**Abstract.** In this work, we performed a preliminary investigation on the redox behaviour of  $\text{Sr}_2\text{FeMo}_{0.6}\text{Ni}_{0.4}\text{O}_{6-\delta}$  (SFMN) double perovskite in  $\text{H}_2\text{-H}_2\text{O}$  and  $\text{CH}_4\text{-H}_2\text{O}$  redox cycles in order to explore the potential use of this oxide as an Oxygen Carrier (OC) in fuel-assisted Chemical Looping Water Splitting (CLWS) processes driven by concentrated solar energy. The results were compared with our previous findings on the Reverse Water Gas Shift Chemical Looping (RWGS-CL) reaction. The improvement in performance due to the bimetallic exsolution on the OC surface is observed. This OC exhibits interesting activity and stability over  $\text{CH}_4$ -assisted CLWS cycling. Future investigations are planned to examine the structural transformations that might impact the redox behaviour of this material in water splitting processes.

**Keywords:** Chemical Looping; Perovskite; Exsolution; Water Splitting; Solar Fuels;  $\text{CH}_4$  Reforming.

## 1. Introduction

The urgency of climate change calls for the development of alternative energy pathways to replace fossil fuels with energy renewable sources. Among these, solar energy is the most abundant and could potentially meet the world's energy needs. The intermittent nature of solar energy and its conversion into fuels currently pose technological challenges. A promising route for the storage of solar energy relies on its conversion to chemicals, such as gaseous and liquid fuels, through thermochemical processes [1]. In this regard, Chemical Looping (CL) offers a versatile solution for the efficient conversion of solar thermal energy into fuels, e.g.,  $\text{H}_2$  and syngas. CL uses a solid redox-active material to break up a thermochemical reaction into two steps, thus by separating reaction products, overcoming thermodynamic limitations, and minimizing exergy losses [2]. In  $\text{CH}_4$ -assisted Chemical Looping Water Splitting (CLWS), a solid Oxygen Carrier (OC) is employed to selectively oxidize  $\text{CH}_4$  to  $\text{H}_2$  and CO (reduction step, Equation (1)); subsequently, the OC lattice oxygen is restored by oxidation with  $\text{H}_2\text{O}$  (water splitting step, Equation (2)).

In this way, two separate streams, a syngas with a  $\text{H}_2/\text{CO} \approx 2$ , suitable for Gas-To-Liquid (GTL) processes [3], and a stream of pure  $\text{H}_2$  are generated with a minimal energy penalty for separation. The overall methane steam reforming reaction is endothermic, and supplying the thermal energy required by the OC reduction step using a renewable source raises the energy content of the products by a factor of 1.28 over that of the reactants [1]. One of the most critical aspects in the process development is the selection of the OC material, since its chemical and mechanical performance over prolonged reduction-oxidation cycling determines the economics of the plant [4]. Perovskite-structured oxides (with general formula  $\text{ABO}_3$ ) have shown desirable properties for  $\text{CH}_4$ -assisted CLWS, such as good thermal stability and a high syngas selectivity. Through doping the A-site and B-site, it is possible to effectively tune the concentration of surface lattice oxygen vacancies and the ionic conductivity, thus modulating the redox behavior of the OC [5]. Promising results in terms of stability and selectivity have been obtained by, e.g., the development of core-shell metal oxide-perovskite composite OC materials [6] and by optimizing the composition to promote the exsolution of well-dispersed metallic nanoparticles that could act as catalyst [7], [8].

Sr-Fe-Mo-Ni perovskites (SFMN) with composition  $\text{Sr}_2\text{Fe}_x\text{MoNi}_{1-x}\text{O}_{6.5}$  were recently investigated as catalyst for the Dry Methane Reforming (DMR) [9]. When exposed to high temperature ( $\approx 900$  °C) in  $\text{H}_2$  reducing atmosphere, this material exhibited a morphological activation inducing  $\text{Ni}_3\text{Fe}$  nanoparticles exsolution, able to catalyze the overall DMR. In exsolution, metal alloy nanoparticles grow from inside the structure instead of being deposited from the outside, ensuring better stability because the particles remain socketed into the support surface [10]. In a recent investigation by our group,  $\text{Sr}_2\text{FeMo}_{0.6}\text{Ni}_{0.4}\text{O}_{6.5}$  double perovskite was investigated as OC in the CL Reverse Water-Gas Shift (RWGS-CL) reaction, in which the sample was reduced with  $\text{H}_2$  and oxidized with  $\text{CO}_2$  [11]. SFMN samples were tested *via* thermogravimetry (TGA) and in packed-bed reactor over a wide temperature range, 550 – 950 °C. The material was able to undergo isothermal RWGS-CL cycles, keeping a high CO production yield above 1.5 mmolCO/g after 326 redox cycles at 850 °C. This yield is comparable with or superior to most of the available performance throughout the literature. Exsolution of Ni-Fe alloy nanoparticles was observed and reported in several publications, and it determined the superior redox performance after the material activation.

In the present work, we investigate the role of the  $\text{Ni}_3\text{Fe}$  exsolution on  $\text{CH}_4$ -assisted CLWS redox cycles and compare the results with  $\text{H}_2$ -assisted CLWS and with previous experimental campaign on RWGS cycles.

## 2. Materials and Methods

SFMN powder was prepared and characterized by X-ray diffraction (XRD) and High-Resolution Transmission Electron Microscopy (HRTEM), at the structural and nanoscale, respectively, as described in our recent study [11].

$\text{H}_2$ -assisted CLWS cycles were carried out with an Autochem II 2920 Micromeritics Analyzer equipped with a Thermal Conductivity Detector (TCD). One cycle consisted of a reduction step with a temperature-programmed heating ramp of 10 °C/min starting at the room temperature (RT) and up to 850°C, using 5%  $\text{H}_2$  in  $\text{N}_2$  flow at 35 Nml/min, as a reductant. The sample was idled for 1 h at the final conditions, then purged with  $\text{N}_2$  before of the oxidation step. The latter was performed by pulses of water vapor (injected through a 500  $\mu\text{l}$  loop filled from a saturator operating at 70 °C and 35 Nml/min He flow), to achieve a steady state for  $\text{H}_2$  production. The sample was then completely oxidized with air at 500 °C for 30 min, and then cooled down to room temperature to repeat the cycle.

Temperature-Programmed Reduction (TPR) in  $\text{CH}_4$  atmosphere was conducted in a thermogravimetric analyser (TGA) (STA 2500 Regulus, Netzsch, Germany), both on a pristine

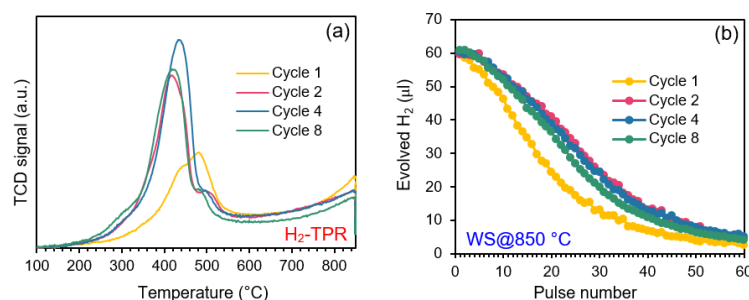

SFMN sample and on a pre-treated sample. For the pretreatment, aimed at promoting metal exsolution, a 30 mg sample was loaded into a packed-bed reactor, and the sample was kept in 10% H<sub>2</sub>/N<sub>2</sub> at 850 °C for 2 h with gas flow rate of 200 Nml/min. Then, the reactor was cooled down in 100% N<sub>2</sub> to ambient temperature, prior to CH<sub>4</sub>-TPR in the TGA. The total gas flow rate in the TGA was kept constant at 80 Nml/min. The temperature was first raised from room temperature to 850 °C (20 °C/min) in 100% Ar, and the sample was oxidized at 850 °C in 50% air/Ar (synthetic air composition: 20% O<sub>2</sub>, 80% N<sub>2</sub>) for 30 min. Then, after it was cooled down back to 250 °C (20 °C/min) in 100% Ar, and maintained at 250 °C for 10 min, the TPR was initiated and performed from 250 °C up to 850 °C (10 °C/min), under a 2.5% CH<sub>4</sub>/Ar mixture. CH<sub>4</sub> concentration was maintained low for safety reasons. Finally, the temperature was rapidly decreased back to room temperature in 100% Ar. Isothermal reduction at 850 °C was avoided to limit CH<sub>4</sub> cracking and carbon deposition.

CH<sub>4</sub>-assisted CLWS cycles were run isothermally at 850 °C. A sample of 100 mg was loaded onto a microreactor connected to a calibrated mass spectrometer. Each cycle consisted in a 10 min reduction 5% CH<sub>4</sub>/He and a 20 min oxidation with 6% H<sub>2</sub>O/He, with a 5 min purge in between. The inlet flow rate in the microreactor was kept constant at 50 Nml/min, obtaining a GHSV ≈ 20.000 h<sup>-1</sup>. The amount of solid carbon deposited on the sample upon exposure to CH<sub>4</sub> was determined from the evolved amounts of CO and CO<sub>2</sub> during the steam oxidation step. To exclude the formation of stable carbon deposits, at the end of each test the samples were kept in air at 850 °C for 30 minutes, and carbon oxidation products were monitored. For all tests, negligible amounts of CO and CO<sub>2</sub> were detected.

### 3. Results and Discussion

#### 3.1 H<sub>2</sub>-assisted Chemical Looping Water Splitting

Before studying the behaviour of SFMN in the CH<sub>4</sub>-assisted CLWS, the water splitting performance and the material stability in water vapor were investigated through multiple H<sub>2</sub>-TPR – H<sub>2</sub>O isothermal oxidation cycles at 850 °C. H<sub>2</sub> is used as a reducing agent instead of CH<sub>4</sub> with the aim of exploring the material redox activity without handling carbonaceous species and thus by-passing cracking and deposition phenomena which can complicate the investigation and affect performance [12]. Figure 1, with H<sub>2</sub>-TPR on the left (Figure 1a) and water splitting on the right (Figure 1b), shows the results of some representative cycles. The first TPR shows two partially overlapping signals with maxima at 460 and 485 °C, that were attributed to the reduction of surface Ni<sup>2+</sup> and Fe<sup>4+</sup> cations and to the reduction of high-valence cations into the bulk (Mo<sup>6+</sup>, Fe<sup>3+</sup> and Ni<sup>2+</sup>), respectively [11], [12], [13]. The high-temperature signal starting around 700 °C can be ascribed to the reduction of Fe<sup>2+</sup> to Fe<sup>0</sup> and to the progression of structural changes in the perovskite lattice. In the second reduction, a large H<sub>2</sub> consumption peak is observed centred at 420 °C, with a small shoulder around 500 °C. Compared to the first TPR, the H<sub>2</sub> consumption below 600 °C is increased by 52%. The higher H<sub>2</sub> consumption in the 300-480 °C range can be attributed to the increased reducibility of Ni<sup>2+</sup> and Fe<sup>3+</sup> cations and the increased content of the Ruddlesden-Popper (RP) phase Sr<sub>3</sub>FeMoO<sub>7.5</sub> in the sample following the irreversible structural transformations that took place during the first reduction, as discussed by Felli et al. [13]. Given the higher reducibility at low to intermediate temperatures, a decrease in the high temperature contribution is observed. The following cycles show the same features as the second cycle, and the total hydrogen consumption stabilizes from the fourth cycle onwards (Table 1). Hydrogen production during the water splitting step also improved at the second cycle and stabilized at the fourth cycle. The corresponding H<sub>2</sub> yield of the cycles was of 50%. This is probably due to the instrumental constraints that do not allow to obtain high concentration of water vapour in each pulse, thus ending up with an equilibrium oxygen partial pressure that allows the stabilization of the nonstoichiometric phases of perovskites formed, rather than their complete oxidation. Further studies are needed to confirm this hypothesis. Thus, SFMN appears to be stable in the H<sub>2</sub>-assisted CLWS cycles, reaching a steady state after four cycles. This behaviour is different from the results obtained in our previous study under RWGS-CL conditions [11], in which the CO<sub>2</sub>-oxidized material reached a steady state in the CO yield after around forty cycles.

**Figure 1.** H<sub>2</sub>-assisted CLWS cycles. (a) H<sub>2</sub>-TPR up to 850 °C. (b) Water splitting at 850 °C.

**Table 1.** Comparison of H<sub>2</sub> consumption, H<sub>2</sub> yield and H<sub>2</sub> production/consumption ratio referred to the selected H<sub>2</sub>-TPR – WS cycles.

Cycle number	H <sub>2</sub> consumed (mL/g)	H <sub>2</sub> produced (mL/g)	% of oxidation
1	53.8	24.1	44.8
2	59.4	33.5	56.4
4	64.1	32.1	50.0
8	63.4	31.5	52.6

### 3.2 CH<sub>4</sub>-assisted Chemical Looping Water Splitting

The SFMN reactivity towards partial oxidation of methane was preliminarily explored *via* CH<sub>4</sub>-TPR in the TGA, comparing the reduction extent and the DTG-based reduction rate in the pristine and pretreated samples, with the latter being representative of an exsolved material [11]. The thermograms are depicted in Figure 2a. The 100% oxidized mass is taken as the stabilized post-oxidation value at 250 °C, just before starting the TPR ramp. While the mass signal is the same for the two samples up to around 700-730 °C, the pretreated sample clearly shows improved reactivity towards methane from 750 °C on, with a consistently higher mass loss (red solid curves) and notably higher DTG-based reduction rate (red dashed curves). This suggests that the exsolved material can achieve higher CH<sub>4</sub> conversion. XRD spectra of the two tested samples, shown in Figure 2b-c-d, highlight the presence of the Ni-Fe alloy and of the RP phase in the pretreated specimen, consistent with previous results, together with a wider shoulder at around 44° 2θ. An incipient Ni<sub>3</sub>Fe peak at 44.5° 2θ can be also observed in the pristine sample, likely resulting from exposure to the CH<sub>4</sub> reducing atmosphere at increasing temperature. However, a concomitant RP phase was not detectable.

**Figure 2.** (a) CH<sub>4</sub>-TPR in a TGA on pristine and pretreated samples. (b, c, d) XRD spectra of the two samples tested in TGA: (b) Full spectra. (c) Detail of the 30-35 2θ range. (d) Detail of the 42-47 2θ range. Ni<sub>3</sub>Fe (♣), RP-phase Sr<sub>3</sub>FeMoO<sub>6</sub> (♠), Sr<sub>2</sub>FeMoO<sub>6</sub> (♣).

Given the high reactivity observed towards methane at 850 °C, SFMN reducibility in CH<sub>4</sub> was investigated in isothermal CH<sub>4</sub>-H<sub>2</sub>O cycles in a fixed bed microreactor at this temperature, which was also previously identified as suitable for long isothermal cycling in RWGS-CL conditions [11]. Firstly, the reducibility in a CH<sub>4</sub>-containing atmosphere was compared to H<sub>2</sub>-assisted reduction in Figure 3. This was done by performing five CLWS cycles using 5% H<sub>2</sub> as reducing agent and ten cycles using 5% CH<sub>4</sub>. The test was preceded by a 2 h reduction with

5% H<sub>2</sub>/He at the same temperature, to induce the exsolution of the Ni-Fe alloy nanoparticles, followed by a 30 min oxidation with 5% O<sub>2</sub>/He. The constant response obtained in the five H<sub>2</sub>-H<sub>2</sub>O cycles confirmed that the transformation has reached a steady state, leading to the production of approximately 2.5 mmolH<sub>2</sub>/g in each cycle (Figure 3a). During the CH<sub>4</sub>-H<sub>2</sub>O cycles the duration of the reduction step was limited to 10 min to limit carbon deposition, which could induce loss of activity and complicate further sample analysis. Despite this precaution, some carbon was deposited on the OC (Figure 3b), and its subsequent gasification by reaction with steam generated initially a higher amount of H<sub>2</sub> than that obtained in H<sub>2</sub>-assisted cycles, also reducing its purity. It is worthy to note that the formation and subsequent gasification of carbon progressively diminished through the cycles, and the H<sub>2</sub> yield upon oxidation approached the same value obtained with H<sub>2</sub>-H<sub>2</sub>O cycles after 10 cycles. In the last cycle, 2.76 mol of H<sub>2</sub> were produced per mole of converted CH<sub>4</sub>, of which 1.73 mol<sub>H<sub>2</sub></sub>/mol<sub>CH<sub>4</sub></sub> from the reduction step, and 1.03 mol<sub>H<sub>2</sub></sub>/mol<sub>CH<sub>4</sub></sub> from the water splitting step. CO selectivity was higher than 90% in all the reduction steps, as evidenced in Figure 3b.

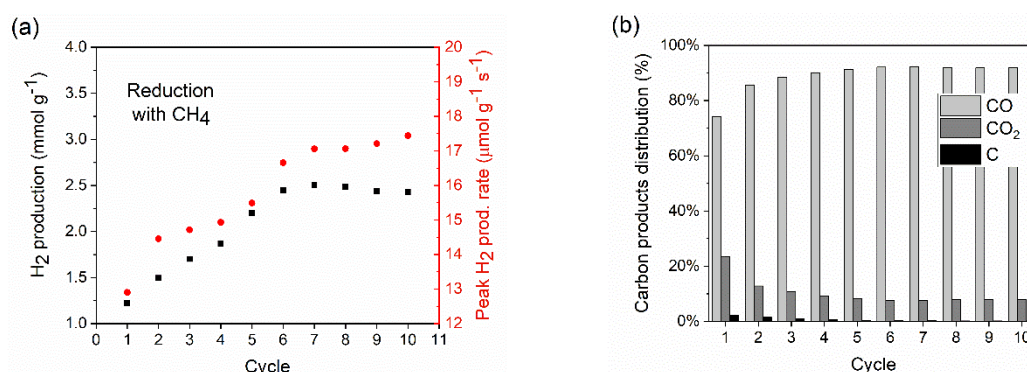

**Figure 3.** Comparison of SFMN performance between H<sub>2</sub>-assisted and CH<sub>4</sub>-assisted reduction. (a) H<sub>2</sub> yield (black squares) and H<sub>2</sub> production rate (red squares) upon H<sub>2</sub>O oxidation. (b) Carbon products distribution upon CH<sub>4</sub>-assisted reduction.

The effect of the microstructure evolution during the CH<sub>4</sub>-assisted reduction at high temperature was investigated by exposing the as-synthesized sample directly to CH<sub>4</sub>-H<sub>2</sub>O cycles at 850 °C, without previous pretreatment. Results are shown in Figure 4. Both H<sub>2</sub> yield and its production rate increase steadily in the first seven cycles, after which they stabilize at the same value obtained with H<sub>2</sub> pretreated samples (2.5 mmolH<sub>2</sub>/g and 17 μmolH<sub>2</sub>/g/s, respectively, Figure 4a). This shows that SFMN transforms upon cycling, similarly to what was observed in the CH<sub>4</sub>-TPR, and that exposure to CH<sub>4</sub> can induce exsolution as well (peak at 44.5° 2θ well matching the Ni<sub>3</sub>Fe alloy, blue spectrum in Figure 2d). This is also consistent with the observation that the pretreated sample ensures a higher reactivity towards methane (Figure 2a). In a similar fashion, CO selectivity during the reduction step grew from 75% to >90% in the first cycles (Figure 4b). The latter phenomenon was attributed to the gradual depletion of highly active surface oxygen species, which could not be restored by steam oxidation. The concentration of surface oxygen vacancies is the main factor affecting CO selectivity of iron-based OCs when reacting with carbonaceous fuels [14], [15], [16], [17]. The H<sub>2</sub> yield of 2.5 mmolH<sub>2</sub>/g observed here is higher than the corresponding long-cycling CO production of 1.5 mmolCO/g estimated in our previous work on RWGS-CL, while the fuel production rate is comparable, with around 17 μmolH<sub>2</sub>/g/s against 15 μmolCO/g/s maintained after 300+ RWGS-CL cycles. The steady state CH<sub>4</sub>-H<sub>2</sub>O cycles seems to be reached in the first ten cycles, similarly to what happens in the preliminary study with H<sub>2</sub>-H<sub>2</sub>O (see Figure 1).

To have a quantitative idea on how SFMN performs with respect to alternative OCs, we compared its performance with previous works from the literature, as summarized in Table 2. The H<sub>2</sub> yield observed here (2.5 mmolH<sub>2</sub>/g) is higher than several OCs proposed previously. Some of the reported OCs show a higher H<sub>2</sub> yield during the oxidation step at similar temperatures (e.g., 3DOM LaFe<sub>0.9</sub>Ni<sub>0.1</sub>O<sub>3</sub> and BaCoO<sub>3</sub>/CeO<sub>2</sub>), but also a lower H<sub>2</sub> purity at the same time. CuFeO<sub>4</sub> reported an outstanding H<sub>2</sub> yield during oxidation, but the CO selectivity (total,

including solid carbon deposition) during reduction is relatively low (<60%), against a value higher than 93% for SFMN. Similar considerations apply for  $\text{La}_{1.6}\text{Sr}_{0.4}\text{FeCoO}_6$ , that reaches a higher  $\text{H}_2$  yield, but a much lower total CO selectivity (40%). Thus, overall, SFMN can be considered a promising candidate for  $\text{CH}_4$ -assisted CLWS.

**Figure 4.** Effect of progressive exposure to  $\text{CH}_4$  on SFMN performance, without previous pre-treatment in  $\text{H}_2$ . (a)  $\text{H}_2$  yield (black squares) and  $\text{H}_2$  production rate (red squares) upon  $\text{H}_2\text{O}$  oxidation. (b) Carbon products distribution upon  $\text{CH}_4$ -assisted reduction.

**Table 2.** Comparison between SFMN and OCs from the literature in  $\text{CH}_4$  assisted chemical looping water splitting. The works were collected from comprehensive reviews [18], [19].

\*Total selectivity (including solid carbon).

\*\*Gas-phase selectivity (excluding solid carbon).

Figure 5 reports the XRD spectra of SFMN samples as pristine, after ten  $\text{H}_2$ - $\text{H}_2\text{O}$  and after ten  $\text{CH}_4$ - $\text{H}_2\text{O}$  cycles. In both CL schemes, the prolonged cyclic exposure of SFMN to a reducing atmosphere at 850 °C induces the appearance of the  $\text{Ni}_3\text{Fe}$  peak at  $44.5^\circ 2\theta$  and of the RP phase  $\text{Sr}_3\text{FeMoO}_{7-\delta}$  at  $31.5^\circ 2\theta$  [20], although the RP phase  $\text{Sr}_3\text{FeMoO}_{7-\delta}$  at  $31.5^\circ 2\theta$  is not clearly visible in the  $\text{CH}_4$ - $\text{H}_2\text{O}$  cycled sample and manifests with a broadening of the peak rather than with an evident shoulder. The presence of  $\text{SrCO}_3$  and  $\text{SrMoO}_4$  can be due either to the interaction of residual carbonaceous deposits with the perovskite, or to the prolonged exposure to air of the sample before the XRD analysis, as previously observed [11]. Overall, these observations are consistent with the literature in which the exsolution was demonstrated

to take place in different reducing conditions in terms of  $pO_2$  and the reducing gas and proved the effectiveness of the  $CH_4$  atmosphere in promoting exsolution of Ni [21], [22].

**Figure 5.** XRD profiles of SFMN as synthesized (blue), after ten  $H_2/H_2O$  cycles at  $850\text{ }^\circ\text{C}$  (red) and after ten  $CH_4/H_2O$  cycles at  $850\text{ }^\circ\text{C}$  (green).  $Ni_3Fe$  ( $\clubsuit$ ), RP-phase  $Sr_3FeMoO_{7-d}$  ( $\spadesuit$ ),  $Sr_2FeMoO_6$  ( $\blacklozenge$ ),  $SrCO_3$  ( $\otimes$ ),  $SrMoO_4$  ( $\nabla$ ). ## 4. Conclusions and Perspectives

In this study we demonstrate that SFMN is a valuable OC for CLWS processes and that exsolution can be promoted by  $CH_4$  as well as by  $H_2$ , without experiencing much detrimental effect from carbon formation. The results were compared with those observed in RWGS-CL process previously published, showing some differences in terms of stability. The yield of  $CH_4\text{-}H_2O$  cycles seems to stabilize faster after ten cycles. Future work will include closer examination of the  $CH_4$ -assisted reduction cycles, along with the exsolution under water splitting conditions and its role on the redox performance, both in terms of reactivity and stability.
