High Frequency Response of Volatile Memristors

Ioannis Messaris,* Alon Ascoli, Ahmet S. Demirkol, Vasileios Ntinias, Dimitrios Prousalis, and Ronald Tetzlaff*

In this theoretical study, the high-frequency response of the electrothermal NbO_2 -Mott threshold switch is focused, a real-world electronic device, which has been proved to be relevant in several applications and is classified as a volatile memristor. Memristors of this kind, have been shown to exhibit distinctive non-linear behaviors crucial for cutting-edge neuromorphic circuits. In accordance with well-established models for these devices, their resistances depend on their body temperatures, which evolve over time following Newton's Law of Cooling. Here, it is demonstrated that HP's NbO_2 -Mott memristor can manifest up to three distinct steady-state oscillatory behaviors under a suitable high-frequency periodic voltage input, showcasing increased versatility despite its volatile nature. Additionally, when subjected to a high-frequency periodic voltage signal, the device body temperature oscillates with a negligible peak-to-peak amplitude. Since the temperature remains almost constant over an input cycle, the devices under study behave as linear resistors during each input cycle. Based on these insights, this paper presents analytical equations characterizing the response of the NbO_2 -Mott memristor to high-frequency voltage inputs, demarcating regions in the state space where distinct initial conditions lead to various asymptotic oscillatory behaviors. Importantly, the mathematical methods introduced in this manuscript are applicable to any volatile electrothermal resistive switch. Additionally, this work presents analytical equations that accurately reproduce the temperature time-waveform of the studied device during both its transient and steady-state phases when subjected to a zero-mean sinusoidal voltage input oscillating in the high-frequency limit. This analytical approach not only increases the comprehension of volatile electrothermal memristors but also provides a theoretical framework to harness the enhanced dynamical capabilities of real-world volatile memristors in practical applications.

machine learning.^[1] The non-volatile memristor has emerged as a promising two-terminal electronic device to enable unlocking the full potential of such smart systems mainly due to its ability to store and process data within a single nanoscale volume. Contrary to a non-volatile memristor, which preserves its programmed resistance even when powered off, the resistance of a volatile memristor resets to a default value after power-off, regardless of any previously applied signals across its terminals. Mott threshold switches based on VO_2 ,^[2,3] ionic threshold switch (OTS) devices,^[4] and NbO_2 nanostructures^[5–8] represent typical examples of volatile memristors, which are notable for featuring a distinctive negative differential resistance (NDR) region in their DC current–voltage plots. In fact, the unique non-linear phenomena, appearing across their nanoscale physical media, have established volatile memristors as critical components in state-of-the-art neuromorphic circuits, serving to mimic specific neuronal activities, including action potential,^[9] as well as all-or-non spiking activity,^[10,11] and plasticity,^[12] among other functions. Moreover, volatile memristors are locally active devices, and the insights presented in refs. [13] and [14] exemplify their application in understanding the intricacies of biological systems.

1. Introduction

As the development of AI, Cyber-Physical Systems, and Internet of Things devices continues apace, there is a growing need for groundbreaking progress in applications such as memory, sensing, in-memory computing, neuromorphic computing, and

The highly non-linear behaviors of volatile and non-volatile memristors make them particularly attractive for circuit-theoretic investigations since they have been shown to exhibit intricate phenomena under bespoke stimuli, unmet in conventional electronic devices. Such is the fading memory phenomenon, according to which the steady-state response of a memristor to an

input from a certain class depends on the input characteristics, rather than the initial conditions of the memristor itself. This memristor behavior was first identified in the study by Ascoli et al. in ref. [15] based on experimental data obtained from a non-volatile nanoscale TaOx-based RRAM device fabricated^[16] and modeled^[17] at Hewlett Packard (HP) Labs. In this study, the fading memory effect emerged when the RRAM device was subjected to a suitable AC voltage input and was further analyzed from a circuit-theoretic perspective. A clarifying mathematical treatment of this phenomenon was provided in ref. [18], verifying a hypothesis suggested in refs. [19] and [20], according to which the asymmetry in the on- and off-switching kinetics in non-volatile memristors, which is ubiquitous in real-world devices of this kind, acts as the main mechanism underpinning its emergence. Having established a better understanding of the mechanisms underlying the emergence of fading memory in non-volatile memristors and identified the main factors that modulate this nonlinear phenomenon, a theoretical method for programming HP's TaOx resistive switch to any target state was proposed in ref. [18]. This programming scheme involved the proper configuration of the DC offset level of a high-frequency square-wave AC periodic voltage input at the MHz frequency limit serving as a promising application example exploiting fading memory in memristors. The method introduced in ref. [18] was based on the study of the time evolution of the mean state value of the HP memristor by applying a time-averaging-based approximation of its model, which was initially proposed by Pershin and Slipko.^[21] In this work, the two authors introduced a graphic method, currently referred to as the Time Average State Dynamic Route (TA-SDR),^[22] which can be used to study first-order memristors under periodic square-wave-based stimuli. Specifically, the TA-SDR may enable the prediction of the asymptotic oscillatory behavior of the memory state, starting from a predefined initial condition. Further developing the research presented in refs. [18] and [21], Ascoli et al.^[23,24] introduced a novel analytical tool coined as the State Change Per Cycle Map (SCPCM), a first-order discrete-time map, which simplifies the exploration of first-order non-autonomous continuous-time systems by illustrating how the stimulus configures each admissible memory state of the device during a single input cycle. By utilizing the SCPCM on HP's TaOx memristor model, the authors in refs. [23] and [24] revealed, for the first time, the potential of non-volatile memristors to exhibit multistability, as an expression of local fading memory, when stimulated by trains with a suitable number of positive and negative voltage pulses per period. Notably, the system- and circuit-theoretic techniques detailed in refs. [18, 21, 23], and [24] were employed in ref. [25] to both predict and experimentally verify that a TaOx ReRAM device, fabricated at Peter Grünberg Institut (PGI-7) of Forschungszentrum Jülich GmbH, exhibits bistable oscillatory behavior, depending on the initial conditions, under a specific pulse train excitation signal. In an input-induced multistable memristor, each locally stable steady-state response has a well-defined basin of attraction in the state space, leading to a unique asymptotic behavior regardless of the initial condition. Importantly, the studies in refs. [23–25] highlighted that to fully

harness the potential of memristors, circuit designers may consider going beyond merely exciting these devices with standard AC and DC inputs, exploring more complex stimuli to fully exploit the dynamical richness that arises from the inherent complexity of the physical processes underlying their operation. In this context, volatile memristors appear more complex than their non-volatile counterparts. As shown in refs. [26] and [27], volatile memristors can exhibit a couple of dynamical regimes even under purely AC sinusoidal inputs, as opposed to the more intricate stimulation schemes necessary to observe bistability in non-volatile memristors, as highlighted in refs. [23–25]. However, no study to date has analytically explained the mechanisms driving local fading memory in volatile real-world memristor devices. This will be the primary focus of the present study.

The analyses presented in this paper will revolve around the NbO₂-Mott threshold switch, which is possibly the dynamically richest nanodevice falling into the class of volatile memristors. This device has been the subject of extensive research in numerous recent publications.^[5,9,28–35] This memristor may exhibit three locally stable steady-state dynamical behaviors under a suitable DC voltage bias stimulus,^[28] which have been found to be contingent upon its body temperature, that is the dominant state variable in this device. Thus, with an appropriate constant voltage level applied across the device terminals, three basins of attraction may emerge, manifested as three contiguous body temperature ranges, where each basin of attraction leads to a distinct asymptotic steady-state device response, regardless of the initial body temperature. Volatile VO₂-based memristors and OTS devices can also display similar behaviors. However, these memristors typically display up to two steady-state responses when subjected to a DC voltage input. It's worth noting that several recently published physics-based compact models for these devices^[2,3,5,6,36] have successfully captured their circuit responses using relatively simple mathematical expressions. In this paper, we leverage the established predictive capability of the NbO₂-Mott memristor model, presented in refs. [5] and [36], to analytically study the fading memory phenomenon in practical volatile threshold switches excited by zero-mean periodic voltage inputs. Even though the device under investigation is the volatile NbO₂-Mott memristor, it's important to emphasize that all the assumptions, mathematical analyzes, and scientific findings presented here can be straightforwardly applied to any electro-thermally driven volatile memristor device.

Our analysis will primarily target the high-frequency limit, where the volatile memristor exhibits the richest dynamical behaviors under AC inputs, particularly within the context of fading memory. Specifically, we will demonstrate that under purely AC voltage stimulation, as the frequency of the AC input increases, the NbO₂-Mott nanodevice initially exhibits a single globally stable steady-state behavior. As the input frequency further increases, it undergoes a bifurcation into two distinct behaviors, eventually reaching a point where it displays three locally stable steady-states, and thus three basins of attraction. Based on the models in refs. [2, 3, 5], and [6] volatile nano-electronic threshold switches are equivalent to linear passive resistors under high-frequency excitation. Here, we present a theoretical approach that harnesses this characteristic behavior to formulate analytical equations capable of accurately predicting the transient and steady-state response of the NbO₂-Mott nanodevice under any

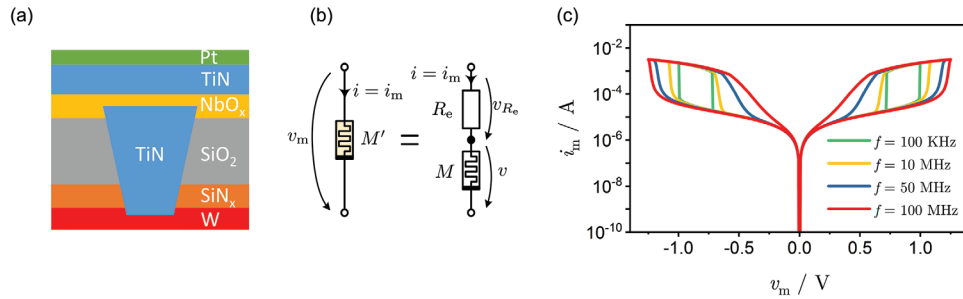

Figure 1. Panel (a) visualizes a cross-section of a sample NbO₂-Mott nano-device manufactured at HP Labs. Panel (b) draws the equivalent circuit schematic of the device shown in (a). Panel (c) illustrates simulated steady-state current–voltage responses of M' under four sinusoidal voltage inputs that share the same amplitude, but differ in frequency (see body text for further details).

sufficiently high-frequency periodic input, and for any initial condition in each of the three admissible basins of attraction. Our methodology is based on the behavioral observation that the net change in the device resistance over each cycle of a zero-mean AC periodic input is negligible when the input frequency is sufficiently high.^[18] Under these conditions, the input power over each cycle of the high-frequency purely-AC periodic input waveform corresponds to its effective RMS value, further simplifying the analysis of the memristor response. Let us initiate our investigations by briefly presenting the DAE set model of the volatile memristor device under study.

2. The NbO₂-Mott Memristor Model

Panel (a), in **Figure 1**, illustrates a cross-section of a NbO₂-Mott memristor sample manufactured at HP Labs. Panel (b) draws its equivalent circuit diagram, where the series resistance R_e is used to model the device Pt and W electrode resistances. The authors of the works presented in refs. [29–31] showed that current-induced joule heating is the main physical mechanism affecting the device resistance and, thus, concluded that the most efficient approach to model the rate at which the device body temperature T changes in terms of the input power p dissipated in the device and of the heat transferred to the environment, was through Newton's Law of cooling, which is expressed as

$$\frac{dT}{dt} = \frac{p}{C_{th}} - \frac{T - T_{amb}}{R_{th}(T)C_{th}} \quad (1)$$

where

$$p = i \cdot v \quad (2)$$

and

$$R_{th}(T) = \begin{cases} R_{th,ins}, & T \leq T_C \\ R_{th,met}, & T > T_C \end{cases} \quad (3)$$

Variables i and v are the memristor core M current and voltage, respectively, as shown in **Figure 1b**. The function $R_{th}(T)$ is used to model the sharp increase in the device thermal resistance when it undergoes the Mott metal-insulator transition (MIT) at $T = T_C = 1070\text{K}$.^[29] Thus, $R_{th,ins} = 1.27 \cdot 10^{-6} \text{ K} \cdot \text{W}^{-1}$ and $R_{th,met} = 1.91 \cdot$

$10^{-6} \text{ K} \cdot \text{W}^{-1}$ are the device thermal resistances in the insulating and metallic states, respectively. Parameter $C_{th} = 10^{-16} \text{ W} \cdot \text{s} \cdot \text{K}^{-1}$ is the thermal capacitance of the device, while $T_{amb} = 300\text{K}$ is the ambient temperature. On the other hand, the works in refs. [5] and [36] revealed that the unique dynamical features of this nano-device can be accurately reproduced by coupling (1)–(3) with a relatively simple Ohm's Law expression, in which the device memductance $G(\cdot)$ depends solely on the device body temperature T . Specifically,

$$i = G(T) \cdot v \quad (4)$$

where,

$$G(T) = G_0 \cdot e^{-\frac{g \cdot E_a}{2 \cdot k_B \cdot T}} \quad (5)$$

with

$$G_0 = \frac{\sigma_0 \cdot (2 \cdot a + 1) \cdot c \cdot A}{2 \cdot d} \quad (6)$$

Parameters $A = 5.02 \cdot 10^{-15} \text{ m}^2$, $d = 8 \cdot 10^{-9} \text{ m}$, and $k_B = 8.62 \cdot 10^{-5} \text{ eV} \cdot \text{K}^{-1}$, are the device lateral area, the NbO₂ film thickness, and the Boltzmann constant, respectively. Parameters $\sigma_0 = 1.55 \cdot 10^{-15} \text{ S} \cdot \text{m}$ and $E_a = 0.301\text{eV}$ are material constants physically described in ref. [31]. Finally, $a_0 = 0.123$, $g = 0.986$, and $c = 1.008$ are constants, that were used to improve the capability of the model to fit physically-obtained experimental data.^[5,36] We should note here, that, based on memristor theory, Equations (1)–(5) classify the NbO₂-Mott memristor core M as a first-order generic memristor.^[37,38] As already shown in ref. [32], when a linear resistance is combined in series with a generic memristor, the resulting one-port is also a generic memristor. This conclusion can be easily demonstrated by using basic algebraic techniques. Hence, the device formed by connecting R_e and M in series, denoted as M' (refer to **Figure 1b**), can be classified as a generic memristor as well. Its DAE set model is expressed as,

$$\frac{dT}{dt} = g(T, v_m) = \frac{1}{C_{th}} \cdot G_{eq}(T) \cdot v_m^2 - \frac{T - T_{amb}}{R_{th}(T)C_{th}} \quad (7)$$

where

$$G_{eq}(T) = \frac{G(T)}{(1 + G(T)R_e)^2} \quad (8)$$

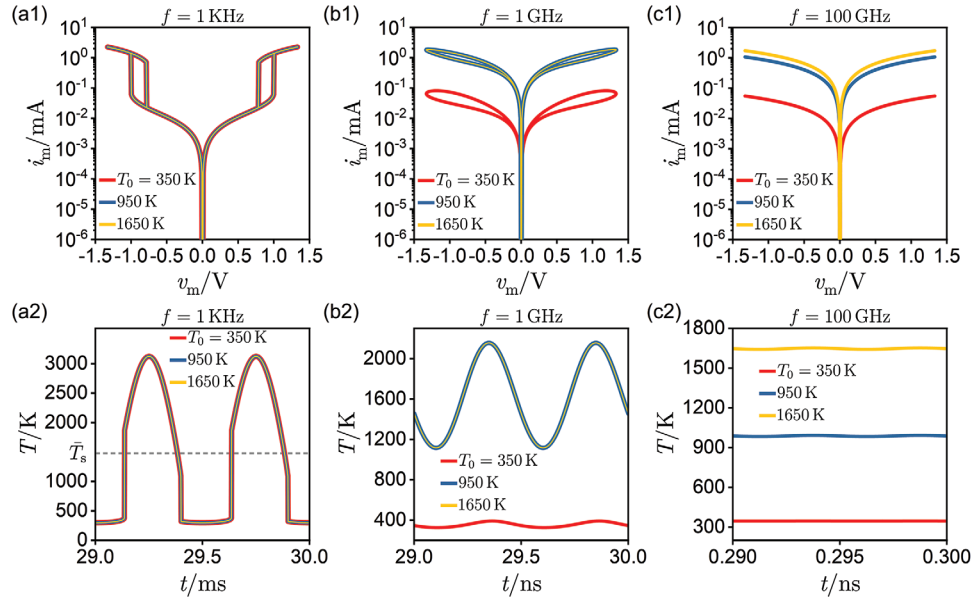

Figure 2. Simulated steady-state current–voltage responses (see panels (a1), (b1), and (c1)) and steady-state temperature time-waveforms (see panels (a2), (b2), and (c2)) for the NbO₂-Mott memristor. The visualized plots were obtained by applying zero-mean sinusoidal voltage inputs across the terminals of M' (see Figure 1b) at frequencies of 1KHz, 1GHz, and 100GHz, with an amplitude $\hat{v}_m = 1.33V$. Each panel displays three curves representing different initial conditions T_0 for the device body temperature T . Specifically, for the red, blue, and yellow curves, T_0 was set to 350, 950, and 1650K, respectively.

and

$$i_m = i = \frac{G(T)}{1 + G(T)R_c} \cdot v_m = G_m(T) \cdot v_m \quad (9)$$

Based on (7), the input power p dissipated on M , expressed as a function of v_m , and $G_{eq}(T)$, reads as,

$$p = G_{eq}(T) \cdot v_m^2 \quad (10)$$

Figure 1c illustrates the steady-state^[39] current–voltage characteristics obtained by applying a zero-mean sinusoidal voltage input v_i to M' with an amplitude of $\hat{v}_i = 1.25V$ and frequencies chosen from the set $f \in \{100KHz, 10MHz, 50MHz, 100MHz\}$. Notably, the frequency dependence of the current–voltage plots in panel (c) seems to contradict a fundamental memristive fingerprint, according to which, the pinched hysteresis lobe area should decrease as the input frequency increases. In fact, as reported in ref. [5], the NbO₂ current–voltage lobe area will keep increasing up to a critical frequency,^[5,40] subsequently reducing toward the zero value as the input frequency tends to infinity. This is a characteristic behavior observed in memristors described by an energy balance equation similar to (1) (or (7)) (see refs. [7] and [41]).

As a final note for this section, it's important to clarify that throughout the manuscript, whenever we refer to a voltage input applied to the nanodevice under investigation, it will imply a zero-mean sinusoidal voltage input, since the forthcoming behavioral observations and mathematical analyzes will revolve around this type of stimulus.

3. Frequency-Induced Bifurcations

The panels in Figure 2 can be divided into columns, with the first, second, and third columns showing simulated steady-state current–voltage responses (see panels (a1), (b1), and (c1)) and steady-state temperature time-waveforms (see panels (a2), (b2), and (c2)) of the NbO₂-Mott memristor. These responses were obtained by applying periodic inputs across M' (see Figure 1b) at frequencies of 10^3 , 10^9 , and 10^{11} Hz, respectively, with an amplitude \hat{v}_i defined as 1.33V. Additionally, each panel in Figure 2 illustrates three curves representing different initial conditions T_0 for the device body temperature T . Specifically, for the red-, blue- and yellow-colored curves, T_0 was set to be equal to 350, 950, and 1650K. Notice from panels (a1) - (a2), that the nanodevice exhibits a single globally asymptotically stable steady-state behavior with an utilized input frequency of 1KHz. As shown in (a2), the memristor temperature T will oscillate periodically at steady-state around a mean value \bar{T}_s (as indicated by the dashed horizontal line), regardless of the initial conditions. In fact, it can be easily verified that for this input frequency, the device will eventually settle to the same steady-state behavior regardless of the chosen value for T_0 . On the other hand, as shown in panels (b1) - (b2), for $f = 10^9$ Hz, the volatile memristor exhibits two distinct behaviors. Notably, the steady-state responses associated with the initial conditions $T_0 = 950K$ and $T_0 = 1650K$ are still merged as in (a1) - (a2). As the input frequency further increases, it displays three locally stable steady-states, as visualized by the three current–voltage plots in panel (c1), and by the three temperature time-responses in (c2). This frequency induced bifurcation phenomenon emerging in the NbO₂-Mott memristor for the selected initial conditions and type of input voltage waveform, is more clearly illustrated in Figure 3, which plots the mean

Figure 3. Frequency induced bifurcation phenomenon in the NbO₂-Mott memristor under a zero-mean sinusoidal input of the form $v_i = v_m = (1.33V) \cdot \sin(2 \cdot \pi \cdot f \cdot t)$. The red, blue, and yellow-colored plots display the mean oscillating value \bar{T}_s of the temperature time-waveform T , at steady-state, as a function of the input frequency f , within the range of $[10^3, 10^{12}]$, Hz, when the volatile memristor is initialized at temperatures 350, 950, and 1650K, respectively.

oscillating value \bar{T}_s of the temperature time-waveform T , at steady-state, as a function of the input frequency f , spanning the range $[10^3, 10^{12}]$ Hz. The first bifurcation occurs around 382.25MHz, marked by the separation of the red points from the blue and yellow ones, and indicated by the red arrow. The second bifurcation, resulting in three locally asymptotic stable steady-state behaviors, happens at ≈ 5.2 GHz, when the blue points deviate abruptly from the yellow ones as the input frequency increases (see the blue-colored arrow).

In the following sections, we will study the high-frequency response of the NbO₂-Mott memristor, focusing on the frequency range, where the device showcases three stable periodic behaviors, given the input characteristics and initial conditions assumed in this section. This behavior is exhibited for $f > 5.2$ GHz (see the gray-colored region in Figure 3).

4. High Frequency Response

The time-responses plotted in red, blue, and yellow (light-red, light-blue, and light-yellow) colors in Figure 4a were obtained by integrating (7), assuming the application of a sinusoidal voltage input v_i with an amplitude of $\hat{v}_i = 1.33V$ and a frequency of $f = 100$ GHz across M' (see Figure 1b). The device body temperature was initialized at $T_0 = 500, 1050, \text{ and } 1800K$ (200, 650, and 1200K) for the respective cases. Each simulation was performed over a total of $n = 1000$ cycles. The yellow-colored time series in Figure 4b zooms in over the first two periods of the T versus t plot for $T_0 = 1800K$, shown in (a). As it may be inferred from the illustrated time-response, the mean temperature values \bar{T}_1 and \bar{T}_2 (see the horizontal dashed lines) over the two depicted input cycles $n = 1$ and $n = 2$ are much larger than ΔT_1^{\max} and ΔT_2^{\max} , denoting the maximum swing of T over their respective cycles. Based on this behavioral observation, we may therefore assume that during the n^{th} input cycle, the device temperature T is approximately equal to the mean value \bar{T}_n of its oscillation over the same cycle ($n \in$

$N > 0$). Let us now assume that ΔT_n is the net change of T over the n^{th} input cycle (see ΔT_1 and ΔT_2 in Figure 4b). Next, for the six temperature time series depicted in Figure 4a, we calculated the net temperature change ΔT_n over each input cycle n . Subsequently, we plotted each of these six sets of $(n, |\Delta T_n|)$ data pairs in Figure 4c, with each data set retaining the same color as its corresponding curve in Figure 4a. Notice that the illustrated plots, whether they decrease monotonically, or they peak before decaying, they all tend to approach the zero value asymptotically, as n increases. In our study, we define the system as having reached steady-state when ΔT has dropped below 10^{-6} K. As discussed in the previous section, the T versus t loci, illustrated in Figure 4a, reveal an interesting feature of the NbO₂-Mott memristor, that is its capability to exhibit three locally-stable steady-state responses, under a high-frequency periodic voltage input, depending on the initial condition T_0 .^[26,27,42] The red-shaded time-waveforms converge asymptotically at time point t_s^A to the same periodic oscillation around \bar{T}_s^A (see Figure 4d). Similarly, the blue and yellow-shaded time-waveforms converge at time points t_s^B and t_s^C to common periodic oscillations around \bar{T}_s^B and \bar{T}_s^C , respectively. The input cycle numbers $n_s^A, n_s^B, \text{ and } n_s^C$, corresponding to time-points $t_s^A, t_s^B, \text{ and } t_s^C$, are highlighted in Figure 4c. The basins of attraction, within which the multistable NbO₂-Mott memristor admits the visualized steady-state trajectories, will be defined toward the end of this section.

The red-colored time series in Figure 4d zooms in across the last two periods of the T versus t plot for $T_0 = 500K$, shown in panel (a). We notice, that the device body temperature responds to the applied periodic voltage input by oscillating periodically about a mean value \bar{T}_s^A with a negligible peak-to-peak amplitude ($\approx 0.6K$), further verifying our assumption, this time during the steady-state phase of the temperature oscillation. As a matter of fact, even though our hypothesis was deduced from a simulation experiment that involved a high-frequency periodic voltage input of sinusoidal shape, it is valid, irrespective of the input voltage waveform shape and amplitude, provided that its frequency is high enough to endow the device with a single-valued current-voltage locus, over each input cycle, such as the ones shown in Figure 5.^[18] Specifically, the colored plots in this figure illustrate the three steady-state $|i_m| - |v_m|$ loci corresponding to the time-responses in Figure 4a. We notice that the high value of the input frequency, gives rise to non-hysteretic device responses on the current-voltage plane. This behavior is a typical memristive fingerprint, as reported in ref. [43]. But why is it necessary to employ such a high input frequency ($f = 100$ GHz) to observe the aforementioned distinctive memristive characteristics in this particular nanodevice? The main reason lies in its extremely small thermal capacitance ($C_{th} = 10^{-16} \text{ W} \cdot \text{s} \cdot \text{K}^{-1}$). This point will be further discussed over the course of the analysis performed in this section.

Considering the above-described behavioral observations, the net change ΔT in the device temperature T , over each cycle of a high-frequency periodic voltage input v_i , can be expressed as a function of the running mean value \bar{T} , over the same cycle, through the following integral:

$$\Delta T = \int_0^{1/f} g(\bar{T}, v_i) dt = \frac{1}{f \cdot C_{th}} \left(\bar{p} - \frac{\bar{T} - T_{amb}}{R_{th}(\bar{T})} \right) \quad (11)$$

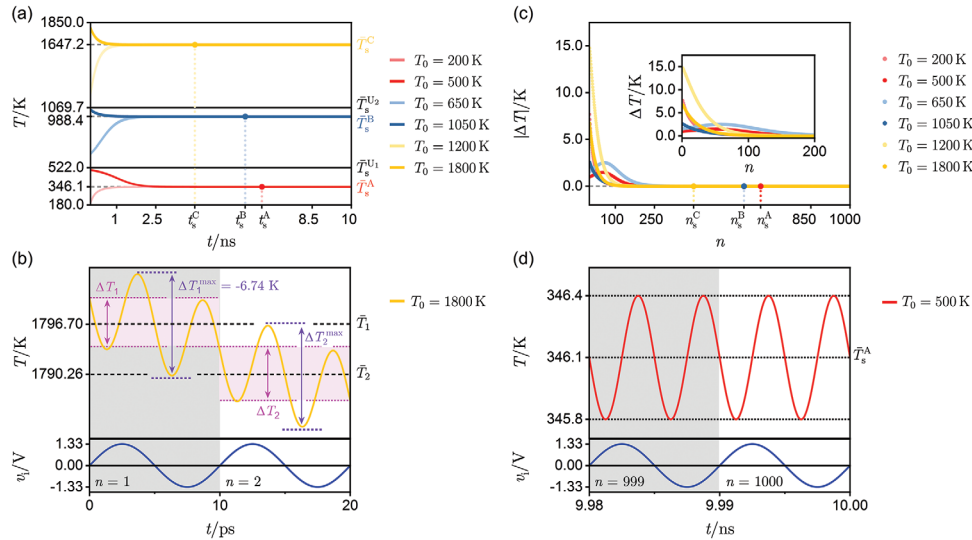

Figure 4. High-frequency response of the NbO₂-Mott memristor. Panel (a): Time-series of the device body temperature T under a sinusoidal voltage stimulus v_1 oscillating with an amplitude of $\hat{v} = 1.33\text{V}$ and a frequency of $f = 100\text{GHz}$, for different initial conditions T_0 (see the legend). The temperature levels \bar{T}_s^A , \bar{T}_s^B , and \bar{T}_s^C , depicted by the lower, middle, and upper horizontal dashed lines, represent the mean values of the red, blue, and yellow-shaded periodic temperature time-responses, at steady-state. The horizontal black lines at $\bar{T}_s^{U_1}$ and $\bar{T}_s^{U_2}$ separate the trajectories that lead to different asymptotic steady-state behaviors (for further details, refer to the analysis located towards the end of Section 3). Symbols t_s^A , t_s^B , and t_s^C , represent the time-points where the red, blue, and yellow-shaded time-responses converge to the same periodic oscillation about \bar{T}_s^A , \bar{T}_s^B , and \bar{T}_s^C , respectively. Panel (b): Yellow-colored locus: Visualization and analysis of the T versus t plot, for $T_0 = 1800\text{K}$, shown in (a), over the first two input cycles (see the blue-colored sinusoidal input voltage time-waveform plotted in the same panel). Symbol ΔT_1 (ΔT_2) indicates the net change of T over the first (second) input cycle, i.e., for $n = 1$ ($n = 2$). Symbol ΔT_1^{\max} (ΔT_2^{\max}) represents the maximum swing of T over the first (second) input cycle, i.e., for $n = 1$ ($n = 2$). The temperature level \bar{T}_1 (\bar{T}_2), defined by the horizontal dashed line, is the mean oscillating value of T over the first (second) input cycle. Panel (c): Net change ΔT of the device temperature T over any input cycle n , for each of the temperature time-responses illustrated in panel (a). Symbols n_s^A , n_s^B , and n_s^C , represent the input cycle numbers where the red, blue, and yellow-shaded time-responses become periodic. The inset figure provides a detailed view of the ΔT values over the first 200 input cycles. Panel (d): Red-colored locus: Zoomed-in view of the time-response in (a), for $T_0 = 500\text{K}$, over the last two input cycles (see the blue colored sinusoidal input voltage time-waveform plotted in the same panel).

Figure 5. Steady-state current–voltage responses of the NbO₂-Mott nanodevice, under the same sinusoidal voltage input and initial conditions as the ones utilized in Figure 4 (see the legend). The gray-colored curve corresponds to the DC $I - V$ plot of the device. The dashed vertical line pinpoints the RMS voltage level V_{rms} of the employed sinusoidal voltage input, which is equal to 0.94V . Points A, B, and C, depict the intersection points of the red, blue, and yellow-colored current–voltage loci, respectively, with the DC $I_m - V_m$ plot, and the dashed vertical line. The DC $I_m - V_m$ plot, and the dashed vertical line, also intersect at points U_1 and U_2 .

where $g(\cdot)$ is the state evolution function (see (7)), and

$$\bar{p} = f \cdot \int_0^{1/f} G_{\text{eq}}(\bar{T}) \cdot v_1^2 dt \quad (12)$$

is the time-averaged power, delivered to a resistance equal to $1/G_{\text{eq}}(\bar{T})$, over each cycle by the high-frequency periodic voltage input v_1 . It happens, that \bar{p} can be calculated in terms of the root mean square voltage V_{rms} of v_1 according to the following equation:

$$\bar{p} = G_{\text{eq}}(\bar{T}) \cdot V_{\text{rms}}^2 \quad (13)$$

since $G_{\text{eq}}(\bar{T})$ is constant over each input period. At this point, it is important to note that the calculation of \bar{p} in terms of the effective input voltage V_{rms} was possible due to the fact that the NbO₂-Mott nanodevice is a *generic* memristor. Thus, its memductance function $G(\cdot)$ (and thus $G_{\text{eq}}(\cdot)$ through Equation (8)), being independent of the input voltage v_1 (see Equation (4)), remains constant and equal to $G(\bar{T})$ over each input cycle. Summarizing our mathematical investigation, by combining Equations (11) and (13), ΔT reads as

$$\Delta T = \frac{1}{f \cdot C_{\text{th}}} \cdot \left(G_{\text{eq}}(\bar{T}) \cdot V_{\text{rms}}^2 - \frac{\bar{T} - T_{\text{amb}}}{R_{\text{th}}(\bar{T})} \right) \quad (14)$$

or

$$\Delta T = \frac{1}{C_{th}} \cdot \Delta E \quad (15)$$

where

$$\Delta E = E_{el} - E_{th} \quad (16)$$

Parameter E_{el} is the mean electrical energy provided to a resistance equal to $1/G_{eq}(\bar{T})$ by the periodic input signal over each cycle, and expressed as

$$E_{el} = \frac{1}{f} \cdot G_{eq}(\bar{T}) \cdot V_{rms}^2 \quad (17)$$

and E_{th} defines the exchange of thermal energy with the surrounding environment over each input cycle, which reads as

$$E_{th} = \frac{1}{f} \cdot \frac{\bar{T} - T_{amb}}{R_{th}(\bar{T})} \quad (18)$$

Essentially, Equations (14)–(16) describe a typical electrothermal device behavior. In this context, the device temperature increases by ΔT during an input cycle when it receives more energy E_{el} from an external power source than it loses as it releases thermal energy E_{th} to the ambient environment, over the same cycle. Conversely, the temperature decreases when the energy loss due to thermal transfer to the environment exceeds the energy absorbed from the external source. Since, the NbO₂-Mott nanodevice is a passive memristor, E_{el} will be positive over each input cycle. On the other hand, the polarity of the thermal energy transferred to the ambient depends on the sign of E_{th} . Based on Equation (18), for each input cycle, where \bar{T} exceeds (is below) T_{amb} , the mean thermal energy E_{th} is positive (negative), i.e., thermal energy is released to (is absorbed from) the ambient. The net change ΔT of the device temperature T over each input cycle, where $E_{el} > E_{th}$ ($E_{el} < E_{th}$), is positive (negative). Based on these physical processes, irrespective of the initial device temperature T_0 , over time, E_{el} and E_{th} become progressively closer one to the other with each input cycle, being practically balanced at t_s , where $\Delta E = E_{el} - E_{th} \approx 0$, and thus $\Delta T \approx 0$. At this time-point we assume that the temperature time-response has reached its steady-state.

As mentioned earlier in this section, the volatile memristor under study is characterized by an extremely small thermal capacitance value ($C_{th} = 10^{-16} \text{ W} \cdot \text{s} \cdot \text{K}^{-1}$). Physically, this means that any lack (excess) of thermal energy is swiftly balanced as the device absorbs it through Joule self-heating effects (as the device releases it to the ambient), leading to a simultaneous rapid increase (decrease) in the device body temperature T . If the input frequency is not high enough (roughly over 1GHz in our case study), the temperature fluctuation during each cycle becomes non-negligible, and the assumptions used to derive Equations (11) – (14) are no longer valid. As a matter of fact, from Equation (14), we notice that ΔT is inversely proportional to the product between the input frequency f and the thermal capacitance C_{th} , i.e., the exceptionally small value of C_{th} necessitates a correspondingly high value for f to ensure that ΔT remains sufficiently small. Let us now investigate the predictive power of

Figure 6. The gray-colored ΔT (ΔE) versus $\bar{T} \in [100, 1800]$ K locus, whose ordinate values may be read along the left (right) vertical axis, was obtained through Equations (14) ((16) – (18)), for $V_{rms} = 0.94\text{V}$ and $f = 100\text{GHz}$. Colored (white-filled gray-shaded) round symbols A, B, and C (U_1 and U_2) depict the points where the gray-colored curve crosses the horizontal axis with negative (positive) slopes. Points U_1 , and U_2 define the basins of attraction, within which the multistable NbO₂-Mott nanodevice exhibits three different steady-state responses, as visualized in Figure 4a (refer to the body text for more details). The red, blue, and yellow-shaded arrowed loci, found to lie over part of the gray-colored curve, were obtained through the simulations illustrated in Figure 4a. The arrows indicate the transient evolution of the trajectory point $(\bar{T}, \Delta T)$ over 1000 input cycles for the simulated time-responses in Figure 4a. Square-shaped white-filled symbols define the mean value \bar{T}_1 and the corresponding net change ΔT_1 for each of the simulated time-responses in Figure 4a.

Equations (14) – (18) and assess the extent to which these equations may be employed to characterize the response of the NbO₂-Mott memristor in the high-frequency limit.

The gray-shaded ΔT versus $\bar{T} \in [100, 1800]$ K in Figure 6 (refer to the left vertical axis to read the values for ΔT) were obtained through Equation (14), assuming that $V_{rms} = \hat{v}_i/\sqrt{2} = 0.94\text{V}$ ($\hat{v}_i = 1.33\text{V}$), and $f = 100\text{GHz}$. Based on the works in refs. [18, 21], and [23], this plot represents the TA-SDR of the NbO₂-Mott memristor for a sinusoidal input characterized by an amplitude and frequency equal to $\hat{v}_i = 1.33\text{V}$ and $f = 100\text{GHz}$, respectively. The aforementioned literature sources provide detailed mathematical analyzes, demonstrating how the input-referred TA-SDR can predict the time evolution of the mean value \bar{T} of the state variable T from any initial condition over a specified number of cycles of the high-frequency periodic input.^[18,21,23,44] Notice, that the TA-SDR of Figure 6 is referred to the same stimulus as the one employed for the simulations illustrated in Figure 4. As discussed earlier in this section (see Equations (14) – (18)), the change in the device body temperature ΔT during each input cycle is determined by the net energy balance ΔE , defined as the difference between the energy delivered to the device by the periodic power source E_{el} and the thermal energy exchanged between the device itself and the ambient environment E_{th} , over the same cycle. According to Equation (16), ΔT is equal to ΔE to within a scaling factor inversely proportional to the thermal capacitance C_{th} , allowing us to add a secondary vertical axis on the right hand side of the graph in Figure 6, to show $\Delta E = E_{el} - E_{th}$ versus \bar{T} . Thus, the TA-SDRs of electrothermal volatile memristor devices, such as the NbO₂-Mott threshold switch, may also offer insights into how these devices respond to the electrical energy generated by periodic voltage inputs, taking into account thermal gains and/or losses besides the device

initial conditions. To facilitate the comparison of the calculations obtained through Equation (14) with simulation results, we extracted both the mean temperature value \bar{T} and the net change in temperature ΔT over each input cycle for all six temperature time-series shown in Figure 4a. Each of the six elicited data-sets of $(\bar{T}, \Delta T)$ pairs was then plotted in Figure 6, while retaining the same color as its corresponding curve in panel (a) of Figure 4. Notably, the colored loci in Figure 6 almost perfectly overlap the gray-shaded curve, verifying the accuracy of Equation (14) as well as the assumptions underlying its derivation. In other words, the gray-colored locus, plotted in Figure 6, predicts how the change ΔT in the device temperature per input cycle (refer to the left vertical axis to read its values) depends on the mean value \bar{T} of the time waveform of the memristor temperature itself per input cycle, for any initial condition T_0 , and for all cycles of the 100GHz sine wave voltage stimulus from Figure 4b. The arrow along each of the colored curves in Figure 6 indicates the direction of the transient evolution of the corresponding point trajectory $(\bar{T}, \Delta T)$ as it approaches asymptotically the temperature axis, where $\Delta T = 0$, or equivalently, $\Delta E = 0$. It follows that the condition describing the periodic steady-state oscillation of T can be derived by setting $\Delta T = 0$ and substituting \bar{T} with \bar{T}_s in Equation (14). The resulting relationship is expressed as

$$g(\bar{T}_s, V_{\text{rms}}) = G_{\text{eq}}(\bar{T}_s) \cdot V_{\text{rms}}^2 - \frac{\bar{T}_s - T_{\text{amb}}}{R_{\text{th}}(\bar{T}_s)} = 0 \quad (19)$$

where \bar{T}_s is the mean value of the device body temperature oscillation, at steady-state. As expected, by setting V_{rms} in Equation (19) equal to 0.94V and solving for \bar{T}_s , we obtain five solutions within the body temperature range of interest, in accordance to the gray-shaded curve in Figure 6, which goes through the x -axis five times within the same temperature range (see points A, U_1 , B, U_2 , and C, along the temperature axis in Figure 6). Note that in Figure 6, since ΔT is positive (negative) on the upper (lower) half-plane, the arrows along the ΔT versus \bar{T} loci converge toward points A, B, and C, while they diverge away from points U_1 and U_2 . Therefore, M' exhibits three locally stable steady-state responses for the assumed high-frequency sinusoidal input. Each of these responses has a well-defined basin of attraction, where a unique asymptotic behavior emerges irrespective of the initial condition. Hence, from the illustration in Figure 6, it can be inferred that if the mean value \bar{T}_1 of the device body temperature T over the first cycle of the assumed sinusoidal voltage input v_i is lower than $\bar{T}_s^{U_1}$ (exceeds $\bar{T}_s^{U_2}$) Equation (19) predicts that, at steady-state, the device body temperature will oscillate with a negligible peak-to-peak amplitude about the mean value $\bar{T}_s^A = 346.12\text{K}$ ($\bar{T}_s^C = 1647.21\text{K}$). If \bar{T} over the first cycle of the stimulus takes values from the open set $(\bar{T}_s^{U_1}, \bar{T}_s^{U_2})$, T will oscillate periodically, at steady-state, about the mean value $\bar{T}_s^B = 988.45\text{K}$. Notice, that the basins of attraction associated to the TA-SDR equilibria A and B (B and C) in Figure 6, are separated by the boundary point U_1 (U_2). Accordingly, the black horizontal lines in Figure 4a, which correspond to the temperature levels $\bar{T}_s^{U_1}$ and $\bar{T}_s^{U_2}$, represent the separatrices located within the phase space of Figure 6 at points U_1 and U_2 , respectively. Since, for $T = \bar{T}_s$ and $v_i = V_{\text{rms}}$ the state evolution function $dT/dt = g(\cdot)$ is nullified (see Equation (19)), the temperature-voltage pairs $(\bar{T}_s^j, V_{\text{rms}})$, where $j: \{A, U_1, B, U_2, C\}$, correspond to

stationary states of M' , i.e., the points A, U_1 , B, U_2 , and C in Figure 6, can be also defined on the current-voltage plane exactly where the dashed vertical line at $V = V_{\text{rms}} = 0.94\text{V}$ (see Figure 5) intersects the DC $I_m - V_m$ plot of M' (see the gray-colored curve in Figure 5). As a matter of fact, points A, B, and C (U_1 and U_2) correspond to stable (unstable) stationary states of the NbO_2 -Mott memristor when driven by a DC voltage input equal to 0.94V. The interested reader may refer to a comprehensive investigation of the NbO_2 -Mott memristor, including the methodology used to derive its DC $I_m - V_m$ plot and the characterization of the stability of its stationary operating points under both current and voltage DC stimulation, in the study performed in ref. [5]. It follows that the red, blue, and yellow-colored current-voltage loci illustrated in Figure 5, corresponding to the lower, middle, and upper locally stable steady-state responses shown in Figure 4a, will pass through the points A, B, and C, respectively (see Figure 5). In fact, one can determine the maximum number of admissible stable or unstable steady-state behaviors for a volatile electrothermal memristor, described by an energy balance equation similar to Equation (1) or (7) (see refs. [2–8]), by identifying a particular voltage interval along the horizontal axis, through each point of which one may draw a vertical line, which crosses the DC $I_m - V_m$ the largest number of time. In particular, the intersections points, corresponding to stable stationary states, define the maximum number of observable steady-state oscillations under a periodic voltage input of sufficiently-high frequency, irrespective if it is sinusoidal, triangular, rectangular etc, as long as its RMS value is selected from the earlier specified voltage interval.

5. Analytical Derivation of the Transient and Steady-State Response

Interestingly, the assumptions made so far may allow for the derivation of a closed-form formula that can accurately approximate the time-waveform of the NbO_2 -Mott memristor body temperature, starting from any initial condition, in response to a high-frequency sinusoidal voltage input. Let us demonstrate how this can be achieved.

Assuming that $T_{0,n}(\bar{T}_n)$ is the initial (mean) temperature value at the start of (over) the n^{th} cycle of the input v_i , by substituting $G_{\text{eq}}(T)$, $R_{\text{th}}(T)$ and v_m in equation (7), with $G_{\text{eq}}(\bar{T}_n)$, $R_{\text{th}}(\bar{T}_n)$ and $v_i = \hat{v}_i \cdot \sin(2 \cdot \pi \cdot f \cdot t)$, respectively, and subsequently integrating dT/dt over time, the time evolution $T_n(t)$ of the device body temperature T during the n^{th} cycle of the high-frequency periodic input, that is for $t \in [(n-1)/f, n/f]$, is expressed as

$$T_n(t) = \delta_n + \epsilon_n \cdot \sin(4 \cdot \pi \cdot f \cdot t + \phi_n) + \zeta_n \cdot \exp\left(-\frac{t}{\tau_n}\right) \quad (20)$$

where $n \in N > 0$, while

$$\delta_n = \bar{T}_n + \Delta T_n \cdot f \cdot \tau_n \quad (21)$$

$$\epsilon_n = \frac{\delta_n - T_{\text{amb}}}{\sqrt{1 + 16 \cdot \pi^2 \cdot f^2 \cdot \tau_n^2}} \quad (22)$$

$$\zeta_n = \frac{T_{0,n} - T_{\text{amb}} - 16 \cdot \pi^2 \cdot f^2 \cdot \tau_n^2 \cdot (\delta_n - T_{0,n})}{1 + 16 \cdot \pi^2 \cdot f^2 \cdot \tau_n^2} \quad (23)$$

Figure 7. Panel (a) compares simulated (see gray-colored waveforms) versus analytically calculated (see colored waveforms) temperature time-responses of the NbO₂-Mott memristor under a sinusoidal voltage input with an effective RMS voltage of 0.94V oscillating at a frequency of 100GHz. The initial conditions are highlighted on the y-axis. Panels α_1 , β_1 , and γ_1 (α_2 , β_2 , and γ_2) provide a detailed view of the time responses in (a) initialized at a temperature T_0 equal to 200, 650, and 1200K (500, 1050, and 1800K), respectively, over the first ten input cycles. Panels α_3 , β_3 , and γ_3 zoom-in across the time responses in (a) oscillating periodically about the mean temperatures $\bar{T}_s^A = 346.12\text{K}$, $\bar{T}_s^B = 988.45\text{K}$, and $\bar{T}_s^C = 1647.21\text{K}$, respectively, over the last ten input cycles.

and

$$\phi_n = \arccos\left(\frac{4 \cdot \pi \cdot f \cdot \tau_n}{\sqrt{1 + 16 \cdot \pi^2 \cdot f^2 \cdot \tau_n^2}}\right) + \pi \quad (24)$$

The parameter ΔT_n , which represents the net change in the device temperature T over the n^{th} cycle of the applied sinusoidal input v_i , may be calculated through Equation (14) after substituting \bar{T} with \bar{T}_n . As mentioned at the beginning of this section, $T_{0,n}$ is the device temperature at the start of the n^{th} input cycle, as defined via

$$T_{0,n} = \begin{cases} T_1(0) = T_0, & \text{for } n = 1 \\ T_{n-1}\left(\frac{n-1}{f}\right), & \text{for } n \geq 2 \end{cases} \quad (25)$$

The parameter τ_n represents the device thermal time constant^[45] during the n^{th} input cycle, which is expressed as

$$\tau_n = R_{\text{th}}(\bar{T}_n) \cdot C_{\text{th}} \quad (26)$$

The thermal time constant τ_n regards to the time evolution of T_n when the device is in the metallic (insulating) state if $\bar{T}_n > T_C$ ($\bar{T}_n \leq T_C$).

The time-evolution $T_1(t)$ of the device body temperature T during the first cycle of the sinusoidal input for a predefined initial condition T_0 can be determined using the system of Equations (20) – (26) for $n = 1$ provided that the mean oscillating value over the first input cycle \bar{T}_1 is already known. To facilitate this process, we can assume \bar{T}_1 is equal to T_0 , as simulation results indicate that these two values are very close to each other in the high-frequency limit. Notice, that \bar{T}_1 and T_0 , for the simulation depicted in Figure 4b, are equal to 1796.70 and 1800K, respec-

tively. An even more accurate \bar{T}_1 value can be obtained through the following equation:

$$\begin{aligned} \bar{T}_1 &= f \cdot \int_0^{1/f} T_1(t) dt \\ &= \delta_1 + f \cdot \epsilon_1 \cdot \tau_1 \cdot \left(1 - \exp\left(-\frac{1}{\tau_1 \cdot f}\right)\right) \end{aligned} \quad (27)$$

where δ_1 , ϵ_1 , and τ_1 , are calculated through Equations (21), (22), and (26), after setting $n = 1$. Notice, that δ_1 , ϵ_1 , and τ_1 , depend on ΔT_1 , which, in turn, is linked to \bar{T}_1 through Equation (14) (refer to the text below Equation (24)). An approximate analytical solution for \bar{T}_1 may be obtained by substituting \bar{T}_1 with T_0 on the right hand side of Equation (27). This is a reasonable approximation, based on the discussion performed a bit earlier in this section. Considering again the system simulated in Figure 4b, \bar{T}_1 is calculated analytically in this manner to the value 1796.71K, which almost matches the one 1796.70K obtained by numerically integrating the device DAE set model (see Figure 4b). Next, the mean value \bar{T}_2 is defined as the sum of \bar{T}_1 and ΔT_1 , i.e., $\bar{T}_2 = \bar{T}_1 + \Delta T_1$. Thus, the time-waveform $T_2(t)$ for the second cycle of the input stimulus can be derived through Equation (20) – (26) with $n = 2$. The same process can be repeated for any subsequent input cycle.

Figure 7a re-plots the simulated temperature time-responses shown in Figure 4a, this time using a gray color for each waveform, instead of the previously employed colored visualization. On the other hand, each colored time-series, plotted in Figure 7a, was generated by employing the just mentioned iterative procedure, utilizing the same initial condition T_0 and input voltage v_i , as the ones used for the corresponding gray-colored simulated waveform. Each colored time-response was obtained by utilizing Equations (20) – (26) to reproduce $T_n(t)$ for each input cycle n . Panels α_1 , α_2 , α_3 , β_1 , β_2 , β_3 , γ_1 , γ_2 , and γ_3 , in Figure 7, present a zoom-in view of the temperature time-series featured in panel (a), enabling a detailed assessment of the simulated and

Figure 8. Panels (a), (b), and (c) showcase steady-state temperature time-responses of the volatile memristor under study. The simulated responses are represented by gray-colored curves, while the analytically calculated ones are visualized by colored curves. These responses were obtained by applying a sinusoidal voltage input with an effective voltage V_{rms} of 0.94V across the device M' (see Figure 1b). The input frequencies f are 20GHz, 6GHz, and 1GHz for panels (a), (b), and (c) respectively. For the displayed steady-state time-waveforms in the lower, middle, and upper sections of panels (a) and (b), the initial condition T_0 (parameter \bar{T}_s in Equations (28) – (31)) for the gray (colored) curves is set to \bar{T}_s^A , \bar{T}_s^B , and \bar{T}_s^C , respectively. In panel (c), T_0 (\bar{T}_s) for the gray-colored (colored) time-responses in the lower and upper sections was set to \bar{T}_s^A and \bar{T}_s^C , respectively. In each plot an inset provides a close-up view of the steady-state time course of the lower oscillation in the body temperature T .

analytically reproduced plots during both their transient and steady-state phases. The excellent accuracy of the proposed methodology is clearly demonstrated. Notice, that as the memristor evolves toward the steady-state phase, with each input period n , the exponential function on the right-hand side of Equation (20) progressively decays toward zero. At steady-state, we can assume its contribution to be negligible, practically zero, and thus the third term on the right-hand side of Equation (20) can be safely ignored. Therefore, the asymptotic oscillation $T_s(t)$ of the device body temperature T about a mean value \bar{T}_s , characterized by a null net change ΔT_n in T over each input steady-state cycle n , can be described by the following periodic function:

$$T_s(t) = \delta_s + \epsilon_s \cdot \sin(4 \cdot \pi \cdot f \cdot t + \phi_s) \quad (28)$$

where

$$\delta_s = \bar{T}_s \quad (29)$$

$$\epsilon_s = \frac{\bar{T}_s - T_{\text{amb}}}{\sqrt{1 + 16 \cdot \pi^2 \cdot f^2 \cdot \tau_s^2}} \quad (30)$$

$$\phi_s = \arccos\left(\frac{4 \cdot \pi \cdot f \cdot \tau_s}{\sqrt{1 + 16 \cdot \pi^2 \cdot f^2 \cdot \tau_s^2}}\right) + \pi \quad (31)$$

Parameters ϵ_s and ϕ_s are the amplitude and phase of $T_s(t)$, while $\tau_s = R_{\text{th}}(\bar{T}_s) \cdot C_{\text{th}}$ is the thermal time constant at steady-state.

Up to this point, we have confirmed the accuracy of the proposed methodology and of the derived analytical equations when the input frequency is as high as 100GHz. Let us now determine the lower frequency limit for the validity of our assumptions, specifically focusing on the applicability of Equations (28) – (31). Panels (a), (b), and (c) in Figure 8 compare simulated (see gray-colored curves) and analytically calculated (see colored curves) temperature time-responses under a sinusoidal voltage input with an effective voltage V_{rms} of 0.94V at frequencies f of 20, 6, and 1GHz, respectively. The initial condition T_0 (The parameter \bar{T}_s in Equations (28) – (31)) for the gray-colored (colored) steady-state time-waveform plotted in the lower, middle,

and upper parts of panels (a) and (b) was set equal to \bar{T}_s^A , \bar{T}_s^B , and \bar{T}_s^C , respectively. In each case the selected T_0 value ensured that each of the numerically obtained time-response exhibits a periodic waveform for $t \geq 0$. As anticipated, the accuracy of the proposed analytical equations reduces as the input frequency decreases, still remaining quite precise, though, for the whole frequency range where the NbO₂-Mott memristor exhibits three distinct steady-state behaviors, i.e., above $f = 1$ GHz. As shown in Figure 7c, at this frequency, the periodically-forced device exhibits two steady-state behaviors instead of the three observed for higher frequencies (this is also indicated in Figure 3). In particular, the initial device temperature T_0 (the mean oscillating value \bar{T}_s of the device temperature T , at steady state) for the simulated gray-colored (analytically derived colored) time-responses seen in the lower and upper parts of Figure 7c was given the values \bar{T}_s^A and \bar{T}_s^C , respectively. All in all, this section has demonstrated the accuracy of the proposed analytical model for the response of the NbO₂-Mott memristor to high-frequency sine wave stimuli.

6. Discussion and Conclusions

Complementing our recent theoretical study on the high-frequency response of non-volatile memristors,^[18] this work explores the behavior of electro-thermal threshold switches, classified as volatile memristor devices, in the high-frequency limit. Although the methods detailed in this manuscript are applied to the HP NbO₂-Mott nano-device, they can be extended to all electrothermal devices, falling into the class of generic memristors,^[37] and described by an energy balance equation similar to Equation (1) or (7) (see refs. [2, 3, 5, 6], and [36]). Unlike non-volatile memristors, the volatile NbO₂-Mott memristor is not programmable. In fact, despite, subjected to external stimuli, its resistance can be configured, it reverts to a default state once powered off. Even so, we showed that this threshold switch is quite versatile, displaying a maximum of three distinct asymptotic steady-state oscillatory behaviors when subjected to an appropriate high-frequency zero-mean periodic voltage input, with the specific oscillatory behavior it settles onto, being determined by its initial body temperature (see Section 3). Quite counter-intuitively, as elucidated by the deep circuit-theoretic analysis

performed in Section 4, this capability is inscribed in its DC $I_m - V_m$ plot. Importantly, in the same section, it was demonstrated how a TA-SDR for the NbO₂-Mott memristor, and thus for any electrothermal threshold switch classified as a generic memristor, can be derived analytically (see Equation (14)) for any high-frequency periodic sine-wave voltage input. Let us stress at this point that the input-referred TA-SDR (see Figure 6) is particularly useful for the study of volatile threshold switches, being endowed with at least a couple of basins of attraction under a high-frequency periodic sine-wave voltage input. The input-referred TA-SDR depicts the locations of all the possible attractors in the 1D memristor state space, around which the memristive system may oscillate at steady-state, and demarcates regions in the same state space, in each of which any initial condition leads to a different asymptotic oscillatory behavior for the device. By examining trajectories within these basins, one can gain insights into how the memristive system evolves toward its periodic steady states. On the other hand, the boundaries between the basins known as separatrices, correspond to admissible yet unstable periodic steady-states for the periodically-forced device. By linking the net change ΔT in the device temperature T over an input cycle, with the mean value \bar{T} of the temperature oscillation, over the same cycle, the input-referred TA-SDR illustrates how the high-frequency input stimulus maps each admissible temperature state of the NbO₂-Mott memristor from the beginning to the end of the cycle itself. Most importantly, the mathematical investigation presented in Section 4 indicates that this extremely useful visualization tool can be derived analytically on the basis of a closed-form formula (see Equation (14)), irrespective of the periodic voltage input type, be it sinusoidal, triangular, rectangular, etc., as long as the input itself oscillates with a frequency that is high enough to induce negligible changes in the device body temperature over each input cycle. Going one step further, in Section 5, we introduced an algorithm, that reproduces the temperature time-waveform of the NbO₂-Mott nano-device, induced by a zero-mean sinusoidal voltage input oscillating in the high-frequency limit. We demonstrated that the steady-state time-waveform of the body temperature of the volatile memristor under study, subjected to a sufficiently-high frequency zero-mean sinusoidal voltage input, can be described by a closed-form analytical formula, which is rather accurate within the frequency range, where the NbO₂-Mott nano-device exhibits tristability.

Our recent study^[18] on the high-frequency response of non-volatile memristors, combined with the findings in this manuscript, have clearly demonstrated that memristors tend to operate as specified by their linearized models, when subjected to high-frequency AC periodic inputs. This discovery offers new opportunities for the application of methods from nonlinear system theory, potentially enhancing our comprehension of the device behavior, and enabling us to model its responses to arbitrary inputs from given classes more effectively. Consequently, by exhibiting a linearized behavior under high-frequency AC periodic inputs, memristors can be treated as weakly nonlinear systems, which enables their modeling with relatively low complexity. The experimental verification of the presented concepts in volatile threshold switches could be exploited, most likely in sensory-oriented applications.

- [38] According to ref. [37], the high level mathematical representation of a first-order voltage-controlled *generic* memristor is described by a differential algebraic equation (DAE) set model, where the Ohm's Law and state equation are expressed as, $i = G(x) \cdot v$ and $\dot{x} = f(x, v)$, respectively. $G(\cdot)$ is the memductance function, while $f(\cdot)$ captures the time-evolution of the device state x . Typically, the state variable in electro-thermal memristors, such as the NbO₂-Mott nano-device under study, is chosen as the device body temperature T . Notice, that by substituting Equation (4) in (1), the time-derivative of the memristor core M body temperature \dot{T} can be expressed as being dependent on the temperature T itself as well as on the voltage drop across the memristor core v (see Figure 1b).
- [39] The steady-state response represents the asymptotic behavior of a system, in our case study under a periodic voltage input, as time progresses toward infinity. A detailed analysis of both transient and steady-state responses of the NbO₂-Mott memristor, when excited by a high-frequency sinusoidal voltage input, is provided in Sections 4 and 5.
- [40] Based on the theoretical analysis in ref. [5], under the application of a sinusoidal voltage input with an amplitude of $\hat{v}_m = 1.2V$, the area of the current–voltage lobe of the memristor M' reaches its maximum value when the input frequency becomes approximately equal to $1.2 \cdot 10^8$ Hz. Beyond this critical value, the lobe area decreases abruptly.

- [42] This phenomenon, referred to as local fading memory, which is present in multistable devices such as the NbO₂-Mott memristor, has been thoroughly investigated in refs. [26] and [27].

- [44] The TA-SDR visualization tool, named in Ascoli et al.[23] and initially introduced by Pershin and Slipko in ref. [21], though not explicitly defined in the latter source, may be used to analyze the response of any first-order non-volatile memristor to square-wave periodic stimuli, which induce negligible changes in its state variable over each input cycle. In the meantime, Messaris *et al.* [18] presented a similar graphical tool, the high-frequency state dynamic route (HF-SDR), which generalized the methodology from ref. [21] to characterize the response of any first-order non-volatile memristor to high-frequency periodic inputs of arbitrary forms. To avoid confusion, in this manuscript, we will adopt the nomenclature defined in ref. [23].
