fetal development, homeostasis in healthy tissues, the host response to tissue injury, and the continuous crosstalk that occurs between the immune system and the stem/progenitor cells. These findings have fundamentally changed tissue engineering/regenerative medicine (TE/RM) strategies to include immunomodulatory biomaterials, nanovesicles as theranostic tools, and the delivery of specific signaling molecules that target regulatory and effector cells to promote functional tissue repair and reconstruction. Cross disciplinary approaches between the TE/RM and immunology fields have never had greater potential to change the practice of medicine.

RETROSPECTIVE ANALYSIS OF ENHANCER ACTIVITY AND TRANSCRIPTOME HISTORY; DEFINING CELL SIGNALING PATHWAYS DIRECTING DEVELOPMENT AND CELL DIFFERENTIATION.

Joost Gribnau[P][1,2]
[1] *Erasmus MC*
[2] *Oncode Institute*
Corresponding author's email: j.gribnau@erasmusmc.nl

The development of more than 300 cell types present in our body requires the action of complex molecular mechanisms. These involve activation of signal transduction pathways that instruct transcription factor networks and the epigenetic landscape to generate the gene expression programs that dictate the cell state. The development of the iPS technology provides a unique opportunity to drive differentiated cell types back in development and generate embryonic stem cells of virtually every patient, to study developmental control, homeostasis, and model disease. Unfortunately, robust and efficient protocols to differentiate these iPSCs to a specific cell type are lacking, and therefore increased knowledge of the mechanisms directing embryonic development is key to be able to establish proper in vitro differentiation models systems. In my lecture I will describe the DCM-time-machine (DCM-TM) technology we developed to establish gene and enhancer activity maps of the past and predict cell signaling pathways that drive differentiation of a stem cell to a differentiated cell type. DCM-TM utilizes an inducible DCM-RNA-polymerase-subunit-b fusion protein, to label active genes and enhancers with a bacterial methylation mark that does not affect gene transcription and is propagated in S-phase. We applied DCM-TM to study intestinal homeostasis providing new insights in cell signaling, and chromatin and transcription factor dynamics in lineage fate decisions. DCM-TM can be applied to follow cell differentiation, embryonic development and tissue regeneration, identifying temporal maps of transcription factor networks and signal transduction pathways that can be used to improve stem cell expansion and cell differentiation models.

SMALL TRICKS TO MEND A BROKEN HEART

Leon de Windt[P][1]
[1] *Maastricht University*
Corresponding author's email: l.dewindt@maastrichtuniversity.nl

Myocardial regeneration is restricted to early postnatal life, when mammalian cardiomyocytes still retain the ability to proliferate. The molecular cues that induce cell cycle arrest of neonatal cardiomyocytes towards terminally differentiated adult heart muscle cells remain obscure. Here we report that a microRNA cluster is higher expressed in the heart of newborns and decreases in expression towards adulthood, especially under conditions of overload, and orchestrates the transition of cardiomyocyte hyperplasia towards cell cycle arrest and hypertrophy by virtue of its targetome. Taking advantage of the regulatory function of this microRNA cluster on cardiomyocyte hyperplasia and hypertrophy, viral gene delivery provoked near complete regeneration of the adult myocardium after ischemic injury. Our data demonstrate that exploitation of conserved molecular programs can enhance the regenerative capacity of the injured heart.

PLURIPOTENT STEM CELL CULTURE, DIFFERENTIATION AND SORTING ON THERMORESPONSIVE SURFACE

Akon Higuchi[P][1]
[1] *National Central University*
Corresponding author's email: higuchi@cc.ncu.edu.tw

Human induced pluripotent stem cells (hiPSCs) and embryonic stem cells (hESCs), which are described as human pluripotent stem cells (hPSCs), are attractive for stem cell therapy [1] and are used for cardiac studies of (a) cardiac disease modeling, (b) cardiotoxicity screening, (c) drug discoveries, and (d) human cardiac development [2]. The development of efficient high production protocols with high purity for hPSC induction into cardiomyocytes is demanded in recent research. The current differentiation process of hPSCs into cardiomyocytes to enhance the purity of hPSC-derived cardiomyocytes requires some purification processes, which are laborious processes. We developed cell sorting plates, which are prepared from coating thermoresponsive poly(N-isopropylacrylamide) and extracellular matrix proteins [3]. After hPSCs were cultured and induced into cardiomyocytes on the thermoresponsive surface coated with laminin-521 for 15 days, the temperature of the cell culture plates was decreased to 8-9 ℃ to detach the cells partially from the thermoresponsive surface. The detached cells exhibited a higher cardiomyocyte marker of cTnT than the remaining cells on the thermoresponsive surface as well as the cardiomyocytes after purification using conventional cell selection. The detached cells expressed several cardiomyocyte markers, such as α-actinin, MLC2a and NKX2.5. This study suggested that the purification of hPSC-derived cardiomyocytes using cell sorting plates with the thermoresponsive surface is a promising method for the purification of hPSC-derived cardiomyocytes without conventional laborious processes.

IN-VIVO-INSPIRED ENVIRONMENTS TO UNDERSTAND CANCER PLASTICITY

Peter Friedl[P][1]
[1] *Radboud University Medical Centre*
Corresponding author's email: peter.friedl@raboudumc.nl

Analysis of the metastatic cascade in defined environments requires to account for multi-parametric mechanical and chemical determinants of the tumor and stromal cells as well as cell deformability and adhesion regulation relative to the 3D tissue topologies. When monitored in vivo, using intravital multiphoton second and third harmonic generation and fluorescence microscopy, tissue microniches provide invasion-promoting tracks that enable collective migration along tracks of least resistance. As main routes, non-destructive contact-guidance is mediated by preformed multi-interface perimuscular, vascular and –neural tracks of 1D, 2D and 3D topography. 3D ultrastructural analysis reveals predefined tissue conduits ("highways") of defined geometry, nanotropography and molecular composition as predominant routes of invasion by contact guidance combined with a cell "jamming" mechanism (1). Using this in vivo data, we have developed 3D collagen-based interface models which reliably predict the basic programs of cancer cell invasion as well as their adaptive plasticity response after molecular intervention (2). The 3D in-vivo-inspired environment reliably predicted tumor plasticity and escape after therapeutic targeting of beta1/beta3 integrins as well as in response to hypoxia, including collective and amoeboid single-cell dissemination, which was followed by enhanced metastasis. In conclusion, interstitial tissue models for modeling the metastatic cascade need to account for the physicochemical programs that balance cell-intrinsic adhesion and mechanocoupling with encountered physical space and molecular cues. The combination of different imaging techniques is critical to dissect cancer tissue dynamics, as well as derive guidance and jamming/unjamming principles of morphogenesis and tissue regeneration.

[3] *Austrian Cluster for Tissue Regeneration*
Corresponding author's email: heinz.redl@trauma.lbg.ac.at

One option to improve tissue regeneration is the use of growth factors. As a promising alternative to recombinant protein therapy, gene therapy allows local and sustained release of growth factors. This moderate and constant release is more suitable for regenerative processes compared to administration of high protein doses. Exogenous growth factors are produced by cells in situ; such highly bioactive amounts of growth factors are produced directly at the defect site, thereby highly limiting adverse off-target effects.
Targeted research areas include (combinatorial) gene therapy approaches for bone/musculoskeletal tissue regeneration in vivo and ex vivo. Amongst them, new techniques such as viral and non-viral gene delivery systems, next-generation therapeutical DNA vectors for example with decreased immunogenicity, enhanced bioactivity of growth factor and enhanced gene expression. Beside DNA based gene therapy also mRNA based technologies are increasingly used and becoming popular by Covid vaccination successes.
Increasing records of clinical success in the last years have constantly improved awareness of gene therapy, strengthening the enthusiasm of the community for novel and effective treatment methods providing the needed momentum for further developments.

Bringing translational research to TRL 5-7 requires a lot of resources including regulatory input with International Organization for Standardization (ISO) studies under good laboratory practice (GLP) and good manufacturing process (GMP) conditions and cannot be completed through academic institutes alone. It is usually difficult to achieve this through grant funding only, therefore the formation of Start-up companies or cooperation with established companies is necessary. While the initial phase of initiating a spin-off is quite well supported in many countries, raising money thereafter can be difficult and some of the SMEs do not survive for long. In the Austrian Cluster for Tissue Regeneration we have 14 Spin-off companies both on the material side (Lithoz, UpNano, CubiCure, MorphoMed, THT-Biomaterials) and human cells/products (Evercyte, Liporegena, Phoenestra) as well as a in vitro and in vivo preclinical models (Trauma Care Consult, Pregenerate, Saico Biosystems). We will give examples how different companies evolved in the field and highlight the challenges faced when translating research to the clinical and further on to the commercial field.

DISSECTING ENDOTHELIAL-STROMAL INTERACTIONS IN A 3D TUMOUR MICROENVIRONMENT MODEL

Laura Bray[P][1]
[1] *Queensland University of Technology*
Corresponding author's email: laura.bray@qut.edu.au

The tumour microenvironment is a key contributor to cancer development and progression. Reciprocal interactions between the epithelium and the adjacent stroma are essential for malignant transformation. Cancer-associated fibroblasts (CAFs) are a fundamental component of the tumour stroma. CAFs contribute to cancer progression through altered paracrine signalling as well as by remodelling of the ECM. The arising aberrant biochemical, biomechanical, and topographical cues promote invasiveness and migration of tumour cells. It is crucial to consider stromal and endothelial features in in vitro cancer models to understand the role of the tumour microenvironment in cancer progression. In this research, bioengineered experimental models provided a more physiologically relevant platform for tumour angiogenesis research in vitro. Primary tissue-specific endothelial and fibroblast cells (non-malignant fibroblasts (NFs) and CAFs) were used to study differential influences of these cell types on tumour angiogenesis and epithelial plasticity within a tissue-specific context. Distinct biomechanical and cytoskeletal characteristics of patient-matched NFs and CAFs were elucidated. Utilising a co-culture model, a decreased cellular stiffness was found in benign epithelial cells grown in the presence of CAFs, which coincided with a more invasive and proliferative phenotype. To mimic early cancer angiogenesis in vitro, tissue-specific microvascular cells were cultured in the presence of NFs or CAFs within 3D semi-synthetic hydrogels. Cell heterogeneity within the tissue-specific tumour angiogenesis model was assessed using high-throughput techniques. Overall, this works contributes to the understanding of the tumour microenvironment by providing novel insights into the differential characteristics between the healthy and the malignant tumour microenvironment.

CURRENT PERSPECTIVES, CHALLENGES AND ADVANCES IN REGENERATIVE MEDICINE THERAPIES

Julie Allickson[P][1]
[1] *Mayo Clinic Center for Regenerative Medicine,*
Corresponding author's email: allickson.julie@mayo.edu

Regenerative Medicine is an extremely broad division of medicine that can repair, replace, or regrow cells, tissues, or organs. The technology can include cells, genes, biomaterials, or scaffolds. Despite the encouragement of preclinical studies, small early-phase clinical trials and record-breaking financial investment in the field, we are not observing many approved regulated therapies. The first six months of 2021 demonstrated the greatest investment in the field, raising more than $14 billion reaching greater than 70% of all of 2021's $19.9 billion dollar investment (1). FDA and other regulatory agencies have worked hard to be transparent on regulatory requirements with heightened education (2). The field has increased educational opportunities in Regenerative Sciences including a PhD program at Mayo Clinic. 2021 was the first-time gene-editing technology was approved for clinical trials using CRISPER to treat amyloidosis (3). Although exciting technology advancements move to clinic, the field is plagued with challenges that do not allow regenerative medicine to be standard of care. Manufacturing is and has been a roadblock including scaling the therapy, cost of therapies, well planned and executed clinical trials including objective endpoints, biological variability, and product reimbursement. There is a need for translational guidance, multi-disciplinary teams, and increased understanding of product functionality.

INDUSTRIALIZATION OF REGENERATIVE MEDICINE

Laura Niklason[P][1]
[1] *Humacyte, Inc.*
Corresponding author's email: Niklason@humacyte.com

Scientific and medical understanding are essential for bringing regenerative medicine products to the clinic. Furthermore, translation of regenerative medicine products requires cutting-edge technology, scaled manufacturing, and clinical trial and regulatory expertise. Since its founding in 2005, Humacyte has worked to sequentially solve the translational hurdles related to the production of Human Acellular Vessels, or HAVs. Humacyte's platform involves the use of differentiated human vascular cells that are cryopreserved and are leveraged to generate engineered vascular tissues of a shape and size dictated by the bioreactor and polymer scaffolding of our manufacturing process. To date, HAVs have been implanted into more than 450 patients having diseases ranging from kidney failure, to peripheral arterial disease, to vascular trauma. Recent progress in commercial-scale manufacturing has produced a system that can produce HAVs in batches of 200, in a highly automated and controlled fashion. Recent clinical data has shown that these HAVs produced in the commercial-scale manufacturing system function as expected when used as dialysis access grafts. In addition, smaller caliber HAVs that are produced in versions of the commercial system are being studied in pre-clinical models of cardiac surgery, showing the broad applicability of the HAV platform. Progress in clinical evaluations, combined with implementation of commercial-scale manufacturing, both contributed to Humacyte's ability to transition to the public markets in August of 2021.

CRACKING OPEN THE BIOFABRICATION WINDOW

Marcy Zenobi-Wong$_P$[1]
[1] *ETH Zürich*
Corresponding author's email: marcy.zenobi@hest.ethz.ch

Bioprinting has been proposed as a disruptive technology to revolutionize the tissue engineering field by enabling the production of more accurate, more complex and more functional tissues. The field has made rapid advances in both the development of bioprinting materials as well as the introduction of new bioprinting technologies. However, the challenge of printing of large-scale tissues which still embody key nano- and micro-scale features might be only possible through the convergence of individual printing technologies and their respective materials. In recent years, there has been much work to identify 'sweet spots' in which both good printing resolution and biocompatibility/bioactivity are possible. For certain techniques, such as extrusion bioprinting, the use of a finer nozzle to improve resolution is inherently in contradiction with improved viability due to the increase shear stress. Here new non-contact or nozzle-free methods could play an important role. Of these, printing methods which address all points in the model simultaneously may enable a larger 'sweet space' in which speed, resolution and excellent cell viability are possible.

BIOENGINEERING 3D TUMOUROIDS TO INTERROGATE THE TUMOUR-STROMA BOUNDARY

Umber Cheema[P][1]
[1] *UCL*
Corresponding author's email: u.cheema@ucl.ac.uk

In vitro models of solid tumours are being developed to further elucidate mechanisms of tumour growth, invasion and metastasis. These models are useful tools to measure the efficacy of specific therapeutic interventions and can be used as platforms to test novel drugs. Current model systems used include spheroid culture, matri-gel cultures, Organ on a chip and organoids. We have developed 3D tumouroids as a biomimetic model with the specific aim to bioengineer the tumour and stroma component with a distinct boundary to allow for precise quantification of cancer invasion. Dependent upon the tissue of interest, we have bioengineered connective tissue stroma and bone stroma, along with engineered primitive vascular networks to enhance tissue biomimicry. As tumouroid models are further developed to add tissue complexity, and thus become more biomimetic, they will eventually replace early testing within in vivo models.

Corresponding author's email: jasper.delaey@ugent.be

Corneal endothelial damage and diseases are two of the major contributors to blindness or severe visual impairment worldwide (1). The corneal endothelium is the innermost cell layer of the cornea and consists of a cellular monolayer that maintains the stroma in a dehydrated state through a “pump-and-leak” mechanism. A critical loss of cells due to damage, disease or aging leads to corneal edema which in turn results in opacification of the cornea (2). Currently, the only treatment consists of a corneal transplantation from healthy cadaveric donor tissue. Unfortunately, only 1 donor is available for every 70 cases (3). To tackle this shortage, the present work focusses on the development of transparent (>90%, 380-700nm), ultra-thin (≤5µm), multilayered sheets that are permeable towards glucose (Papp >2.36*10-3cm/s). These sheets constitute a poly(D,L-lactide) (PDLLA) layer to provide structural rigidity (E=4.95 ± 0.81MPa) and a crosslinkable gelatin-based hydrogel (Gel-MA-AEMA (4)) as an extracellular matrix (ECM) mimic. These sheets provide a substrate for corneal endothelial cells (CECs) (primary human CECs and B4G12 immortalized CECs) to enable subsequent ocular implantation with the aim to restore the damaged endothelium and the patient’s vision (5). Successful membrane production and coating were verified using X-ray photoelectron spectroscopy (XPS) and static contact angle measurements. Cells seeded on the membranes showed their characteristic hexagonal morphology, the presence of Na+/K+ ATPase pumps and tight junctions (ZO-1) as evidenced using immunocytochemical staining. Additionally, research has been devoted towards upscaling of the membranes while ensuring straightforward tunability of the thickness, through doctor blading.

In the field of bone regeneration, the TGFβ-superfamily of growth factors contains candidate proteins offering the possibility to improve the healing process. Belonging to this family of proteins, bone morphogenetic proteins (BMPs) have been studied intensively in respect to their involvement in bone development.
Several BMPs are known for their osteoinductive activity - BMP-2, -4, -6, -7, and -9 constituting the most promising candidates. In clinics, BMPs are applied as recombinant proteins. A major bottleneck is the need for relatively high doses and repeated administration. Gene therapy constitutes an attractive alternative, not only because of lower production costs when compared to recombinant proteins, but also in terms of efficiency by enabling locally restricted and prolonged production of the respective proteins.

In their active form, BMPs can act as either homodimers or heterodimers. It has been reported that heterodimers exhibit a higher potential to induce osteogenic differentiation.
In this study, sequence optimized versions of BMP-2, -4, -6, -7 and -9 were cloned into gene expression vectors under the control of a constitutive EF1α-promoter. Subsequently, different BMP combinations were analysed regarding their capability to induce osteogenesis in transfected mouse myoblast C2C12 via alkaline phosphatase activity assay (ALP) and realtime-PCR.
Results showed significantly improved osteoinduction compared to transfection with single BMPs. In addition to the already known strong osteoinductive capacity of BMP-2 and -7 heterodimers we identified several equally potent combinations of BMPs. Interestingly, single transfection with BMP-9 showed similar osteoinduction.

Osteoarthritis is the most widespread degenerative condition of joint cartilage leading to chronic pain and immobility. The lack of drug therapies providing tissue restoration and the relatively short lifespan of joint-replacement implants, indicates the need for an articular cartilage regeneration strategy. Articular cartilage is derived from lateral plate mesoderm and limb bud during development. Our group established protocols for the differentiation of pluripotent human embryonic stem cells (hESCs) to osteochondral progenitors [1-2]. TTNPB (4-[(E)-2-(5,6,7,8-Tetrahydro-5,5,8,8-tetramethyl-2-naphthalenyl)-1-propenyl]benzoic acid), a retinoic acid receptor agonist, has been reported to induce chondrogenesis in stem cells [3]. Analysis by qRT-PCR showed that addition of TTNPB to our previous protocol significantly improved the expression of SOX9 and COL2A1 while reducing expression of hypertrophic markers such as COL1A1 and RUNX2. Although the reported protocol could provide a promising and robust cell source for better understanding the mechanism of articular joint development in humans, off-target subpopulations may form during the process of differentiation, hindering further application of this protocol. In this regard, we developed a CRISPR-Cas9-edited hESC line with a COL2A1-SOX9 response element reporter to select cells in combination with reported chondrogenic cell surface markers such as BMPR1b, CD146 and CD166. We are now evaluating their differentiation potential in comparison to non-selected cells. The implementation of a cell sorting strategy based on markers for the discrimination of chondro- and osteo-progenitors would improve the potential and safety of our protocol. When fully characterised by RNA-seq, this protocol could lay the foundations for possible cell therapy strategies for osteoarthritis.

ENGINEERING THE BIOMATERIAL INTERFACE FOR TRANSLATIONAL REGENERATIVE MEDICINE

Molly M Stevens[P][1]
[1] *Imperial College London*
Corresponding author's email: m.stevens@imperial.ac.uk

This talk will provide an overview of our recent developments in bio-instructive, self-assembling and gradient materials for applications in regenerative medicine with focus on establishing translational pipelines to bring our innovations to the clinic [1]. I will present how we are using remote fields to engineer complex 3D architectures that mimic anisotropic and multiscale tissue structures and generate spatially arranged bioinstructive biochemical cues, such as acoustic stimulation to produce engineered muscle with bundles of aligned fibres [2]. I will discuss recent developments in our tunable nanoneedle arrays for multiplexed intracellular biosensing at sub-cellular resolution and modulation of biological processes [3], and will talk about our portfolio of nanoparticle-based sensing probes for disease monitoring in vivo such as renal clearable gold nanoclusters for cancer detection [4]. Finally, I will present our advances in Raman spectroscopy characterisation techniques for high-throughput label-free characterization of single nanoparticles (SPARTA) which is becoming an integral tool for the design of advanced nanotherapeutics [5]. I will explore how these versatile technologies can be applied to transformative regenerative medicine innovations.

A 3D BIOPRINTED MODEL OF THE HUMAN INTERVERTEBRAL DISC

Sam R Moxon[P][1], Marco Domingos[1], Julie Gough[1], Stephen M Richardson[1]
[1] *University of Manchester*
Corresponding author's email: s.richardson@manchester.ac.uk

The intervertebral disc (IVD) aids the flexible movement of the spinal column by providing vertebra with support against mechanical loads. At its core, the IVD contains a soft and gelatinous nucleus pulposus (NP) populated by spherical NP cells embedded in a polysaccharide-rich matrix. Conversely, the surrounding annulus fibrosus (AF) is much stiffer and comprised of elongated AF cells in an aligned, collagenous matrix. Age-related IVD degeneration leads to chronic pain and can result in permanent disability. IVD repair is impaired by an inability to regenerate the two distinct regions of the disc simultaneously. In this study a newly developed suspended hydrogel (SLAM) bioprinting system was employed to fabricate IVD analogues for tissue regeneration and modelling of developmental and degenerative processes. Constructs were fabricated with distinct regions of gellan gum polysaccharide and type I collagen in order to mimic the structural and mechanical gradients within IVD tissue microenvironments. Moreover, cell-laden IVD constructs were bioprinted without compromising cell viability. Human NP cells embedded within the central “NP-like” gellan gum region of the construct retained a spherical morphology resembling what is observed in vivo. Within the outer collagenous “AF-like” region, human AF cells exhibited an elongated morphology and showed evidence of regions of cell alignment. Further inspection of these regions with transmission electron microscopy revealed the presence of aligned collagen fibres. These data highlight the potential to utilise SLAM for the generation of constructs that can reflect the heterogeneous nature of the IVD for disease modelling and regenerative medicine applications.

PRODUCTION OF UROCORTIN-1 LOADED NANOPARTICLES FOR CHONDROPROTECTION APPLICATIONS

Zara Smith[P][1], Annalisa Tirella[1], Paul Townsend[1,2], Stephen M Richardson[1]
[1] *University of Manchester*

Corresponding author's email: s.richardson@manchester.ac.uk

Traumatic impact of cartilage within the joint and can lead to rapid chondrocyte cell death by excessive calcium influx and eventually matrix degradation, resulting in the development of post-traumatic osteoarthritis (PTOA). PTOA accounts for 5.6 million cases of osteoarthritis annually and costs $11.79 billion dollars annually. We have previously demonstrated that urocortin-1 has a protective effect on chondrocytes, preventing cell death following impact loading. Here we aimed to fabricate colloidal/liposomal nanoparticles for the delivery of urocortin-1 to joints to prevent chondrocyte death.
Colloidal (hyaluronic acid-chitosan) nanoparticles with urocortin-1 were loaded at 10-40% (w/w to CS). All particles showed a time-dependent increase in size. Chitosan-urocortin-1 complexation appeared unstable, compared with the addition of hyaluronic acid, suggesting urocortin-1-hyaluronic acid complexation. All PDI values remained below 0.25 over 15 days for up to 40% loading of urocortin-1. Liposomes (DMPC/cholesterol) were fabricated using a microfluidics approach (Dolomite, UK; flow rate ratios (FRR) 1:9-1:49; total flow rates (TFR) 250-750 µl/min). Larger FRRs (1:19, 1:49) displayed a smaller polydispersity index (PDI) with larger TFRs (500, 750 µl/min, $p<0.0001$). Zeta potential remained constant. Urocortin-1 (10% v/v, 100 µg/ml) loading resulted in increased size ($p<0.001$). Urocortin-1 mechanism of action was validated using the agonist Yoda1 on porcine articular chondrocytes. Intracellular Ca2+ showed decreased staining following supplementation with urocortin-1.
These results show the possibility of successful loading in biocompatible delivery mechanisms for sustained release of urocortin-1. These results detail the primary steps in producing a disease modifying OA drug (DMOAD) for use following cartilage injury in prevention of PTOA.

Both versatility and biocompatibility of superparamagnetic iron oxide nanoparticles (SPIONs) make them ideal candidates to be used in a wide range of biomedical applications.[1,2] Herein, SPIONs have been synthesized, characterized and incorporated into different 3D scaffolds fabricated by either electrospun or Fused Deposition Modelling (FDM) techniques. For this purpose, stable and homogeneous SPIONs with a particle size of 12 nm were synthetized by thermal decomposition and transferred to aqueous medium via ligand exchange with dimercaptosuccinic acid obtaining stable colloidal suspensions.[3] Subsequently, the incorporation of the SPIONs into each type of 3D scaffold has been optimized. For electrospun scaffolds, the SPIONs were incorporated into type I collagen solutions resulting in a hybrid formulation suitable for electrospinning deposition. For FDM scaffolds the incorporation of SPIONs was performed by thermal Drop-on-Demand inkjet printing onto polymeric FDM scaffolds. This technique consists of ejecting picoliter droplets of liquid material through a nozzle thanks to a heating element that produces bubbles inside the solution [4]. Physicochemical characterization as well as in vitro stability assays of SPIONs-containing scaffolds have been conducted. Furthermore, their biological response in pre-osteoblastic MC3T3-E1 cells and human bone marrow derived mesenchymal stem cells (hBM-MSCs) has been evaluated to determine if the presence of SPIONs affects cell viability, adhesion and spreading. These findings confirm that both types of SPIONs-containing scaffolds constitute ideal platforms to explore magnetic mechano-stimulation to promote bone tissue regeneration. This research has been carried out within the framework of the GIOTTO project from the European Commission (GA 814410).

MULTISCALE FRACTAL SHAPE CUES SUPPORT HIERARCHICAL ASSEMBLY AND MATURATION OF PODOCYTES VIA CURVATURE-INDUCED EXTRACELLULAR MATRIX PATTERNING

Anastasia Koroljp[1]

[1] *University of Toronto*

Corresponding author's email: anastasia.korolj@gmail.com

Nature efficiently self-organizes cells and tissues into complex fractal forms. Whether fractal patterning contributes functionally to maturation, and how cells sense and interpret such shape cues, is not well understood. Using kidney podocytes as a model system, bioinspired templating of glomerular histology was leveraged to design controlled fractal 2½ - D surfaces for cell culture. Microcurvature was associated with charge density gradients in space, found to direct extracellular matrix protein organization resulting in hierarchical assembly of cell structures and fractally-branching podocyte morphology in vitro, outlined with a novel fluorescent assaying technique. Shape simulation was uniquely associated with mature-like foot processes on an organized ECM. In applications of drug testing, coronavirus infection, and a cells-as-sensors approach to patient serum diagnostics, fractally stimulated cells were more responsive than flat cultures. Fractal frameworks may thus provide a functional role in podocyte maturation and could serve to advance other bioengineered systems.

Biofilm-related infections associated to orthopaedic implants constitute one of most problematic chronic infection diseases with high morbidity, and high medical care expenses. The efforts are focused on the design of anti-infective biomaterials for both prevention and cure. The properties of these materials must be adapted to achieve anti-infective performance and biocompatibility, which permit a good integration of the implant with the surrounding tissue. Herein, the different strategies developed by our research group to engineer antibacterial nanomaterials will be described. In particular, the design of antimicrobial coatings, comprising innovative technological advances in surface modification; multifunctional 3D scaffolds with both antimicrobial and bone regeneration capabilities; and multifunctional hybrid nanomaterials as targeted therapies based on mesoporous silica nanoparticles, will be presented.

Corresponding author's email: kurt.gielen@medacespace.com

Too many promising medical innovations never reach the market or the patient. One of the hurdles to take is finding your way through the ever more stringent and difficult landscape of medical devices and cell therapy (GMP) legislation and technical validation.
Medace offers a full service work-learning environment where customers (being academics or entrepreneurs) are guided in how to set up and develop the technical dossier needed for clinical validation whilst producing their clinical grade product.
Medace works with an EN ISO 13485:2016 certified quality and service package available for our customers on a use by need basis.
Medace provides:
• Specialized infrastructure (e.g. ISO7 and 8, and Class C and B cleanrooms)
• Validated and specialized equipment
• Quality Management System
• Trained professionals for hands-on guidance and support during development and validation
• Dedicated in-house training programs

Wrist osteoarthritis is a result of mechanical abnormalities resulting in joint destruction occurring in the wrist. These abnormalities include degeneration of cartilage and hypertrophic bone changes, which can lead to pain, swelling and loss of function, occupational disability with a significant socio -economic impact.
25% of injuries in the Netherlands presented in the emergency departments in the Netherlands are hand and wrist injuries. Post-traumatic osteoarthritis of the wrist, especially the radiocarpal joint, is a possible consequence of wrist trauma and can lead to severe functional impairment and pain.
Clinical results of available surgical techniques for treatment of post-traumatic radiocarpal osteo-arthritis are disappointing due to limited mechanical properties and poor fit of the available materials. A possible solution might be the insertion of a patient specific interpositional arthroplasty in the affected joint with materials with improved ergonomic and mechanical properties.
In this study, we will describe the clinical, regulatory and technical challenges (3D printing versus rapid tooling) that were addressed in preparation of patient matched wrist implants for a first in human clinical trial planned in 2022.

Acknowledgments: This research was performed under the framework of Chemelot InSciTe

ENGINEERED SCAFFOLDS FOR THE DELIVERY OF GENE THERAPEUTICS FOR ENHANCED TISSUE REPAIR

Fergal J O'Brien[P][1]
[1] *Royal College of Surgeons in Ireland*
Corresponding author's email: fjobrien@rcsi.ie

The COVID-19 pandemic has shown how revolutionary treatments based on gene therapeutics has helped overcome a once-in-a-century pandemic and has given new momentum to gene therapy research for a myriad of applications. The field of regenerative medicine is well placed to be a beneficiary whereby, for example, gene therapy might be a valuable tool to avoid the limitations of local delivery of growth factors. While non-viral vectors are typically inefficient at transfecting cells, our group have had significant success in this area using a scaffold-mediated gene therapy approach for regenerative applications[1, 2]. These gene activated scaffold platforms not only act as a template for cell infiltration and tissue formation, but also can be engineered to direct autologous host cells to take up specific genes and then produce therapeutic proteins in a sustained but eventually transient fashion. Similarly, we have demonstrated how scaffold-mediated delivery of siRNAs[3] and miRNA[4, 5] can be used to silence specific genes associated with reduced repair or pathological states. This presentation will provide an overview of ongoing research in our lab in this area with a particular focus on gene-activated biomaterials for promoting bone, cartilage, nerve and wound repair. Focus will also be placed on advances we are making in using 3D printing of gene activated bioinks to produce next generation medical devices for tissue repair.

The potential role of mesenchymal stem cells (MSC) to impact osteoarthritis (OA) mechanisms has been established in preclinical models and in pilot clinical trials. Multipotent Adult Progenitor Cells (MAPC®) represent a unique stem cell population with regenerative properties that differ from MSCs by morphology, gene expression profile, proliferative capacity, and functions. This study was conducted to test the effect of canine MAPC (cMAPC; ML-223) on cartilage disruption and inflammation in the groove model (GM) and in the medial meniscal release model (MMRM), 42 and 70 days after cell therapy initiation. These two cartilage disease models of OA were evaluated because each model represents different pathologic mechanisms of the natural disease.
cMAPC prevented disease progression and promoted cartilage repair in the GM but not in the MMRM. cMAPC protected against index cartilage lesion enlargement, conferred protection in adjacent and apposing joint surfaces, and subdued subchondral bone sclerosis. This suggests cMAPC have potential clinical applications for cartilage repair in: (1) aging where slowly progressive OA arises from superficial cartilage wear lines and small erosions that coalesce to create global joint degeneration and (2) acute mechanical cartilage injury (bone bruise or bone marrow edema).
The gene expression data demonstrate that cMAPC treatment impacted immunological components in both OA models. Treated dogs have an altered immune cell phenotype involving Tregs. These data also demonstrate the importance of understanding the time course of immunologic perturbations induced by the GM and MMRM and optimizing treatment time points when designing investigation of regenerative therapeutics.

MOLECULAR ASPECTS OF CELLULAR SENESCENCE IN MSCS AND ITS IMPACTS ON DIFFERENTIATION

Roberto Narcisi[1]
[1] *Department of Orthopaedics and Sports Medicine, Erasmus MC, University Medical Center, 3015 CN Rotterdam, the Netherlands*
Corresponding author's email: r.narcisi@erasmusmc.nl

Cellular senescence is an irreversible state in which cells stop proliferating, while remaining metabolically active, showing a specific senescence-associated secretory phenotype (SASP). Extensive proliferation is one of the factors leading to cellular senescence. In mesenchymal stem/stromal cells (MSCs), progenitor cells present in several body tissues, senescence can be also observed both in vitro and in vivo. However, the molecular aspects of cellular senescence in MSCs are still poorly understood, as well as the possible impact of senescence on the differentiation capacity of these cells.
Previously we observed that activation of the WNT/β-catenin pathway sustains MSC expansion, while maintaining their multilineage differentiation capacity [1-2]. Interestingly, later we observed that the WNT/β-catenin pathway is sustaining expansion not by acting as direct pro-proliferative signal, but by blocking senescence instead, via repressing the SASP-related factors (under review). Further characterization showed that the transcription factor TWIST1, a WNT/β-catenin target, appeared as one of the main responsible for the effect observed on senescence and on differentiation capacity of MSCs [3-4]. Additional investigations highlighted the role of senescence as negative regulator of MSC differentiation, with a greater impact on reducing chondrogenesis capacity rather than adipogenesis or osteogenesis (under review). Finally, we also found that senescent MSCs have an altered capacity to respond to TGFβ, the main pro-chondrogenic factor of MSCs (under review).
Overall, our data indicate that the effect of senescence on MSCs depends on the differentiation stage of the cells, highlighting the role of WNT and TWIST1 as potential targets for blocking senescence in MSCs.

Keywords
Senescence; Differentiation; Cellular metabolism

ROLE OF VASCULAR SMOOTH MUSCLE CELLS IN VASCULAR REMODELING

Leon Schurgers[P][1]
[1] *Maastricht University*
Corresponding author's email: l.schurgers@maastrichtuniversity.nl

Vascular calcification is a feature of vascular remodeling and was regarded as a bystander in cardiovascular disease. Vascular calcification was considered to be the passive chemical nucleation of calcium and phosphate on cellular debris and therefore the end-stage of atherosclerosis. This view has changed over the last two decades with cells and proteins involved in the vascular calcification homeostasis and vascular calcification being an independent risk factor for cardiovascular disease. Vascular smooth muscle cells (SMCs) are key cells in vascular remodeling, and phenotypic switching has been shown to be involved in vascular calcification.
SMCs, which build the arterial wall, show phenotypic plasticity. In physiological conditions they exist as contractile cells, regulating vascular tone. In response to stress and/ or injury SMCs lose expression of contractility-related proteins and proliferate, migrate and secrete extracellular matrix-related proteins in order to repair the damaged vessel. Dysregulated SMC phenotype switching lies at the heart of many vascular pathologies, such as atherosclerosis, aortic aneurysms, remodeling of hypertensive blood vessels and vascular calcification. The molecular determinants of phenotype switching are not fully understood.
To unravel these mechanisms, we employ a molecular biological approach, using primary patient derived SMCs and iPSC derived iSMCs. iPSCs allow us to generate vascular smooth muscle cells specific from a series of loci of the cardiovascular system. This approach will help us unraveling why in the clinic certain vascular sites exhibit a higher propensity of calcifications.

Abstract **#2293**

VIRTUAL MODELS FOR HUMAN DEVELOPMENTAL TOXICOLOGY DRIVEN BY NEW APPROACH METHODOLOGIES

Aldert Piersma[P][1], Harm Heusinkveld[1], Yvonne Staal[1], George Daston[2], Richard Spencer[3], Thomas Knudsen[3]

Quantitative in silico modeling of network dynamics is an important goal toward predicting toxicological hazard from chemical-biological interaction. Systems toxicology mapping of network structure-function would reveal threshold events at the toxicological tipping point between adaptive and adverse biology. These events can be tested in dedicated new approach methodologies (NAMs) focusing on the molecular and/or cellular scale. Concentration-dependent compound-induced effects from targeted in vitro studies fed into the network model provide toxicity prediction at the level of the intact organism. These systems models utilize the extensive knowledge that exists on biological control of morphogenesis and the conservation of key biological pathways and processes enabling integration of data on among diverse species, . Current efforts towards in silico modeling of specific morphogenetic processes include, for example, neural tube closure. In a CEFIC-LRI sponsored project we described the biological pathway network underlying vertebrate neural tube closure, using a text mining tool applied to the open scientific literature. This network is the input for developing a 3-dimensional computational model for in silico testing of compound effects on neural tube closure. The principal idea is that by adapting parameter settings in the in silico model based on effects on gene expression observed in relevant in vitro cell assays, their consequences at the higher integration level of neural tube closure can be predicted. In due course these models are expected to revolutionize toxicity testing, enhancing human relevance based on enhanced insight into mechanisms of toxicity. Does not reflect EPA policy.

STEM CELL DERIVED KIDNEY TISSUE, AND ITS CHALLENGES FOR CLINICAL TRANSLATION

Ton J. Rabelink[P][1]
[1] *LUMC*
Corresponding author's email: t.rabelink@lumc.nl

The field of regenerative medicine aims to engineer, replace, or regenerate cells, organs or tissues in order to restore function after damage or loss. It has seen tremendous growth with the introduction of human induced pluripotent stem cells (hiPSC) Human adult kidneys filter the blood and are important for maintaining homeostasis by regulating electrolyte concentration, blood pressure and secreting hormones. The functioning units of the kidney are called nephrons and each kidney has on average 1 million nephrons. Due to chronic kidney disease, progressive loss of renal function can result in the need for renal replacement therapy. While dialysis is costly, time consuming, and only partially restores kidney function, transplantation is dependent on the availability of donor organs, and patients need immunosuppressive drugs and have the risk for acute or chronic rejection. Therefore, generation of bioengineered iPSC derived kidney tissue to replace kidney function is a field of interest. Knowledge on nephron progenitors obtained by studying the developing embryo in mice, resulted in advanced protocols for the generation of these structures, organoids in vitro. Kidney organoids show a remarkable level of complexity containing multiple cell types and upon transplantation these structures become vascularized and further mature. While these organoids are interesting candidates for kidney replacement tissue, there are still major hurdles to be overcome before they can be clinically applied. In this talk these challenges will be systematically addressed.

Abstract **#2296**

HYALURONAN HYDROGELS ATTENUATE THE IMMUNE RESPONSE IN THE CENTRAL NERVOUS SYSTEM

Molly S. Shoichet[P][1], Michael J. Cooke[1], Brian G. Ballios[1], Nikolaos Mitrousis[1], Dimpy Gupta[1], Catherine E. Kang[1], Tobias Fuehrmann[1], Samantha L. Payne[1], Jaclyn M. Obermeyer[1], Anup Tuladhar[1]

Corresponding author's email: molly.shoichet@utoronto.ca

Regeneration in the central nervous system remains a significant challenge, complicated further by that complexity of the system itself. To promote regeneration, we have been investigating strategies to overcome key challenges associated with survival and integration of cell therapy.

We found that a hyaluronan-based hydrogel comprised of hyaluronan and methyl cellulose (HAMC) attenuates the inflammatory response after traumatic injury in the spinal cord, brain and retina at the back of the eye [1]. To further build on this positive effect, we have investigated both exogenous cell transplantation and endogenous cell stimulation strategies using the HAMC hydrogel.

For example, in a rodent model of stroke, we found that the delivery of HAMC promoted tissue repair itself that was enhanced with either the delivery of neural stem cells [2] or brain-derived neurotrophic factor [3].

Similarly, in a rodent model of blindness, we found that HAMC enhanced the survival of retinal stem cell-derived photoreceptors via a CD44-mediated mechanism [4]; and that the co-delivery of photoreceptors with hESC-derived retinal pigmented epithelium further enhanced functional vision repair [5]. Interestingly, even in vitro, hyaluronan-based hydrogels improved photoreceptor cell survival [6].

The positive effects of the hydrogel itself and its combination with biologics and/or cells will be described.

MACHINE LEARNING AND MATHEMATICAL MODELS FROM MULTI-OMICS DATA FOR PERSONALIZED MEDICINE

Julio Saez-Rodriguez[P][1]
[1] *University Hospital Heidelberg*
Corresponding author's email: admin.saez@uni-heidelberg.de

Modern technologies allow us to profile in high detail biological and medical samples at fast decreasing costs. New technologies are opening new data modalities, including to measure at the single-cell level and with spatial resolution. Computational models, in particular those built with machine learning, are expected to help us to extract insight form these data. Using biological knowledge to aid machine learning can significantly improve the results. Towards this end, we have developed a number of tools that range from a meta-resource of biological knowledge to methods to infer pathway and transcription factor activities from gene expression and subsequently infer causal paths among them. Furthermore, and to complement a large-scale basal profiling of samples, we have develop approaches to build dynamic logic models of molecular networks and how they response to perturbations such as drug treatment. I will illustrate their utility in cases of biomedical relevance and show how they improve our understanding of molecular processes, identify biomarkers, and point at novel therapeutic opportunities.

INNOVATION IN REGENERATIVE MEDICINE: PERSPECTIVES FROM A LARGE MEDICAL DEVICE COMPANY

Markus Reiterer[P][1]
[1] *Medtronic, PLC*
Corresponding author's email: markus.w.reiterer@medtronic.com

Over the last 70 years medical technology has positively impacted millions of lives every year. While, devices like spinal implants, cardiac stents, and pacemakers have restored function and improved health, healing is hardly ever achieved. Regenerative medicine provides a promise of cure that is achieved by administering bioactive materials, biologics, cell therapies or tissue engineered products. Although the regenerative medicine market has been estimated to be in the $10B by the mid-2020s, only very few successful products exist today. The problems are manyfold, from failed clinical trials to difficulties with cost-effective and quality-controlled high volume manufacturing, to regulatory uncertainty that slow down investments. A large medical device company like Medtronic needs to be super vigilant due to our size an ability to impact many patients. Understanding underlying technologies of manufacturing in regenerative medicine, mechanisms of action of the proposed therapies and leveraging technological and market adjacencies will contribute to successful implementation.

Chitin nanofibrils (CNs) are a bio-based nanomaterial obtained from the purification of chitin. Their nanometric size and high crystallinity enable anti-inflammatory, cicatrizing, and anti-ageing activity [1]. We investigate the possible use of CNs to modulate the inflammatory and immune response occurring upon tympanic membrane (TM) scaffold implantation as a consequence of infections, in order to avoid device rejection or accelerated degradation [2].

In this study, two different types of CN integration in TM scaffolds were investigated. A nanocomposite was produced by melt extrusion of CN/polyethylene glycol (PEG) pre-composite (50/50 weight ratio) and poly(ethylene oxide terephthalate)/poly(butylene terephthalate) (PEOT/PBT), achieving a final CN concentration of 2% (w/w%). The composite was electrospun into fibrous scaffolds, which were coated by CNs from crustacean or fungal sources via electrospray. The degradation behaviour of the scaffolds was investigated during 4 months at 37°C in an otitis-simulating fluid.

In vitro tests were performed to assess cytocompatibility and immune response. Human mesenchymal stem cells (hMSCs) and human dermal keratinocytes (HaCaT cells) were cultured as models of connective and epithelial tissues, respectively. HMSCs were able to colonize the scaffolds and produce collagen type I. HaCaT cells in contact with the CN-coated scaffolds revealed a marked downregulation of the proinflammatory cytokines. CN-coated PEOT/PBT/(CN/PEG 50:50) scaffolds showed a significant indirect antimicrobial activity. The nanocomposite was biostable until the endpoint.

Materials recovered from biowaste can still be used to produce effective skincare product with a reduced environmental impact. Chitin is a natural polysaccharide found in the shells of crustaceans, cuticles of insects, and fungal cell walls. In nanofibrillar form, chitin loses its pro-inflammatory and allergenic character, and proficiently interacts with many cellular compounds in biological tissues [1].
This research investigated electrospray as a method for surface functionalization of cellulose tissues with chitin nanofibrils (CNs) using two different sources (from fungi and crustaceans) and different solvent systems to obtain a biobased, skin compatible product with enhanced anti-inflammatory activity [2].
The surface of cellulose tissues was uniformly decorated with electrosprayed CNs. The effects of different solvents (i.e., water-based and organic) were investigated to assess the surface nanostructure via scanning electron microscopy (SEM) and the final skin compatibility using human dermal keratinocytes (HaCaT cells). Biological analysis revealed that all treated samples were suitable for skin applications. These results indicate that the use of solvents did not affect the final cytocompatibility due to their effective evaporation during the electrospray process. Such treatments did not affect the characteristics of cellulose; in addition, they showed promising in vitro anti-inflammatory and indirect antimicrobial activity. The results prove that electrospray could represent a green method for surface modification of sustainable and biofunctional skincare products.

Acute myocardial infraction (AMI), traditionally defined as a decrease of stoppage of blood flow to a portion of the cardiac muscle leading to a necrotic tissue. It is usually result as a consequence of a discrepancy between the amount of oxygen that the cardiac muscle requires and the supply that effectively receives. This discrepancy may lead to a myocardial damage, usually in the left ventricle. As in any other muscular tissue, the subsequent ischemia produces a necrotic wound with reduction of the capacity of the affected area to develop its normal function. Elastin like recombinamers (ELRs) are synthetic recombinantly produced polypeptides that mimic natural elastin, an essential ECM component. These polypeptides can be scaled up and are amenable to mechanical and bioactive customization. Several strategies to obtain angiogenesis and a better scaffold colonization searching for a functional tissue reparation have been explored with ELRs along the last five years. From evaluate the porosity to the inclusion of different bioactivities that open the possibility to modulate and control the level of angiogenesis, program controlled spatial-temporal degradations ELRs are playing an important role in cardiac tissue engineering applications, reaching preclinical tests in animals with excellent outcomes.

INNER EAR ORGANOIDS: A NEW TOOL FOR UNDERSTANDING AND TREATING DEAFNESS

Brigitte Malgrange[P][1]
[1] *University of LIEGE - GIGA stem cells*
Corresponding author's email: bmalgrange@uliege.be

Sensorineural hearing impairment is a common pathology affecting more than 16% of the population worldwide. It depends on a specialized sensory organ called the cochlea containing auditory hair cells and the spiral ganglion neurons. To date, treatment options are limited to hearing aids and cochlear implants. Therefore, developing therapies to replace missing cells is essential. The discovery of human-induced pluripotent stem cells (hiPSCs) has allowed the derivation of patient-specific stem cells that can differentiate into otic sensorineural cell derivatives. This promising tool will facilitate the study of disease mechanisms, bioengineering, and stem cell-based cell replacement therapies either as individual cell types or as organoid three-dimensional cultures. Here, we will highlight significant accomplishments and challenges associated with hiPSC-derived otic cells as a new tool to understand pathogenesis and identify novel therapies.

IMMUNOGENIC REACTIONS TO BIOMATERIALS

Martijn van Griensven[P][1]
[1] *Department cBITE, MERLN Institute, Maastricht University*
Corresponding author's email: m.vangriensven@maastrichtuniversity.nl

Biomaterials are implanted in organisms in an array of different tissues and for the purpose of several applications. This will always lead to local tissue injury and an interaction of the biomaterial with the surrounding tissues. Moreover, vascular injury is also present. This results in a contact of the biomaterial with the blood coming from the disrupted vessels. Both in the tissues as well as in the blood, immunologic active cells are present. Depending on the material, a minimal or stronger immunological reaction will occur. This talk deals with these immunogenic reactions to implanted biomaterials based on different sources such as natural, allogeneic, xenogeneic, or synthetic. The immunogenic reaction is part of the biocompatible properties of a biomaterial. Biocompatibility is defined as 'the ability of a material to perform with an appropriate host response in a specific application'. The host response is mainly constituted by the host immune reaction. When the immune reaction towards the biomaterial is too strong, that is an inappropriate host response, the material may be rejected. On the other hand, a minimal immune reaction is necessary for the biomaterial to be integrated in the organism. When no interaction with the biomaterial takes place, it will have no immediate interaction with the tissue. Thereby, most of its function will get lost. Thus, the intensity combined with the duration of the inflammatory reaction is an important aspect of biocompatibility and thus for regenerative success.

BOOSTING ENDOGENOUS REPAIR OF CARTILAGE: FOCUS ON THE MOLECULAR IDENTITY OF THE ARTICULAR CHONDROCYTE

Rik Lories[P][1]

[1] *KU Leuven*

Corresponding author's email: rik.lories@kuleuven.be

Osteoarthritis (OA), the most common chronic joint disease, is characterized by progressive damage to the articular cartilage, increased joint-associated bone remodeling and varying degrees of inflammation. OA leads to loss of joint function and is one of the leading causes of disability worldwide. Current therapy is limited to symptom relief and in severe cases joint replacement surgery, while interventions that arrest or reverse disease progression are lacking. The onset of clinical symptoms (pain, stiffness and impaired mobility) is preceded by molecular and cellular changes in the joint that result in loss of homeostasis. Different factors can initiate such a process and include trauma, aging and mechanical stress, all in interaction with the genetic predisposition of the individual patient. The articular chondrocytes, the unique cells of the articular cartilage, are embedded in a self-produced extracellular matrix of collagen fibers and proteoglycans. In OA, these chondrocytes lose their characteristic molecular identity, and often acquire a hypertrophy-like phenotype. The switch from the quiescent and stable molecular phenotype of articular chondrocytes to the metabolically more active hypertrophic phenotype observed in OA is associated with hyper-activation of the Wnt Wnt/β-catenin signaling pathway. Thus, unravelling regulatory mechanisms that control Wnt signaling and Wnt-mediated chondrocyte hypertrophy may lead to identification of effective therapeutic targets

UNIQUE SUPPLY CHAIN SOLUTION FOR STEM CELL TREATMENT WITH SHORT SHELF-LIFE.

Sebastian Wehle[P][1]

[1] *Takeda Pharmaceutical Int. AG, Zürich, Switzerland*

Corresponding author's email: sebastian.wehle@takeda.com

Darvadstrocel is a live human mesenchymal stem cell treatment indicated for complex perianal fistula(s) in adult patients with non-active/mildly active luminal Crohn's disease, when fistula(s) have shown an inadequate response to at least one conventional or biologic therapy. By the nature of a living cell formulation the shelf-life of the finished product is 72 hrs. which requires a unique supply chain and innovative engineering solutions.

Since the program ideation phase, the Darvastrocel team has been envisioning a unique bespoke end-to-end supply chain solution spanning over donor´s tissue extraction up to drug product administration to patients within the short product shelf-life of 72 hrs.

The unique features relate to:

• Fit for purpose combination of Takeda´s resource planning (ERP) system and the logistic service provider led by a control tower function. The seamless connectivity of key information system with IoT cloud based communication tools at the hospital level unlocks capabilities for order placement, order status monitoring, on-time delivery tracking and coordination across multiple stakeholders.

• Dedicated in-house manufacturing network able to parametric release the finished product precise on the aligned hour for pick up by the courier service provider.

• Supply network "horizontal" patient oriented along the end to end supply chain rather than "vertical" by site functions.

• High automated degree to be nearly paper free to support parametric release on the hour.

• Rapid analytical methods installed to accomplish short shelf-life of the product.

CELLULAR ORGANELLE-MIMICKING SUPRAMOLECULAR PEPTIDE NANOSTRUCTURES FOR MEDICINAL APPLICATIONS

Tanja Weil[1], David Y.W. Ng[1], Christopher V. Synatschke[1]
[1] *Max Planck Institute for Polymer Research*
Corresponding author's email: weil@mpip-mainz.mpg.de

The extracellular matrix (EM) forms a complex, supportive environment for cells providing mechanical and biochemical cues, and enabling cells to communicate. [1] Evolution has created these unique heterogeneous matrices with inner structure and various functional entities that control e.g. pathogen binding and stimulate cell growth and division. We focus on the synthesis of peptide-polymer biomaterials that can serve as synthetic EM-mimicking environments by forming 3D fibril networks [2] or soft polymers with inner fibril structure [3]. Rational optimization of monomer sequences and fibril morphologies facilitated dynamic supramolecular networks supporting neuronal cells growth in vitro and vivo [4] as well as pathogen binding [5]. Responsiveness towards various stimuli such as pH changes, light and reactive oxygen species was implemented into the biopolymer sequences. In this way, materials properties were optimized towards enhanced bioactivity and customized for their respective microenvironments for e.g. local drug delivery [6], which offers new avenues for tissue engineering.

THE INTERPLAY BETWEEN HEMOSTASIS AND IMMUNE RESPONSE IN BIOMATERIAL DEVELOPMENT FOR OSTEOGENESIS

Corresponding author's email: yin.xiao@qut.edu.au

Treatment of large bone defects remains a clinical challenge, especially in the sizeable segmental defect, which usually results in bone non-union. In such a clinical scenario, bone substitutes are often applied. The gold standard bone substitute is still the autologous bone graft and is difficult to be replaced by synthetic biomaterials, suggesting that strategies should be made to improve the material for functional bone regeneration. Recent studies have revealed that hematoma, the first tissue structure formed at the bone injury site, plays an indispensable role in bone healing. Hematoma consists of fibrin clot, inflamed immune cells and tissue progenitor cells, which not only bridges the bone defect, but also provides a microenvironment for the interplay between hemostasis and immune systems. Previous studies have found that an ideal fibrin structure with proper fiber thickness and density was found to benefit progenitor cell infiltration and differentiation, and biomaterial implantation could affect bone healing by altering fibrin structure. Meanwhile, immunoregulation plays an indispensable role in bone healing, especially, materials inducing a shift from inflammatory to anti-inflammatory phenotypes in immune cells showed enhanced osteoinductivity. More importantly, the interaction between the hemostasis and immune systems should play a vital part in bone regeneration, by determining both the fibrin structure and the bone healing microenvironment. The hemostasis and immune systems are entangled to mediate the balance between coagulation and anti-coagulation, as well as to restrain the inflammation at a certain level. Coagulants triggered inflammation could in-turn facilitate coagulation cascades, which forming a positive feed-back to amplify both processes. On the other hand, anti-coagulants neutralize coagulation and inhibit inflammation, thereby control the coagulation and inflammation to prevent thrombosis. The balance between coagulation—inflammation and anti-coagulation—anti-inflammation plays a determinant role in not only fibrin structure but also the fibrinolysis process, during which the inflammation could be gradually “quenched” hence benefiting osteogenesis, and resulting in fibrin fragments favoring angiogenesis, thereby generating an ideal microenvironment for the following bone regeneration. Currently there are limited biomaterial studies targeting the bone-healing hematoma, especially the hemostasis-immune interplay. Thereby, this presentation summarizes the current materials for hemostasis and immunomodulation, the critical role of hemostasis-immune correlation in bone regeneration, and further propose the potential strategies to develop materials with the capacities to generate an ideal bone healing hematoma, by modulating the hemostasis-immune interplay to maintain the balance between coagulation—inflammation for osteogenesis.
