Abstract

Attention deficit hyperactivity disorder (ADHD) is a heterogenous pediatric disorder that affects the neurodevelopment of the frontal cortex. ADHD patients exhibit combinations of inattention, impulsiveness, and/or hyperactivity. With early treatment and diagnosis, there is potential to modify neuronal connections and improve symptoms. However, the heterogeneous nature of ADHD, combined with its comorbidities and a global shortage of diagnostic clinicians, means diagnosis for ADHD is often delayed. Hence, it is important to consider other pathways to improve the efficiency of early diagnosis, including the role of artificial intelligence. In this study, we reviewed the current literature on machine learning and deep learning studies on ADHD diagnosis and identified the various diagnostic tools used. Subsequently, we categorized these studies according to their diagnostic tool as: brain magnetic resonance imaging (MRI), physiological signals, questionnaires, game simulator and performance test, and motion data. We identified research gaps include the paucity of publicly available database for all modalities in ADHD assessment other than MRI, as well as a lack of focus on using data from wearable devices for ADHD diagnosis, such as ECG, PPG, and motion data. We hope that this review will inspire future work to create more publicly available datasets and conduct research for other modes of ADHD diagnosis and monitoring. Ultimately, we hope that artificial intelligence can be extended

to multiple ADHD diagnostic tools, allowing for the development of a powerful clinical decision support pathway that can be used both in and out of the hospital.

1. Introduction

Attention Deficit Hyperactivity Disorder (ADHD) is a common childhood-onset neurodevelopmental condition. According to a 2016 World Health Organization-World Mental Health Surveys for 10 countries, the global prevalence rate of adult ADHD was found to be 2.8%, with a higher proportion in high-income countries, and a significant association with low education and male gender [1]. Children and adults with ADHD frequently exhibit three key symptoms: inattention, impulsivity, and hyperactivity, although symptoms are heterogeneous and individuals may display more or less of these individual symptoms, for example being classified as having inattention, or hyperactivity/ impulsivity or combined subtypes of ADHD [2].

There is increasing evidence that there are distinct differences in the structure and function of the brain in individuals clinically diagnosed with ADHD: in particular changes in neuronal connections between the specific brain regions, often accompanied by changes in brain volume on neuroimaging [3], [4] (Figure 1). These neuroanatomical differences have been linked to changes in individual's cognitive function, regulation of motivation and attention [5]. The brain's reward system, which predominantly uses the neurotransmitter dopamine, is altered in individuals with ADHD [6]. For example, the prefrontal cortex of an ADHD patient, in particular, was discovered to have abnormally low presynaptic dopamine storage [7], [8]; critically impairing the individual's attention function, cognitive process, and working memory. [7], [9].

This reward deficit syndrome has been linked to individuals with a diagnosis of ADHD being more prone to engage in behaviors that promote the production of dopamine in the brain, such as alcoholism, drug addiction, and even aggressive conduct [2]. Individuals with ADHD are, for example, twice as likely to have Substance Use Disorder (SUD) than those without [10]–[13]. For those individuals with comorbid conduct disorder, the risk of SUD is even higher - four times the rate in the general population [10].

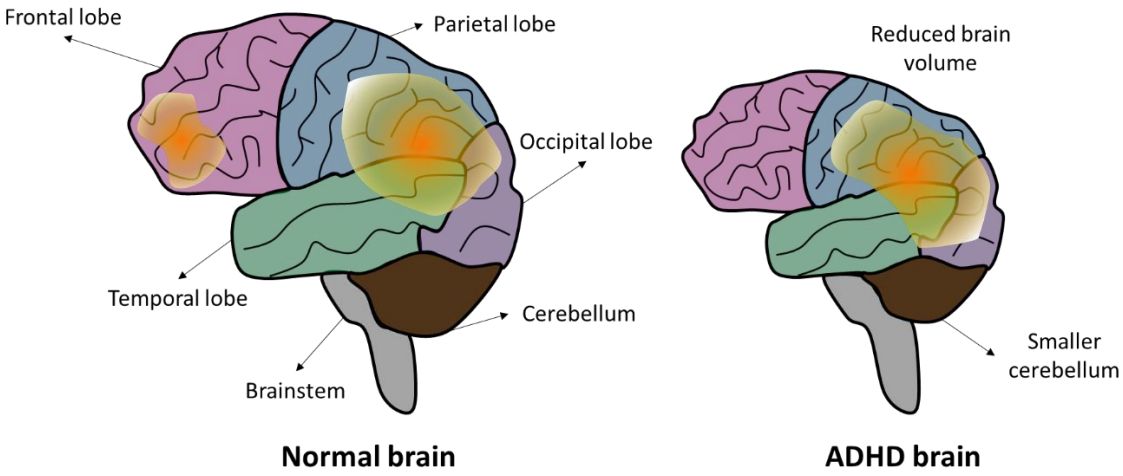

Figure 1. Schematic drawing of brains in neurotypical individuals and those diagnosed with ADHD. Yellow glowing regions represent regions of brain functional connectivity; individuals with ADHD have less neuronal connections to the prefrontal cortex as compared to normal brain.

Encouragingly, there is growing evidence that the neuroanatomical and functional changes may not be static. With appropriate early identification and treatment of ADHD symptoms, the neuroanatomy and function may resemble neurotypical individuals. For example, Mattfeld et al. [3] found that adults who had previously recovered from ADHD had restored normal brain connectivity while their minds are at rest, compared to adults who remained symptomatic with ADHD (Figure 1). Successful ADHD management can result in a significant improvement in quality of life and improved societal integration. Therefore, it is critical that ADHD is identified as early as possible, and management is evidence based, to optimize long term outcomes [14].

Currently, the diagnosis of ADHD is primarily a clinical one. An expert in ADHD diagnosis, typically a psychiatrist or specialist pediatricians, will conduct a series of clinical assessments to determine if an individual has five or more symptoms of inattention or impulsivity/hyperactivity and fulfil the DSM-5 diagnostic criteria [15]. However, clinical assessment by specialists takes a minimum of an hour, and there is a global shortages of trained specialist, meaning that diagnoses after often delayed [16]. For instance, Whitney et al. [17] reported that in Michigan, USA, there are only 11 trained psychiatrists to attend to over 100,000 children with likely mental health diagnoses. The ratio of psychiatrist-to-population is 11:100,000 for the United Kingdom, and 14:100,000 for Australia [18].

There is also evidence that adjunctive data may be helpful in diagnosing the full spectrum of individuals with ADHD, who may be overlooked or underrecognized by current clinical assessments [15]. For example, numerous studies had attempted to diagnose ADHD via neuroimaging modalities like Magnetic Resonance Imaging (MRI) [19], [20], physiological signals like electroencephalogram (EEG) [21], [22] and electrocardiogram (ECG) [23], and other modalities like accelerometers [24] and game simulators [25]. These studies aim to reduce the

workload of clinical diagnosticians by proposing artificial intelligence (AI) techniques, namely machine learning (ML) and deep learning (DL), for faster and more cost-effective ADHD diagnoses.

In this review, we aim to uncover all the different types of modalities that have been adopted by previous studies on automated ADHD diagnosis using ML or DL techniques. Machine learning is not a fully automated technique as feature extraction of the input information (e.g. MRI images, EEG, ECG, etc.) must be carried out manually, followed by feature selection of the most significant features which will ultimately be used to train the ML classifiers for automated diagnosis of ADHD [26], [27]. The DL model, on the other hand, is a fully automated process where input information can be analyzed in its original format. Hence, feature extraction and selection procedures are not mandatory in DL models [27].

2. Methods

The PRISMA guideline 2020 [28] was used in this systematic review to analyze the most relevant studies on ADHD diagnosis using either the ML or DL approach. Using the following Boolean search strings as shown in Table 1, all publications were systematically searched through PubMed, Google Scholar, IEEE, and Science Direct. All publications up to December 2021, were included in the first identification phase of the PRISMA flowchart, as illustrated in Figure 2. As a result, we began with 467 publications which was reduced to 298 after removing 165 publications with duplicated titles. Subsequently, we screened the title and abstract of the publications, and removed 165 articles that were either animal studies, conference papers, non-AI studies, non-English articles, books, review papers, and non-journal articles. We were left with 133 articles, which were downloaded and read thoroughly to assess its eligibility for this review study. Upon detailed screening of the article, we further removed more conference papers, non-journal articles, non-AI studies, review papers and irrelevant articles. We also removed articles that did not provide model accuracy results and articles which we had no access to. Finally, 91 journal articles were found eligible for inclusion in this review.

Table 1. Boolean search string used for all journal article databases.

	Boolean search string	
Database	**[Title]**	**AND [Title/Abstract]**
PubMed Google Scholar IEEE Science direct	"ADHD" OR "attention deficit hyperactivity disorder"	“Machine learning” OR “deep learning” OR “artificial intelligence

3. Results

In total, there were seven types of ADHD diagnostic tools utilized to develop AI models (Figure 3). These are discussed in the following results sections: MRI in subsection 3.1, physiological signals in subsection 3.2, questionnaire data in subsection 3.3, game simulation and performance tests in subsection 3.4, motion data in subsection 3.5, and all other studies in subsection 3.6.

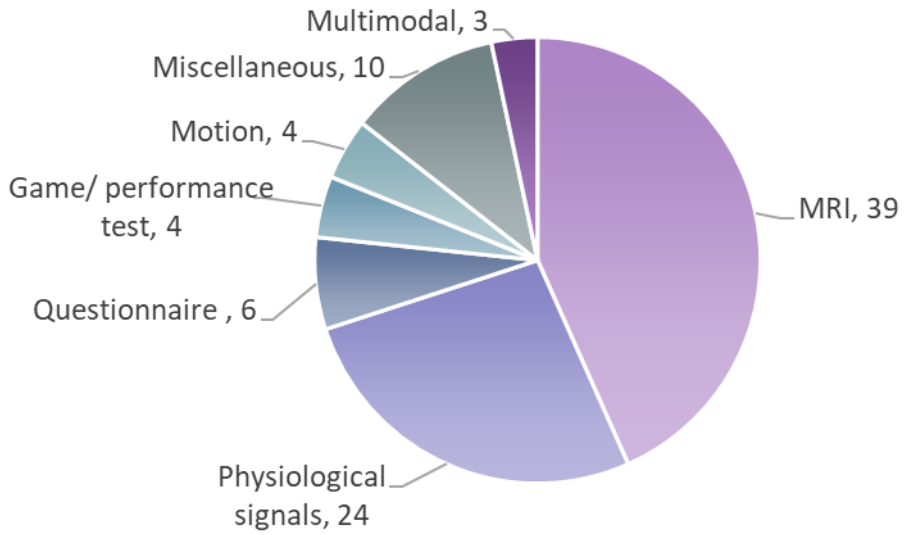

Figure 3. Pie chart representation of the ADHD assessment tools used in AI studies.

3.1 MRI

Brain MRI is the most widely studied modality for automated ADHD diagnosis, with 39 out of the 91 studies analyzing brain MRI images of ADHD patients and normal control (Table A.1). Most of the studies obtained their MRI images from one public database: the Neuro Bureau ADHD-200 Preprocessed repository (ADHD-200) [29] (Figure 4). ADHD-200 is a consortium that had collected structural and resting-state functional MRI images from 585 controls and 362 ADHD children and adolescents. Eight international imaging sites were involved in the data collection of ADHD-200, however, two out of the eight sites only provided MRI images of controls and not the ADHD individuals (Table 2). Hence, imaging data from these two sites are usually excluded from the studies. In this review, a total of 32 out of 39 MRI studies had used MRI images from ADHD-200 (Figure 4).

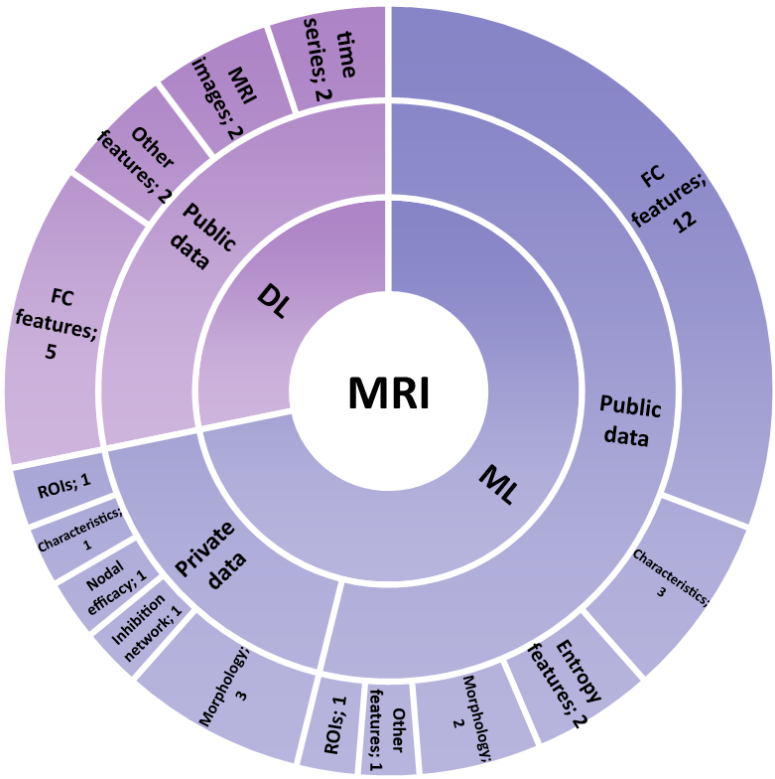

Figure 4. Sunburst plot of AI studies using MRI data. First level indicates type of AI studies, second level indicates type of dataset used, and third level indicates type of features used to train the AI models.

It is also evident in Figure 4 that ML occupied a bigger proportion than DL in the MRI analysis for ADHD; where 28 out of 39 studies had implemented ML techniques. In addition, brain functional connectivity is the most common input feature for ADHD diagnosis; 12 ML studies and 5 DL studies had utilized function connectivity (FC) features for their studies (Figure 4, Table A.1). Functional connectivity of the brain is presented in the form on a matrix, illustrating the connection between different areas of the brain [30]. Pearson correlation coefficient is commonly employed to measure if there is a strong correlation between the different brain regions, hence, resulting in a heatmap where strong and weak FC between the brain regions is evident [30].

3.2 Physiological signals

Twenty-four studies utilized physiological signals to detect ADHD, most commonly electroencephalogram (EEG: 23 studies) and electrocardiogram (ECG: 1 study) (Figure 5, Table A.2). We also observed that studies using physiological signals for the detection of ADHD had high model performances; all models had accuracy results above 80% for ML and DL (Table A.2). Only one [31] out of the 24 studies had used a public EEG database: the National Brain Mapping Laboratory of Iran [32]. The rest had used their own private datasets.

As for the type of feature most extracted from EEG signals, seven ML and three DL studies had attempted to obtain power spectral features (Figure 5). Spectral analysis of EEG involves decomposing the signal into medically established frequency sub-bands, namely, alpha rhythm (8–13 Hz), beta rhythm (13–30 Hz), delta rhythm (1–4 Hz), theta rhythm (4–8 Hz), and gamma rhythm (30–80 Hz) [33]. These frequency sub-bands are evidently different between children with ADHD and controls. A study by Kamida et al. [34] discovered that children with ADHD have higher beta activity in all brain regions except for the occipital region. Another study [35] which investigated the power spectral differences between ADHD of the inattentive type and the combined type found higher theta and alpha activities in the combined type, while higher theta/beta ratio was observed in the inattentive type.

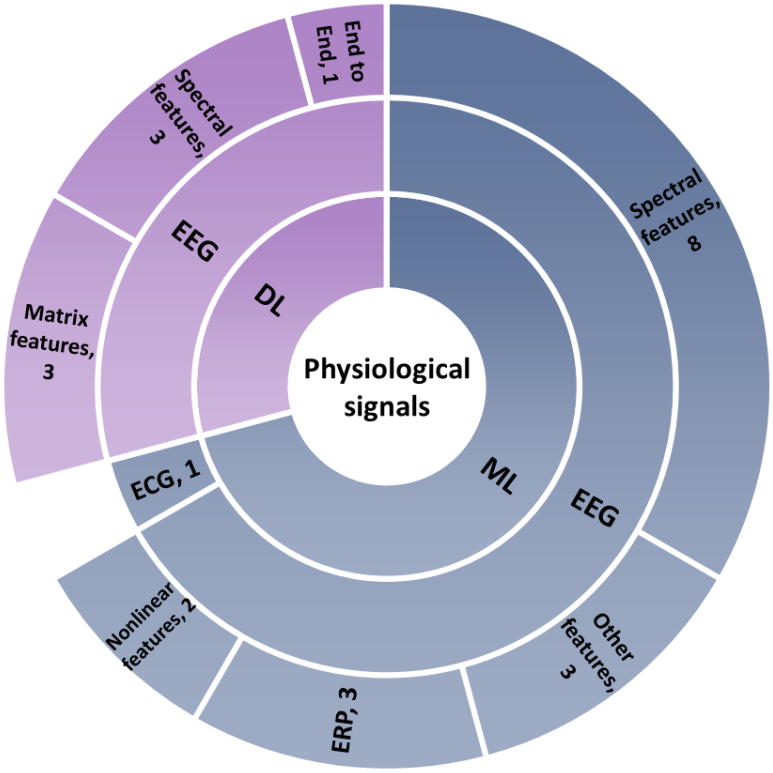

Figure 5. Sunburst plot of AI studies using physiological signals. First level indicates type of AI studies, second level indicates type of physiological signal, and third level indicates type of feature used to train the AI models.

There is only one study which utilized ECG signals (Figure 5). Even though ECG does not provide direct information on the brain activity, the autonomic nervous system links the brain to body interaction, causing fluctuations in physiological signals like ECG when an individual senses danger. For instance, an individual under acute stress will have significant increase in the heart rate (ECG) and the same phenomenon was also observed in ADHD individuals [23], [36]. Koh et al. [23] proposed ensemble ML classifier with entropy features extracted from ECG signals and detected ADHD individuals with high classification accuracy of 87.2%.

3.3 Questionnaires/ rating scales

There are various types of questionnaires or rating scales that medical professionals use to diagnose ADHD. In this section, there are only six studies that analyzed questionnaire/ rating scales data and only ML models were proposed (Table 3). It can also be seen in table 3 that decision tree (DT) classifier, including random forest classifier, are commonly proposed to analyze questionnaire data. We will only cover the questionnaires that studies have utilized to develop their best performing models (Table 3).

- **Conners' Rating Scales** are widely implemented to assess the social impact of ADHD, for example an individual's behavior in school or work [37]. Conners' parent rating scales (CPRS) used by Bledsoe et al. [38] is a parentally completed report, while Conners' adult ADHD rating scales (CAARS) used by Christiansen et al. [39], is a self-reported questionnaire.

- **Diagnostic Interview for ADHD in adults (DIVA)** [40] adopted by Tachmazidis et al. [41], is a semi-structured interview constructed based on Diagnostic and Statistical Manual of Mental Disorders, Fourth Edition (DSM-IV) criteria for ADHD diagnosis. The interview aims to assess the symptom of ADHD in five aspects of daily life: social contact; hobbies; self-confidence; relationships; work and education.

- **Behavior Rating Inventory of Executive Function – Preschool version (BRIEF-P)** is a 63-item questionnaire for parents or teacher to rate the child's executive functions such as emotions control, working memory, organization and planning skills [42]. This questionnaire was utilized by Öztekin et al. [43] to develop their ML model.

- **Adult ADHD Self-Report Scale (ASRS)** used by Kim et al. [44] is created by the World Health Organization and it consists of 18 items based on the DSM-IV criteria. ASRS is a symptoms checklist for individuals to self-evaluate if they exhibit any symptoms relating to ADHD [45].

- **Minnesota Multiphasic Personality Inventory-2 (MMPI-2)** is a 567-item questionnaire where individuals are only required to answer 'true' or 'false' [46]. MMPI-2 is also used by Kim et al. [44], alongside ASRS to develop their ML model, and it is widely implemented to assess various mental health problem apart from ADHD such as depression, anxiety, and psychopathy [46].

- **Social Responsiveness Scale (SRS)** is a 65-item questionnaire that attempts to measure the social ability of individuals between ages 4 to 18 years [47]. This questionnaire is adopted by Duda et al. [48] to differentiate ADHD individuals from patient with Autistic Spectrum Disorder (ASD).

3.4 Game simulation and performance tests

This section discusses the use of conventional performance tests and game simulation to diagnose ADHD. There are two ML studies each, which utilized performance tests and game simulation respectively, to train their model (Table 4). Continuous Performance Test (CPT) and Reverse Stroop task (RST) are neuropsychological tests to evaluate the selective and sustained attention of an individual [49], [50]. The CPT is a computerized test which requires participants to react correctly to a specific stimulus [25]. For instance, participants are told to press the spacebar for all letters except for 'O'. In traditional Stroop task, participants are given words, for example 'Blue', which can be presented in different colors: '**Blue**' (incongruent color red), '**Blue**' (congruent color blue), and '**Blue**' (neutral color black). Participants are then required to provide the color of the word, instead of the meaning of the word. Hence, in RST, the task is reversed where participants have to read out the meaning of the word regardless of the color it is printed in [51].

As for game simulations, its main purpose is creating an interactive environment that is customizable to best suit the user's needs [25], [52]. Yeh et al. [52] created a virtual reality (VR) classroom and incorporated a series of tests, including CPT, for ADHD diagnosis. In their VR system, some 'distractions' such as 'teacher standing up', 'door open', or 'thunder shower', were also included. They then recorded the test results, reaction time, and focus time for the user to complete the test. On the other hand, Heller et al. [25] utilized a videogame known as 'Groundskeeper' that is specially developed by CogCubed [53] for early ADHD detection. They extracted 33 game data variables, and trained four different ML classifier: random forest,

AdaBoost, J48, and JRip. However, they did not specify which classifier provided the best performance result.

Table 4. Summary of list of AI studies that used standard performance test or game simulation data to develop their model.

Author [ref]	Private datasets	Mode	Tests	ML models	Accuracy
Slobodin et al. [54]	213 ADHD 245 normal	Performance	CPT	Random Forest	87.0

Yeh et al. [52]	37 ADHD 31 normal	Game	VR system	SVM	83.2
Heller et al. [25]	26 ADHD 26 normal	Game	Groundskeeper (CogCubed)	-	78.0

3.5 Motion data (actigraphy & accelerometer)

Motion activity can also be a diagnostic marker for ADHD. In this section, two types of motion activity measure - actigraphy and accelerometer - are covered along with the four studies that utilized these motion data as listed in Table 5. Both actigraphy and accelerometer data are recorded via an accelerometer device that is usually worn on the wrist of the dominant arm and ankle of the dominant leg [56], [57]. The difference between the studies that analyzed the two types of motion data is the type of activity the subject is doing; actigraphy studies the subject's sleep efficiency [56], whereas accelerometer analyzes the subject's motion during normal daily activities [57]. As such, there are some studies that reported ADHD patients exhibited more movement than the controls during sleep [58] which correlates to increased daytime sleepiness [59]. This demonstrates that increased activity level is a well-known feature of ADHD, which is also reflected in their daily routine, and can be easily monitored with wrist-worn accelerometer devices [60], [61].

In either case, the accelerometer device used to record the motion data is designed to be unobtrusive, allowing the participants to be natural in their own environment. This would not be possible with EEG or polysomnography recording procedures because data collection takes place in a laboratory that the participants are unfamiliar with, and they are also required to attach a large number of electrodes, which can be very uncomfortable [62]. This, in turn, may have an impact on the quality of data collected.

Table 5. Summary of AI studies that used actigraphy or accelerometer data.

Muñoz-Organero et al. [63]	11 ADHD 11 normal	Accelerometer	Acceleration image	DL (CNN)	93.8

3.8 Miscellaneous (pupillometric, twitter and genetic)

In this section, we cover the least common modalities of ADHD diagnosis that ML studies have used. Two ML studies had utilized pupillometric data while only one study had analyzed twitter data (Table 6).

Interestingly, studies have shown that the brain norepinephrine system which is associated to pupil-size dynamics, is found to be impaired in ADHD patients [64]. Another study has also demonstrated that ADHD patients (off-medication) have decreased pupil diameter when performing visuo-spatial working memory task as compared to the controls [65]. This could be due to the difficulty in suppressing saccadic eye movements in ADHD patients who need to fixate [66]. Hence, uncontrollable eye movement in ADHD patients can be a potential biomarker for diagnosis, as Varela Casal et al. [66] and Das et al. [64] have implemented in their ML studies.

With the rise of social media, Twitter has become a potential platform of ADHD detection among the Twitter users [67]. A majority of the mentally ill are reluctant to seek help from mental health care professionals, which results in gradual accumulation of suicidal thoughts in the absence of professional help [68]. Hence, social media platform like Twitter, has become a source of comfort for these individuals to discuss mental health issues openly, as they seek connection and support from people of the same community [69]. Therefore, social media platform can be utilized for early detection of various mental illnesses and intervene suicidal actions [69]. In the study by Guntuku et al. [70], they identified highly correlated topics in Twitter and used it as a learning feature for their support vector machine (SVM) classifier (with 76% accuracy).

Table 6. Summary of AI studies that used pupillometric or Twitter data to develop their model.

There is a known genetic influence on the likelihood that an individual will be diagnosed with ADHD [71], [72]. Numerous twin studies have reported a high heritability estimate of approximately 80% for both monozygotic and dizygotic twins [73]. ML and DL have recently been applied in seven studies to help identify ADHD genetic biomarkers. A summary on the four ML and three DL studies for ADHD are listed in Table 7. However, it is important to note that the genetic biomarkers identified [74]–[78] in Table 7 did not follow the standard genome-wide association studies (GWAS), which identify risk genetic variants via its significant P-values (i.e. not be lower than 5×10^{-8}) [75].

Table 7. Summary of AI studies that used genetic data to develop their model and identify ADHD genetic variant.

Author [ref]	**Dataset**	**Model**	**Findings**
Sokolova et al. [74]	87 ADHD 77 normal	ML (Bayesian Constraint-based Causal Discovery algorithm)	DAT1 risk haplotype only has direct influence on the ADHD inattentive type.
Liu et al. [75]	1033 ADHD 950 normal	DL (CNN)	EPHA5 is identified as a potential risk gene of ADHD. Model diagnostic accuracy = 90.2%
Liu et al. [76]	116 ADHD 408 normal	DL (MLP)	GRM1 and GRM8 genes are identified to have the highest weight in ADHD diagnosis Model diagnostic accuracy = 78.0%

Esteller-Cucala et al. [79]	20,000 ADHD 35,000 normal	DL (Approximate Bayesian Computation coupled + deep learning framework)	Frequency of ADHD-risk alleles decreased since ancient time and have become maladaptive in today's society.
Cervantes-Henríquez et al. [77]	408 ADHD	ML (ensemble)	The proposed model identifies ADGRL3, DRD4, and SNAP25 genes as contributing to the severity of ADHD.
Sudre et al. [80]	362 ADHD	ML (Random Forest)	Participants with the highest polygenic risk score for ADHD usually have worsening symptoms.
Jung et al. [78]	39 ADHD 34 normal	ML (SVM)	The proposed model identified the COMT gene as having an impact on the abnormal development of the frontal cortex in ADHD patients.

4. Discussion

The 'gold standard' to diagnose ADHD usually relies on a combination of neuropsychological tests, rating scales, behavioral observations, examinations, and evaluation of the impact of treatment trials [81]. This is time consuming and limited by the number of trained diagnostic specialists globally. We reviewed the accuracy of the application of ML and DL to a range of well-established diagnostic tools, such as questionnaires/ rating scales, as well as more innovative diagnostic tools, including MRI and EEG, as summarized in Table 8. All but three ML studies adopted single modality approaches for ADHD diagnosis, however a multimodal approach may be well suited to ADHD, due to its heterogeneous clinical nature.

Table 8. Summary of AI studies using multiple modalities to develop their model.

It is estimated that 60 to 100% of ADHD children will develop one or more comorbid mental health or behavioral disorders as they reach adulthood [85], [86] including conduct disorder, depression, autism spectrum disorder (ASD) and bipolar disorder. The presence of comorbidities can make accurate diagnosis even more challenging [87]. An accurate diagnosis is required in order to tailor appropriate therapies. The preliminary evidence reviewed in this study suggests that AI can play a helpful role in diagnosing individuals with ADHD with and without comorbidities. There are nine ML studies in this review that had attempted to differentiate ADHD from other mental disorders or diagnose ADHD in individuals with a range of comorbidities (Table 9).

Table 9. Summary of AI studies that had considered other comorbidities of ADHD.

In total, we report on 68 ML studies and 23 DL studies for ADHD diagnosis. SVM is the most commonly used classifier in ML research, while convolutional neural network (CNN) is the most commonly proposed model in DL research (Figure 6). This is not to say that SVM or CNN are superior to other ML or DL models. The suitability of an ML or DL model is determined by the type of dataset and feature used to train the classifier, while the practicality of the ML or DL model is determined by a well-structured clinical trial in which their models are tested in real clinical settings with direct interaction with ADHD patients [27]. There is definitely scope for improvement with AI methodology for ADHD diagnosis before it can be considered for clinical use. From Figure 7, we can see that DL research started only in 2017 and has yet to reach maturity in its technological advancement, whereas the percentage of ML studies has declined with the rise of DL research. This is not surprising given the large number of ML studies in ADHD diagnosis, which has made it extremely competitive and difficult for new studies to outperform previous ones. The average model accuracy reported by these ML and DL studies has remained stable between 80 and 90% since 2013. Nonetheless, the rapid increase in AI studies in recent years, as technology advances, indicates that computer-aided ADHD diagnosis is improving. As such, we hope to encourage more DL studies in ADHD diagnosis so that its feasibility can be demonstrated, and a clinical trial can be conducted.

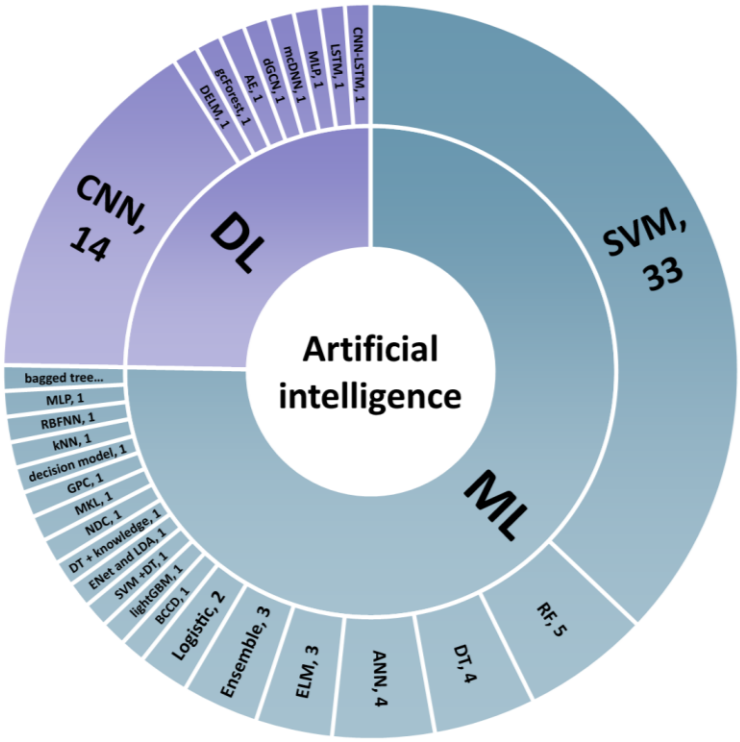

Figure 6. Sunburst plot of AI studies analyzed in this review. First level indicates type of AI studies, and second level indicates type of classifier proposed by AI studies.

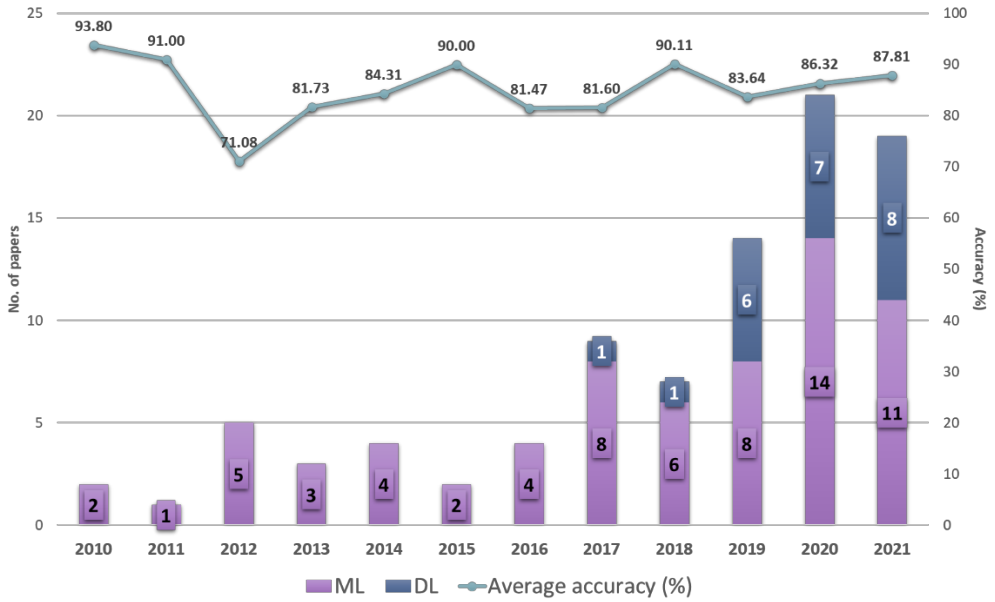

Figure 7. Bar chart representation of the number of AI studies in ADHD diagnosis published across the years from 2010 to 2021. Line graph represents the average model accuracy of AI studies across the years.

In summary, the significance of this review is as follows:

- We have followed PRISMA guideline and gathered 91 AI studies for this review.
- From the 91 studies, we have categorized them according to the type of modality or dataset used to train their model for ADHD diagnosis. Namely, MRI, physiological signals, questionnaires, game simulation, performance test, motion data, and miscellaneous which includes pupillometric, twitter and genetic data.
- For modalities like MRI and EEG signals, which are adopted by a large number of studies in this review, we have identified the most commonly used features for ADHD diagnosis, which is functional connectivity features and power spectral features for MRI and EEG respectively.
- For studies that have used questionnaire/ rating scales data, we have listed the standard ADHD assessment questionnaires that have successfully helped ML models to achieve high diagnostic performance.
- We have also identified ML studies that have utilized parameters from computerized neuropsychological tests like RST and CPT for ADHD diagnosis. This could reduce the burden on clinical diagnosticians if AI can analyze the performance result in their place.
- Two studies had attempted to create a customizable environment for ADHD diagnosis. One study had also created a virtual reality environment to conduct a CPT test [52]. Another study had used game parameters for ADHD diagnosis [25].
- We identified a small number of studies that used motion data from accelerometers and actigraphy- they prioritized subjects' comfort and collected motion data in the subjects' natural environment.
- Lastly, we identified a small number of studies using pupillometric and Twitter data. We also found a few studies that used both ML and DL on genomic sequencing data to help identify genetic biomarkers for ADHD.

This review also has some limitations:

- Apart from the popular ADHD-200 MRI database, the scarcity of large publicly available ADHD databases for the rest of the modality category caused majority of the studies in this review to use private datasets.
- For private datasets, the number of subjects and the methods used to collect data varied greatly.
- Even for study that had used ADHD-200 database, the number of subjects included in their studies varied greatly as well.
- It is difficult to compare the results of ADHD studies as different datasets were used, and there was a great variation in the number of subject and data acquisition methods.

5. Future direction for AI in ADHD diagnosis.

There are several future research pathways that could be followed to further explore the use of AI as a clinical decision support tool for ADHD. One optimal pathway could be the use of a cloud system, as depicted in Figure 8, that has unified data covering all ADHD diagnostic tools. As a result, clinicians could have ready access to all the information needed to confirm a diagnosis. For example, parents, teachers, or ADHD patients could complete the questionnaires on their own and have the AI models in the cloud system analyze the questionnaire data for psychiatrists or pediatricians. Questionnaires have the potential to be open to bias, and somewhat subjective interpretation, whereas wearable devices, on the other hand, may be able to provide objective measurements that provide a useful adjunct to ADHD diagnosis. There is also scope for researchers to apply AI not only as part of a diagnostic pathway, but also as a precision medicine clinical decision support system to help with tailoring and monitoring treatments.

Firstly, it is critical that more publicly accessible ADHD databases are available. Other than the publicly available MRI ADHD-200 database, which was used by 32 studies in this review, other studies needed to utilize private datasets. Since ADHD is a heterogenous disorder, it is important that databases of different types of ADHD diagnostic tools are available. In particular physiological signals (ECG) and motion data (accelerometer), would be highly desirable, as these were the biological tools that have shown more effectiveness representing the inattentiveness, impulsiveness, and hyperactivity symptoms of individuals during their daily routines.

Secondly, further exploration of the utility and effectiveness of wearable devices for ADHD diagnosis and monitoring would be warranted. Currently, only ECG signals and motion signals gathered from accelerometers are suitable to be collected from wearable devices. However, very few AI studies have attempted to use these data to diagnose ADHD; only one study used ECG signals, while four studies used motion data. There is also another study that had used heart rate variability (HRV) for ADHD diagnosis, but no accuracy data was reported hence this study was not included in this review [91]. Nonetheless, this shows that HRV is also another possible parameter for ADHD diagnosis. Another parameter that could be explored is photoplethysmography (PPG) signals which can easily be acquired from smartwatches, smartphones and oximeters [92]. An advantage of PPG signals is that they have low bandwidth requirements which do not deplete battery's capacity excessively [93], making them excellent candidates for signals storage in a cloud system, as shown in Figure 8. Ambulatory signal collection is also very helpful in telehealth situations, which is increasingly being used clinically since the COVID-19 pandemic.

Furthermore, despite the large amount of AI research in MRI and EEG for ADHD diagnosis found in this review, it is important to note that neither diagnostic tool is currently used by psychiatrists or pediatricians to diagnose ADHD in routine clinical settings [94], [95]. As both diagnostic tools can only be used in hospital settings or laboratories, gathering data from individuals with a diagnosis of ADHD is a time-consuming and expensive process [95], [96]. MRI requires patients to be still, which can be particularly challenging for people with ADHD, resulting in a higher chance of motion artifacts that render interpretation very difficult [97], [98]. Therefore, wearable

devices such as PPGs or accelerometers may be better suited as data acquisition devices for ADHD patients and should be investigated further for future AI studies.

AI methodologies like ML and DL can suffer from poor interpretability [99], [100]. Because of the complicated algorithm used to derive the result, DL models are referred to as a "black box", and clinicians find it hard to understand their outputs. The poor interpretability of AI algorithms has hampered their adoption in healthcare as a clinical decision support tool [101]. Therefore, future work for DL models should focus on the explainability of the model. For instance, there are a few techniques such as LIME, SHAP or integrated gradients, that can improve the interpretability of ML or DL models [102]. We hope to encourage the development of a practical AI model for ADHD diagnosis and monitoring, which will be an important component of the cloud system depicted in Figure 8.

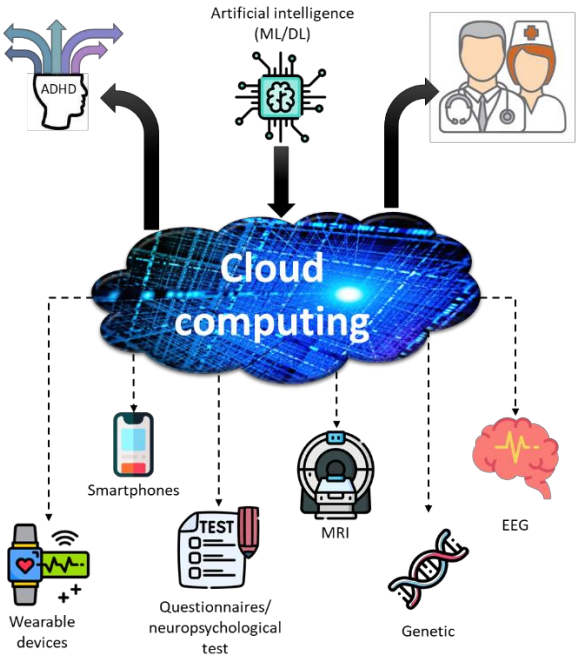

Figure 8. Cloud system designed for ADHD diagnosis and monitoring.

6. Conclusion

This review surveyed various ADHD diagnostic tools and included studies that used ML and DL AI techniques to perform the diagnosis. Ninety-one studies were determined to be eligible for this review, and they were further subdivided into their respective modalities for critical analysis. As a result, we notice that the majority of the studies were inclined towards hospital settings modalities like MRI and EEG, while the rest of the modalities were reported by very few studies. In addition, there was lack of publicly available dataset for the majority of the modalities except for MRI. There were limited studies using data acquired from wearable devices like ECG and accelerometer, and there were no studies that attempted to use PPG signals. Therefore, we propose that future research should focus on developing more publicly available datasets for the

other modalities in ADHD assessment and develop AI models that utilized data from wearable devices for ADHD diagnosis and monitoring. We also suggest future AI studies in ADHD to improve the interpretability of their models to encourage adoption in healthcare. With more robust research in AI techniques, a cloud system capable of reaching out to various ADHD diagnostic tools could become a reality and serve as an indispensable clinical decision support tool for clinicians.
