ABSTRACT

The rise of information technologies has led to the need for collecting vast amounts of multidisciplinary data related to human habits, social interactions, and physical activities. This demand has intensified the challenge of integrating rigid electronics with the flexibility of human tissue. Wearable sensors have emerged as a solution to detect several biometric signals from human body. Among these applications, pressure sensing is particularly crucial. In this work, we present a flexible, sandwich-structured pressure sensor based on a porous PDMS sponge. Two distinct fabrication methods were investigated with a critical analysis of their advantages and limitations. A templating technique using a common sugar cube as a sacrificial mold, and a molding method where a sugar-PDMS slurry was shaped using a predefined mold. While the templating approach offers simplicity and accessibility, the molding method provides greater control over geometry and customization. All fabricated sensors demonstrated excellent piezocapacitive performance under mechanical compression, characterized by minimal hysteresis during cyclic loading—an essential feature for consistent and reliable sensing. To boost sensitivity, silver nanoflakes were incorporated into the polymer matrix, resulting in a 65 % increase in pressure sensitivity, achieving up to 0.047 kPa^{-1} , one of the highest values reached by PDMS-based foam sensors, and lowering the detection threshold to just 0.6 g (40 Pa). The successful implementation of these sensors in wearable formats underscores their potential as lightweight, scalable, and cost-effective platforms for continuous biometric monitoring in real-world applications.

1. Introduction

The recent development of Information Technologies requires to collect a large amount of multidisciplinary data derived from humans' habits, social life and physical activities. Consequently, the need for new ways to interface rigid electronic devices with soft and flexible human tissues has drastically grown. Nowadays, wearable sensors and devices constitute the link between the two realms. Wearable devices have such a pervasive and widespread range of applications thanks to the ability to be suitable for a lot of different scenarios and to detect and monitor a full range of signals, from heart rate to anxiety. Among them, pressure is a crucial physical quantity to be sensed in real-time health monitoring [1–4].

A variety of feasible transduction mechanisms of pressure and, in general, of mechanical stimuli have been explored so far, such as piezoresistivity [5–8], piezocapacity [9,10], piezoelectricity [11,12] and triboelectricity [13,14]. Capacitive pressure sensors have attracted more interest compared to other types of sensors such as resistive,

piezoelectric and triboelectric, thanks to their simple structure, low fabrication cost, low power consumption, high sensitivity, good dynamic response performance and strong adaptability to harsh conditions such as high temperature, radiation and strong vibration [15,16]. For capacitive pressure sensor a highly deformable dielectric layer is the crucial component for enhancing the sensitivity [15,17]. Promising candidates for this task are the hydrogels, 3D crosslinked networks of hydrophilic polymers capable of retaining large volumes of water. They are either chemically or physically crosslinked and possess highly tunable structural and mechanical properties that can be tailored to the specific requirements of flexible pressure sensors [18]. Water evaporation is one of the main issue with hydrogels since they become dry and losses their physical properties, while the other great challenge with conductive hydrogels is to overcome the incompatibility between mechanical elasticity and high electrical conductivity [19].

Sponges made up of porous polymers are an interesting alternative to hydrogel. The porous structure lends flexibility and lightweight without the risk to lose the physical and mechanical properties over time.

Moreover, they merge an high pressure sensitivity with a wide sensing range, because of the softness guarantee by the porous structure. Porous polymer foam has been prepared following different approaches. Most commons are based on the use of preformed templates infiltrated with uncured polymer, such as sugar cubes [20–24], but also the use of salt and sugar powder as filler to be later removed [25–27] or emulsion based on liquid templates [28–30] has been investigated, together with more exotic technique such as infiltration into natural or synthetic sponges [31–33] and microfluidic emulsion approach [34]. Porous structures have also the possibility to load huge amounts of filler to modify the dielectric or conductive properties of the sponge with the goal to increase pressure sensitivity [35,36].

In this study, we developed a high-performance piezocapacitive wearable pressure sensor utilizing a polymer sponge as a soft, compressible dielectric material. Polydimethylsiloxane (PDMS) was selected as the base polymer and rendered porous via two distinct fabrication strategies. The first method used a sugar cube templating technique, where PDMS precursor infiltrated the template by capillary action. The resulting porous sensors exhibited a pronounced piezocapacitive response under compressive stress, which was significantly enhanced by the incorporation of silver nanoflakes. These sponge-based sensors demonstrated excellent mechanical stability, high reproducibility, and negligible hysteresis, alongside an exceptionally low limit of detection (LOD), key parameters for reliable pressure sensing. To overcome limitations in shape control imposed by the cubic sugar templates, we adopted an alternative method using sugar powder. By directly mixing sugar powder with liquid PDMS and casting the mixture into molds, we fabricated flexible, mold-conforming foams. After curing and sugar removal, the resulting sensors retained precise geometries and superior mechanical flexibility. Notably, the molded PDMS foams loaded with silver nanoflakes outperformed the templated counterparts, achieving a twofold increase in pressure sensitivity (0.047 kPa^{-1}) and lowering the LOD to just 0.6 g (40 Pa), among the highest sensitivities

reported for PDMS-based capacitive pressure sensors. These exceptional properties underscore the potential of our sensors for integration into next-generation wearable and flexible electronic devices.

2. Materials and methods

2.1. Templating method

Samples were prepared using bi-component PDMS (Sylgard-184 from Dow Corning), silver nanoflakes (average size $4\text{--}8 \mu\text{m}$, Sigma Aldrich) and sugar cubes acquired from food market. The main steps to prepare a PDMS sponge sensor are sketch in Fig. 1a. PDMS base elastomer and curing agent are mixed in 5:1 or 10:1 ratio in a beaker and are manually stirred with a metallic spatula for 2 min. For composite samples, Ag flakes were added to the PDMS solution at this point. The mixture was then degassed in a container connected with a vacuum pump for 15 min to remove incorporated air bubbles. At this stage a lump of sugar is soaked by half in the blend and placed again in vacuum container for 15 min to facilitate the liquid PDMS mixture to totally fill the inner pores of the sugar cube. The process is repeated for the other half of the cube and then the sample is inserted into an oven (Memmert) at 60°C for 1 h to cure the PDMS. After curing, the cube is submerged in a beaker full of deionized water at 60°C for 30 min in order to dissolve the sugar template. The water is kept in constant agitation by a magnetic stirrer to facilitate the complete dissolution of sugar template which results in a porous PDMS (pPDMS) foam with pore sizes comparable to those of the sugar grains of the template. The as-prepared pPDMS is finally washed a couple of times with DI water and dried into the oven at 60°C .

2.2. Molding method

The uncured PDMS and the sugar powder were directly mixed to be

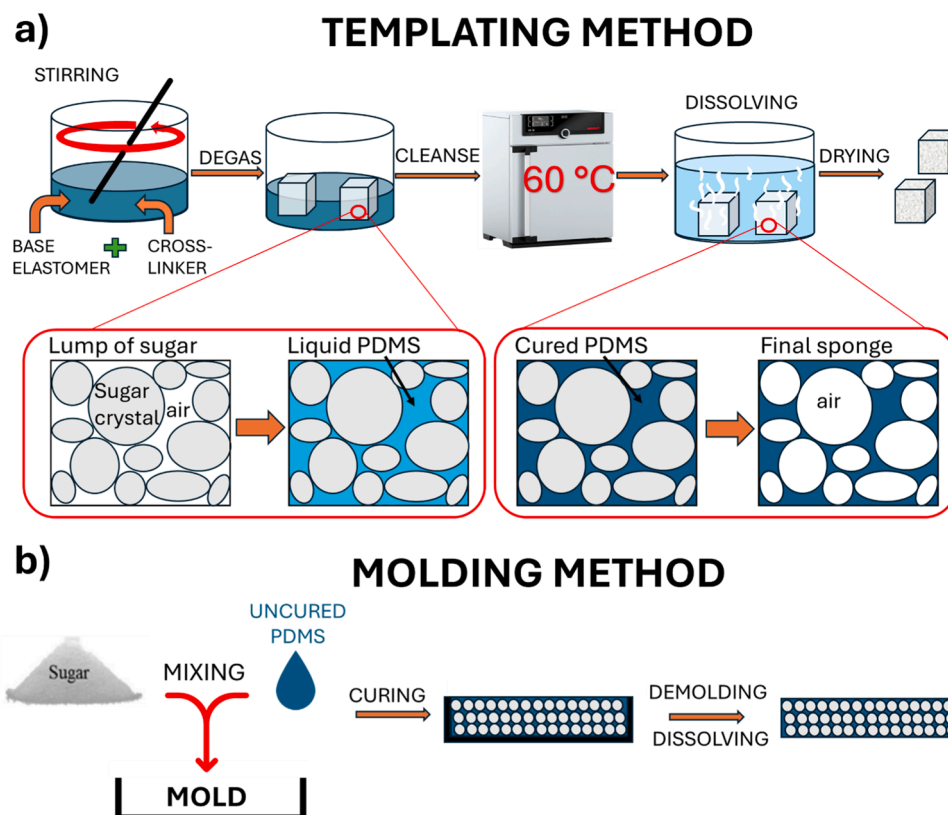

Fig. 1. a) Sketch of the templating method to obtain PDMS sponge sensor with a scheme of PDMS infiltration in the sugar cube and b) sketch of the molding method.

poured in a case. First of all, base elastomer and curing agent were mixed in 5:1 ratio and degassed. Later, commercial white sugar powder was added in a 3:1 wt ratio with respect to the uncured PDMS. For composite samples, Ag flakes were added to the blend at this point. The paste was vigorously stirred by hand for a couple of minutes to reach a sufficient degree of homogeneity and to avoid PDMS sediment. Thereafter, the mixture was poured on a mold, compacted, and cured in the oven at 60°C for 2 h. After the curing process, the sugar was washed away through a deionized water bath in a magnetic stirrer (60°C, 30 min) and the resulting molded porous foam was washed and dried. The main steps are summarized in Fig. 1b

2.3. Characterizations

The pressure sensors were assembled cutting PDMS foam in piece of 3 mm thickness and 1 cm² area and coupling with polyimide-copper foils as electrodes. Electromechanical performances of porous sensors were evaluated by means of compressive tests (at velocity of 10 mm min⁻¹) using a universal testing machine (FZ3- X500) while measuring electrical capacitance with a LCR meter (BK precision 894). For all the electrical measures a voltage amplitude of 500 mV and a

testing frequency of 300 kHz were used. Relative capacitance variations ($\Delta C/C_0$) were computed according to the following formula:

$$\frac{\Delta C}{C_0} = \frac{C(t) - C_0}{C_0}$$

where where C is the capacitance measured at a certain time t and C_0 is its value when sample is not subjected to any load. Sensitivity (S) was evaluated using:

$$S = \frac{\frac{\Delta C}{C_0}}{p}$$

where p is the pressure applied to the sample. Limit of detection was extracted with static test performed with calibration weights.

Electron microscope characterization was performed by Field Emission Scanning Electron Microscopy (FESEM, Zeiss Supra 40).

3. Results

Polymeric PDMS foam was produced using two different approaches. The first is a casting method with sugar cubes as a template (scheme in Fig. 1a). Sugar cubes were dipped into uncured PDMS and placed in a

vacuum container to facilitate the polymer infiltration in the space among the sugar crystals. Uncured PDMS excess was removed from the cubes surfaces to avoid the formation of a polymeric layer on the surface which prevents the accessibility of the pore. After thermal curing, the sugar was dissolved into deionized water leaving a polymeric porous structure. The advantages of this approach lay in its simplicity and reproducibility of the process to obtain polymeric foams, while the limitation resided in the shape of the final sample which is restricted to the starting sugar cube. With the aim of decoupling the shape of the sponge from that of the cubic sugar template a second approach based on a molding method (Fig. 1b) was used. In this approach, white sugar powder and uncured PDMS were mixed together in a 3:1 ratio by weight. The blend was then poured in a mold and cured to reach polymer reticulation. The sample was then demolded and the sugar dissolved in hot water bath leaving the final foam with desired shape.

Given that the polymeric foam can act as a highly deformable dielectric under mechanical stress, the prepared samples can work as pressure sensors exhibiting piezocapacitive properties. These properties were tested using mechanical compression cycles applied with a universal testing machine coupled with electrical impedance measurement. Firstly, the polymeric foam prepared with templating approach were tested. Fig. 2a and b show that the foam shape is strictly dependent on the sugar cube template used and evidence how the PDMS is able to infiltrate in the space among sugar crystals. Foam samples were prepared using 5:1 and 10:1 ratio of PDMS copolymer to curing agent to understand the role of the different mechanical properties of the polymer (i.e. higher content of curing agent will increase the rigidity of the bulk polymer). Stress-strain curves (Fig. 2c) evidence how the mechanical properties are similar for both foams since the porous structure dominates over the mechanical properties of the polymer, especially for lower deformation values. PDMS sponge sensors showed an increase in electrical capacitance under compression (Fig. 2d), due to the reduction in thickness. Both 5:1 and 10:1 foams showed the same behavior, thus for all the following samples presented in this work a 5:1 ratio of PDMS copolymer to curing agent was chosen due to the low viscosity of the mixture before polymerization, which facilitated the infiltration process into the pores of the sugar cubes. The porous structures easily deform under mechanical compression, resulting in a notable capacitance increase even at low pressures. The relative capacitance variation curve is not linear across the entire range but tends to grow slowly under higher pressures. This trend is expected and relates to the relationship between applied stress and induced deformation as shown in Fig. 2c. The PDMS sponge exhibited significant deformation under low stress because the pores close with low mechanical resistance. As the pores close completely, the mechanical resistance increases, and higher pressure results in only slight deformation. Low applied stress values are more relevant for wearable sensing, as this pressure range is typical in human-related applications [37]. The sensor's sensitivity in the 0–50 kPa range, where our sensor exhibits a linear trend with a slope of 0.014 kPa^{-1} , a value comparable to the sensitivity reported for porous sensors prepared using the template approach, whether operating via piezoresistive or piezocapacitive mechanisms [36,38,39]. Moreover, the sensors demonstrated excellent response stability and repeatability. This behavior is evidenced by the piezocapacitive analysis under different applied compression velocities and by the cyclic characterizations. Fig. 2e shows that sensor response is independent on the velocity of applied stress since the transfer curves completely overlap. At the same time the relative capacitance variation curve under ten compressive cycles shows a very good repeatability (Fig. 2f) and overlap of different cycles with almost negligible hysteresis. Excellent stability of foam response is observed also for a higher number of cycles (Fig. 2g). This behavior is attributed to the mechanical properties of the sensor, as the porous structure of the foam reduces the viscoelastic behavior of the PDMS polymer within the investigated pressure range. Moreover, the PDMS foam shows also a fast response to the applied strain, with response time and of recovery time below 500 ms (Fig. 2h), fundamental

properties for sensing applications.

To enhance the sensor's sensitivity, we explored the effect of incorporating a metallic filler into the polymer foam, which influenced both its mechanical and electrical properties. Silver nanoflake powder was added to the PDMS mixture before the sugar cube infiltration step at concentrations of 5 %, 10 %, 20 %, 40 %, 60 %, and 80 % by weight relative to the polymer. As the silver nanoflake concentration increased from 5 wt% to 80 wt%, the resulting sponges progressively darkened in color (Fig. 3a). However, the 80 wt% sample exhibited multiple structural voids due to the high viscosity of the precursor solution, which prevented effective capillary infiltration. Consequently, portions of the template remained composed solely of sugar, which were entirely removed during the template dissolution step. Due to these structural inconsistencies, the 80 wt% sample was excluded from electromechanical testing. Piezocapacitive characterizations (Fig. 3b) revealed that the relative capacitance variation increased with higher silver nanoflake content. Sensor sensitivity was evaluated across three pressure ranges (0–50 kPa, 50–150 kPa, and 150–250 kPa), where all samples displayed a linear response. Sensitivity was highest in the low-pressure range but decreased at higher pressures. This behavior corresponds to the stress-strain response of the porous foams. At low applied stress, the material undergoes significant deformation due to pore compression, whereas at higher stress levels, all pores are fully compressed, and only the polymer itself deforms. Across all pressure ranges, sensitivity increased with silver nanoflake content (Fig. 3c). The 60 wt% sensor achieved a sensitivity of 0.023 kPa^{-1} , marking a 65 % improvement over the bare PDMS sponge sensor. Previous works demonstrated that the addition of filler in porous polymeric structure improved the sensitivity in the piezocapacitive effect [40,41]. In this composite foam, increasing the filler content leads to a rise in the dielectric constant due to enhanced interfacial polarization between the conductive silver nanoflakes and the insulating PDMS matrix (or air). This increase in dielectric constant, derived from capacitive measurements using the parallel plate capacitor model, correlates directly with an improvement in pressure sensitivity. This relationship is evidenced by the overlapping trends of the two parameters shown in Fig. 3d. Cyclic testing demonstrated stable device performance with negligible hysteresis, even in composite foam sensors. In addition to sensitivity to applied stress, another key figure of merit for pressure sensors was analyzed. The limit of detection (LOD), defined as the minimum detectable weight with sufficient confidence, was determined using the sensor's response curve under extremely low applied pressures and the noise level of the electrical signal. It was calculated as three times the uncertainty of the zero pressure signal, a standard threshold used in spectroscopy to confirm resonance peaks and in biological assay statistics to validate data points (three times the standard deviation) [42–44]. While the LOD did not show a clear correlation with silver nanoflake concentration, it remained around 1 g (60 Pa) for all devices. These results highlight the potential of PDMS-decorated sponge sensors for detecting small pressures with high sensitivity.

The templating method, combined with the addition of silver fillers, successfully enabled the fabrication of highly sensitive pressure sensors. However, the main limitation of this approach lies in the geometric constraints imposed by using sugar cubes as templating structures. To overcome this restriction, a molding approach was explored for creating porous capacitive sensors, and devices fabricated using both methods were compared. Using the molding approach (Fig. 1b), foam-based sensors with various geometries were produced, both with pure PDMS and PDMS filled with silver nanoflakes. For this method, only 40 wt% and 60 wt% silver nanoflake concentrations were used, as previous characterization of templated samples indicated that foam sensitivity increase with filler content and these concentrations yielded the highest sensing response. Similar to templating approach, 80 % filler results in multiple structural voids in the final material, as the high viscosity of the precursor solution at this level prevented effective capillary infiltration. Fig. 4a presents an example of a dumbbell-shaped structure created

through molding with 60 wt% Ag-NFLs content, while SEM images highlight the porous structure and the uniform dispersion of the filler within the PDMS matrix. The piezocapacitive response of the molded foams closely resembled that of the templated samples. Sensitivity increased with the addition of silver nanoflakes (Fig. 4b), and cyclic deformation tests showed no hysteresis in the electrical signal (Fig. 4c). Sensitivity was evaluated across three pressure ranges, with the molded sample reaching a maximum value of 0.047 kPa⁻¹ for the 60 wt% composition in the low-pressure range. This sensitivity represents one of the higher values present in the literature for capacitive sensors using porous PDMS as dielectric layer, as evidences in the literature

comparison shown in Table 1.

A final comparison between the two fabrication approaches was conducted using both bare PDMS samples and composite foams containing 60 wt% silver nanoflakes. By analyzing the piezocapacitive curves and sensitivity (Fig. 5a–b), it was observed that the bare PDMS foams exhibited similar responses and sensitivities, regardless of whether they were produced via templating or molding. However, for composite foams, the molding approach led to a significant improvement in sensitivity, yielding nearly double the response compared to the templating method. This enhancement is attributed to the presence of larger pores in the molded foam structures, resulting from the

aggregation of sugar crystals during processing, as well as the lower uniformity in sugar dispersion compared to the consistent structure provided by sugar cubes in the templating method. To validate this hypothesis, a morphological analysis was conducted on 60 wt% Ag-NFLs templated and molded foams using electron microscopy to assess pore size distribution. The average pore size in the templated sample was found to be $415 \pm 124 \mu\text{m}$, whereas the molded foam exhibited a larger average pore size of $658 \pm 176 \mu\text{m}$. Both foams showed significant variability in pore size, primarily due to the non-uniform dimensions of

the initial sugar crystals and the complex geometry of the pores, which complicates visual analysis. Nonetheless, the consistently larger pore size observed in the molded samples is likely responsible for the higher pressure sensitivity exhibited by this foam sensor. Under equivalent compressive loading conditions, foam-based sensors with larger pore diameters undergo greater compressive strain relative to those with smaller pores, due to their intrinsically lower Young's modulus. This increased mechanical deformation yields a more substantial reduction in the dielectric layer thickness, thereby resulting in a more pronounced

increase in capacitance. These improvements were also reflected in the limit of detection (LOD), which was lower for the molded samples, reaching a value of 0.6 g, corresponding to 40 Pa (Fig. 5c).

The potential application of the prepared foams as wearable sensors was demonstrated by assembling a 60 wt% Ag-NFLs molded foam device with polyimide-copper foil electrodes in a sandwich configuration. The device was mounted on different parts of the body to assess its ability to detect various biometric signals. When placed on a finger, the sensor effectively monitored different bending angles, producing a stable signal over time with good repeatability, as indicated by the consistent response to identical bending angles (Fig. 5d). More notably, the sensor also demonstrated the ability to detect biometric signals characterized by subtle motions. When attached to the wrist of an adult male, it successfully measured the peripheral pulse wave, showcasing its potential for real-time health monitoring. As illustrated in Fig. 5e, the sensor accurately captured the pulse wave's shape, with characteristic points matching those reported in previous studies [45], confirming its capability to track heart rate. Additionally, when positioned on the throat, the sensor detected the minute vibrations of the vocal cords during speech. The capacitive signal patterns remained consistent when the same word (e.g., “hello”) was pronounced, with each syllable corresponding to a distinct signal peak (Fig. 5f). These findings suggest that the tactile sensor could serve as an alternative to microphones for speech recognition, particularly in noisy environments where traditional audio-based methods are unreliable.

4. Conclusion

In summary, a piezocapacitive wearable pressure sensor made from a soft, flexible polymer sponge was developed and studied. The PDMS sponge, enhanced with silver nanoflakes, was fabricated using two different approaches, a templating method, which involved capillary infiltration of the precursor solution into sugar cubes, and a molding method, where a slurry of sugar and uncured PDMS was cast into shape.

While the templating approach offers simplicity, it is constrained by the geometry of the template. This limitation is overcome by the molding method, which also provides greater sensitivity to applied pressure. The resulting sensors exhibit a piezocapacitive response, with compressive pressure sensitivity in the 0–50 kPa range, reaching up to 0.0473 kPa⁻¹ for molded foam with a 60 wt% concentration of silver nanoflakes. Additionally, the sensors achieve an impressive limit of detection (LOD) of 0.6 g (40 Pa). When tested as wearable devices, these sensors demonstrated their potential for lightweight, easily manufacturable applications capable of monitoring biometric signals in real-time.

Giorgio Mogli is a PhD student of Electric, Electronic and Communication engineering at the Department of Applied Science and Technology (DISAT) at Politecnico di Torino. He earned his Master's Degree in Biomedical Engineering from Politecnico di Torino in 2021. His research is mainly centered on the development of soft tactile sensors exploiting additive manufacturing techniques for wearables applications.

Matteo Costantini obtained his Master degree in Nanotechnologies for ICT at Politecnico di Torino in 2023 with a thesis work on the development of foam based capacitive pressure sensors.

Stefano Stassi is an Associate Professor of Matter Physics at the Department of Applied Science and Technology (DISAT) of the Politecnico di Torino. He obtained his Ph.D. in Physics from the Politecnico di Torino in 2013. Between 2014 and 2015, he was a visiting

researcher at the Lawrence Berkeley National Laboratory in Berkeley (CA), USA. His research focuses on the theory, fabrication, and characterization of nanomechanical resonant devices, the development of wearable flexible sensors based on piezoresistive and piezoelectric materials, and the fabrication of devices for mechanical energy harvesting, with particular attention to piezoelectric and triboelectric nanogenerators. He is the author of over 80 articles in international peer-reviewed scientific journals and co-inventor of one patent.
