## ABSTRACT

Mayonnaise is a stable liquid-liquid emulsion with high content of the dispersed oil phase. In the last step of its production, the emulsion is fluxed into a high-shear mixer, where the oil droplets undergo breakage until the final size distribution is reached. This step is crucial to fine-tune the droplet size distribution (DSD), in order to result in the desired structure, stability, taste, and color. In this work, we aim to model this last step via computational fluid dynamics (CFD) and population balance modeling (PBM), to properly describe both the non-Newtonian dynamics of the emulsion and the evolution of the DSD. 2D and 3D CFD simulations show that attention should be paid to the grid resolution to properly describe recognizable patterns observed in experiments. Moreover, CFD and PBM simulations clarify the role of the pre- and post-mixing zones in the high-shear mixer, as well as the effect of the type of flow, pure shear vs elongational, on droplet breakage. We thus propose a physics-based model as a computational tool in order to possibly develop a digital twin of the industrial food emulsion preparation.

---

## 1. Introduction

Emulsions are constituted of two immiscible liquid phases of which one is dispersed in the form of drops. Mayonnaise, the food emulsion investigated in this work, is made of a continuous aqueous phase and a dispersed phase with high content of oil. The stability of the dispersion is provided by molecules present in the egg yolk that act as surfactants and accumulate at the oil-water interface preventing the coalescence of the oil droplets. The droplet size distribution (DSD) is the most important property of the emulsion since it determines the structure, stability, taste, and color of the final product (McClements, 2005). The DSD in turn depends on the composition of the system, the type of process, and the operating conditions in which the production process operates (Walstra, 1993). In general, the production of emulsions is based on mixing the ingredients and applying enough mechanical energy to reach the desired DSD. In the case of mayonnaise, this is accomplished by first mixing the ingredients (mainly egg yolk, vinegar, oil, and water) in large stirred vessels at moderate rotational speed, and subsequently feeding such premixed emulsion into a high-shear device. Several high-shear devices are used in the process industry (Icardi et al., 2011; Lince et al., 2011; Marchisio et al., 2008; Vashisth et al., 2021) and for emulsions a popular option is the cone mill mixer, where the oil droplets undergo breakage until the final DSD is reached. This last step is crucial to fine-tune the DSD, in order to determine the properties of the final product.

ORCID(s):

16 A typical cone mill mixer is constituted of a solid conical frustum rotor inside a slightly larger stator of the same  
17 shape, forming a small gap in which the emulsion flows and experiences high shear stresses, due to the high rotational  
18 speed of the rotor. The emulsion, before transiting through the high-shear region, flows into a pre-mixing chamber,  
19 followed by a post-mixing chamber.

20 Over time several attempts to model the DSD of mayonnaise have been made (Almeida-Rivera and Bongers, 2010;  
21 Dubbelboer, 2016; Dubbelboer et al., 2016; Maindarkar et al., 2014; Wieringa et al., 1996), but there are still many  
22 issues that need to be completely understood. For example, in the range of shear stresses developed inside the cone  
23 mill, highly concentrated emulsions show non-Newtonian dynamics, depending on both the oil content and the DSD,  
24 that need to be accounted for (Barnes, 1994; Dubbelboer, 2016). In addition, when processing very viscous liquids  
25 the cone mill operates in the laminar regime; however, a simple Poiseuille-Couette flow field can undergo a transition  
26 to the Taylor-Couette regime above a critical operating condition (Li et al., 2010, 2014; Noui-Mehidi et al., 2005;  
27 Wimmer, 2000; Wimmer and Zierep, 2000), where counter-rotating toroidal vortices (also known as Taylor vortices)  
28 appear. Since the transition to Taylor vortices depends strongly on the geometry of the system (Wimmer, 2000) and the  
29 contribution of the axial flow component that has a stabilizing effect on the formation of these instabilities (Giordano  
30 et al., 1998), a detailed flow field analysis must be carried out in order to predict the occurrence of these peculiar flow  
31 patterns. Previous modeling efforts focused on the high-shear zone in the cone mill, while the role of the pre- and  
32 post-mixing zones, before and after the high-shear region, was not investigated (Dubbelboer et al., 2016; Janssen and  
33 Hoogland, 2014; Maindarkar et al., 2014; Vashisth et al., 2021), neglecting their effect on the final drop size. Moreover,  
34 the influence of the local type of flow on drop breakage, namely pure-shear versus elongational, is not completely clear  
35 (Lupieri et al., 2021; Zinchenko and Davis, 2015).

36 Here, we aim to model this last step of the mayonnaise production process in a cone mill by means of 2D and 3D  
37 computational fluid dynamics (CFD) simulations and population balance modeling (PBM) in order to: (1) properly  
38 describe the non-Newtonian dynamics of the emulsion, (2) investigate the role of the pre- and post-mixing zones and  
39 (3) clarify the importance of the local type of flow. In particular, although mayonnaise consists of two distinct phases,  
40 high internal phase emulsions can be considered as a shear-thinning pseudo-single phase system with an apparent  
41 density and viscosity. Although neglecting the distinct characteristics of both oil and water may lead to inaccurate  
42 predictions (Li et al., 2015), many previous works modeled highly concentrated emulsions showing a shear thinning  
43 non-Newtonian rheological behavior as a pseudo-single phase (Alade et al., 2020; Bulgarelli et al., 2021; Dubbelboer  
44 et al., 2016; Goodarzi and Zendejboudi, 2019; Janssen and Hoogland, 2014). This hypothesis is consistent and strictly  
45 related to the mean field model, which assumes simply that the breakup of a droplet in a concentrated emulsion is  
46 determined by the average emulsion viscosity rather than the continuous phase viscosity (Jansen et al., 2001). The  
47 apparent emulsion viscosity, as a function of oil content, was evaluated through fitting of experimental data, by using a

48 power law model with a plateau at the high shear rate end (Dubbelboer, 2016). In order to describe the evolution of the  
49 DSD, the Population Balance Equation (PBE) is employed, in which the coalescence and breakage of the oil droplets  
50 are taken into account by appropriate kernels, which in turn depend on the local flow conditions, which range from  
51 rotation to pure-shear and finally to elongation, depending on the relative contribution of rotation and strain. In fact,  
52 while the gap section mostly exhibits a simple shear flow, a component of elongational flow is expected in the pre- and  
53 post-chambers of the cone mill that may contribute to the droplet breakage (Maffettone and Minale, 1998). Previous  
54 PBM were not capable of providing accurate predictions due to their restrictive assumptions, since coalescence was  
55 neglected (Almeida-Rivera and Bongers, 2010; Wieringa et al., 1996). In fact, although cone mills are designed to  
56 promote drop breakage, colliding droplets may coalesce under certain conditions (Maindarkar et al., 2014, 2012).  
57 Moreover, the individual and combined influence of the local type of flow (simple shear and elongational) on the  
58 final drop size can be elucidated by suitably applying a more accurate method for the solution of the PBM. Here, the  
59 Quadrature Method of Moments (QMOM) (Lavino et al., 2021; Marchisio and Fox, 2013; Marchisio et al., 2003a,b;  
60 Mazzei et al., 2012; McGraw, 1997; Sierra-Pallares et al., 2012) is used in order to solve the PBE, whereas CFD  
61 simulations are performed with the open source CFD code OpenFOAM (version 6.0) (Buffo et al., 2016b; Passalacqua  
62 et al., 2018).

63 This paper is organized as follows: Section 2 summarizes the main equations used to describe the flow field and the  
64 DSD evolution, Section 3 reports the details about the simulation test cases and their implementation into OpenFOAM,  
65 Section 4 focuses on the most important results obtained, and finally Section 5 presents the main conclusions of this  
66 work.

## 67 **2. Theoretical background**

68 The emulsification within the rotor-stator system investigated in this work is a steady-state process. Therefore, the  
69 well-known momentum balance equation for an incompressible, non-Newtonian, and stationary flow is solved in order  
70 to obtain the flow field (Bird et al., 1960). In this geometry, the centrifugal force that acts on the rotating fluid is not  
71 perpendicular to the surfaces of the rotor and stator. The flow field between two coaxial conical cylinders can present  
72 instabilities, known as Taylor vortices (Wimmer, 2000). These vortices are superimposed to the main Couette flow  
73 with an axial throughput (Giordano et al., 1998). For such a particular system, very different flow patterns can develop  
74 inside the cone mill with varying operating conditions (Noui-Mehidi et al., 2005); however, as it will be shown in  
75 Section 4, the conditions investigated in this work only result in the appearance of laminar Taylor vortices. Therefore,  
76 the implementation of a turbulence model is not necessary since the cone mill is designed to operate under laminar  
77 conditions when processing very viscous liquids that exhibit a shear thinning non-Newtonian rheological behavior like

78 mayonnaise (McClements, 2005). This condition is also verified here in line with previous works (Dubbelboer et al.,  
79 2016; Lupieri et al., 2021).

80 In order to evaluate this particular flow pattern, the Reynolds number in the cone mill gap is calculated as follows:

$$\text{Re}_{\text{gap}} = \frac{\omega R_{\text{max}} d}{\langle v_{\text{emul}} \rangle}, \quad (1)$$

81 where  $\omega$  is the angular velocity of the rotor and  $d$  is the distance (gap) between the rotor and the stator. In general, the  
82 Reynolds number for the investigated system is not constant, since the rotor radius increases from the top to the bottom  
83 of the cone mill and the viscosity changes locally as a function of the local shear rate  $\dot{\gamma}$ . Therefore, the maximum rotor  
84 radius  $R_{\text{max}}$  and the volume-averaged kinematic apparent viscosity of the emulsion  $\langle v_{\text{emul}} \rangle$  are used in Equation (1).  
85 This corresponds to the definition used in previous simulation works with whose results we compared our work. For  
86 specific operating conditions, it is a good approximation to only consider the volume average of the emulsion viscosity  
87  $\langle v_{\text{emul}} \rangle$ , since the local shear rate inside the gap section of the cone mill mostly depends on the tangential velocity  
88 gradient. As it will be shown in Section 4, the tangential component of velocity shows a linear profile (and a constant  
89 gradient) along the gap width for a specific rotor radius. On the other hand, along the height of the cone mill, there are  
90 just small variations of the tangential velocity gradient, since the difference between the maximum and the minimum  
91 rotor radius is small (see Figure 2).

92 As regards the pre- and post-mixing zones, the Reynolds number is defined instead as  $\text{Re} = \langle U \rangle d_{\text{max}} / \langle v_{\text{emul}} \rangle$ ,  
93 where  $U$  is the velocity magnitude,  $d_{\text{max}}$  is the maximum cone mill diameter of the pre- and post-mixing zones, while  
94 the symbol  $\langle \cdot \rangle$  indicates a volume-average in the pre- and post-chamber of the cone mill (for  $\text{Re}_{\text{pre}}$  and  $\text{Re}_{\text{post}}$  in Table  
95 1, respectively).

## 96 2.1. Non-Newtonian rheology model

97 In order to properly describe the non-Newtonian dynamics of the emulsion, the fluid is considered as a shear-  
98 thinning pseudo-single phase system, with an apparent emulsion viscosity  $\eta_{\text{emul}}$  evaluated through a power law model  
99 with a plateau at high shear rates fitted with experiments and reasonably accurate in the range of the local shear rate  $\dot{\gamma}$   
100 developed inside the cone mill mixer ( $10^3 - 10^5 \text{ s}^{-1}$ ) (Dubbelboer, 2016; Dubbelboer et al., 2016):

$$\frac{\eta_{\text{emul}}}{\eta_c} = \eta_r = \eta_{r,\infty} + K \dot{\gamma}^m. \quad (2)$$

101 In Eq. (2),  $\eta_r$  is the dimensionless relative viscosity, expressed as the ratio of apparent emulsion viscosity  $\eta_{\text{emul}}$  to  
102 continuous water phase viscosity  $\eta_c$ . The continuous phase consists of egg yolk, salt, and vinegar dissolved in water,  
103 and its viscosity was measured to be Newtonian over the range of shear rates investigated and equal to  $10 \text{ mPa} \cdot \text{s}$

104 (Dubbelboer, 2016; Dubbelboer et al., 2016). In Eq. (2),  $\eta_{r,\infty}$  is the relative plateau viscosity for high shear rates.  
 105 The parameters  $\eta_{r,\infty}$ ,  $K$ , and  $m$  result from experimental data fitting and they only depend on the oil concentration  
 106 (Dubbelboer, 2016). The kinematic apparent emulsion viscosity is  $\nu_{emul} = \eta_{emul} / \rho_{emul}$ , where  $\rho_{emul}$  is the apparent  
 107 emulsion density, calculated as  $\rho_{emul} = \rho_{oil} \phi_v / \phi_w$ . Here,  $\phi_v$  and  $\phi_w$  are respectively the oil volume and the oil weight  
 108 fractions, as reported in the reference experimental work (Dubbelboer, 2016; Dubbelboer et al., 2016). It is important  
 109 to point out here that Dubbelboer (2016); Dubbelboer et al. (2016) provided a relationship for the apparent emulsion  
 110 viscosity as a function of the equilibrium mean oil droplet diameter, which instead is a local variable in this work.  
 111 Therefore, the relation expressed in Eq. (2) to describe the non-Newtonian dynamics of the emulsion is employed here  
 112 in order to make viscosity locally varies with the shear rate within the cone mill and to be intrinsically dependent on  
 113 the DSD through the experimental fitting parameters themselves. It is also important to point out that emulsions can  
 114 generally be treated as pseudo-homogeneous fluids with averaged properties as the dispersed droplets of emulsions  
 115 are small and well distributed (Chhabra and Richardson, 2008; Pal, 1993; Pal and Hwang, 1999), leading to two key  
 116 assumptions to be fulfilled: the continuum description and the homogeneity. The former is valid when the distribution  
 117 of particles in the liquid phase is not influenced by the channel dimensions. In this work, the largest oil droplets are  
 118 around 10 times smaller than the gap section, so it is reasonable to consider the DSD independent of cone mill geometry.  
 119 Secondly, the homogeneity leads to the use of space-averaged fluid properties. This can be valid when the emulsion  
 120 is stabilized by surfactants, so no phase transition occurs. Here, the emulsion was pre-mixed together with the main  
 121 ingredients including egg yolk surfactants in a previous production step. Thus, oil droplets were already stabilized and  
 122 a coarse inlet DSD is fluxed into the cone mill.

## 123 2.2. CFD and PBM description

124 As mentioned, the flow field of the liquid-liquid emulsion in the cone mill is described by solving the steady-  
 125 state continuity and momentum balance equations for an incompressible pseudo-single phase non-Newtonian flow, as  
 126 detailed in previous works (Boccardo et al., 2014; Tosco et al., 2013). By solving these equations the emulsion velocity  
 127 in the cone mill,  $\mathbf{U}$ , described as a pseudo-single phase fluid, is calculated. Numerous interesting flow features can be  
 128 extracted via this variable. For example, the local shear rate is calculated as follows:

$$\dot{\gamma} = 2\sqrt{II_{\mathbf{E}}}, \quad (3)$$

129 where  $II_{\mathbf{E}}$  is the second invariant of the symmetric rate-of-strain tensor  $\mathbf{E}$ , which is in turn defined as:

$$\mathbf{E} = \frac{1}{2} [\nabla\mathbf{U} + (\nabla\mathbf{U})^T]. \quad (4)$$

130 Another interesting flow feature is the so-called Manas-Zloczower mixing index, defined as follows:

$$\alpha = \frac{\sqrt{II_{\mathbf{E}}}}{\sqrt{II_{\mathbf{E}}} + \sqrt{II_{\mathbf{\Omega}}}}, \quad (5)$$

131 where  $II_{\mathbf{\Omega}}$  is the second invariant of the skew-symmetric rate-of-rotation tensor  $\mathbf{\Omega}$ , which in turn is defined as:

$$\mathbf{\Omega} = \frac{1}{2} [\nabla \mathbf{U} - (\nabla \mathbf{U})^T]. \quad (6)$$

132 The mixing index  $\alpha$  has a 0-1 range, with 0 indicating a rotational motion, and 0.5 and 1 indicating pure shear and  
 133 pure elongational flows, respectively (Frungieri et al., 2022, 2020). As we will see both  $\dot{\gamma}$  and  $\alpha$  play an important role  
 134 during droplet breakup.

135 The evolution of the droplet size distribution (DSD) is properly described by the PBE, accounting for the birth and  
 136 death of droplets due to coalescence and breakage. Assuming the emulsification process at steady-state and omitting  
 137 explicit indications of space and time dependencies, the PBE can be written as follows (Ramkrishna, 2000):

$$\begin{aligned} \nabla \cdot (\mathbf{U} n(L)) = & \frac{L^2}{2} \int_0^L \frac{C \left( (L^3 - L'^3)^{1/3}, L' \right)}{(L^3 - L'^3)^{2/3}} n \left( (L^3 - L'^3)^{1/3} \right) n(L') dL' \\ & - n(L) \int_0^\infty C(L, L') n(L') dL' + \int_L^\infty g(L') \beta(L|L') n(L') dL' - g(L)n(L), \quad (7) \end{aligned}$$

138 where  $n(L)$  is the DSD (Marchisio and Fox, 2013),  $L$  is the droplet diameter as well as the internal coordinate of the  
 139 PBE. The coalescence kernel,  $C(L, L')$ , and the breakage kernel,  $g(L)$ , quantify the rate with which droplets coalesce  
 140 and break. The daughter distribution function,  $\beta(L|L')$ , defines instead the size distribution of the droplets formed by  
 141 the breakup of a droplet of size  $L'$ .

142 Thanks to the assumption of considering the emulsion as a shear-thinning pseudo-single phase,  $\mathbf{U}$  in Eq. (7) is  
 143 the fluid velocity obtained by solving the flow field equation (as explained above). Therefore,  $\mathbf{U}$  represents the first  
 144 coupling variable used in this work, and from the flow field, it is possible to calculate the local shear rates  $\dot{\gamma}$  (Bird  
 145 et al., 1960). The right-hand side of Eq. (7) is the source term due to the coalescence and breakage of the oil droplets,  
 146 which are described by means of phenomenological models called kernels (Li et al., 2017). As previously mentioned,  
 147 in this work QMOM (Marchisio et al., 2003a,b) is employed to solve the PBM (Equation (7)). The general idea behind  
 148 this method is to solve transport equations for the moments of the DSD. By approximating the unknown DSD,  $n(L)$ ,  
 149 as a summation of Dirac functions and using a quadrature approximation of order  $N$ , QMOM leads to the following

150 expression for the moment of order  $k$  (Marchisio et al., 2003b):

$$M_k = \int_0^{+\infty} n(L)L^k dL \approx \sum_{\alpha=1}^N w_{\alpha} L_{\alpha}^k \quad \text{with } k \in 0, \dots, 2N - 1, \quad (8)$$

151 where  $w_{\alpha}$  and  $L_{\alpha}$  are the  $N$  quadrature weights and  $N$  quadrature abscissas, in turn calculated from the first  $2N$  lower-  
 152 order moments through so-called moment inversion algorithms, such as the Product-Difference (PD) (Marchisio and  
 153 Fox, 2013) algorithm employed in this work. The reader can refer to the literature for further details (Boccardo et al.,  
 154 2019; Li et al., 2017; Marchisio and Fox, 2013; Marchisio et al., 2003a,b; McGraw, 1997). Moreover, it is important  
 155 to remark that the moments represent integral properties of the DSD. For example, in the case investigated here,  $M_0$   
 156 represents the number of oil droplets per unit volume, while  $M_3$ , if multiplied by a shape volume coefficient equal  
 157 to  $\pi/6$  due to spherical shape of the droplets, is equal to the oil volume fraction. Most importantly, the mean Sauter  
 158 diameter used in this work for evaluating the evolution of the DSD is simply defined as follows:  $d_{32} = M_3/M_2$ .

159 The coupling between CFD and PBM is realized here by using two approaches. Some of the simulations are run  
 160 with the classical on-the-fly coupling, where the governing equations are solved simultaneously (Gao et al., 2016),  
 161 whereas another part of the simulations is run with the off-line coupling, where first the CFD equations for the flow  
 162 field are solved, the relevant information for the flow field is extracted (i.e. shear rate and mixing index) and finally a  
 163 volume-averaged PBM is solved for the evolution of the DSD (Buffo et al., 2016a; De Bona et al., 2016).

164 Three important functions appear which determine the evolution and the final shape of the DSD: the coalescence  
 165 kernel  $C(L, L')$ , the breakage kernel  $g(L)$ , and the daughter-size distribution function  $\beta(L|L')$ . The coalescence  
 166 kernel  $C(L, L')$ , quantifying the rate of coalescence of droplets of diameter  $L$  and  $L'$ , and the breakage kernel  $g(L)$ ,  
 167 quantifying the rate of breakage of droplets of size  $L$ , take respectively the following forms (Maindarkar et al., 2014):

$$C(L, L') = K_1 \frac{\pi}{6} \left( \frac{\dot{\gamma}}{1 - \phi_v} \right) (L + L')^3 \exp \left( -K_2 \lambda \text{Ca}^{\frac{3}{2}} \left( \frac{8\pi\sigma R_{eq}^2}{A_H} \right)^{\frac{1}{3}} \right), \quad (9)$$

$$g(L) = K_3 \dot{\gamma} \exp \left( -K_4 \frac{\text{Ca}_{cr}}{\text{Ca}} \right),$$

168 where  $\phi_v$  is the oil volume fraction,  $A_H$  is the Hamaker constant,  $\lambda$  is the ratio between the oil viscosity  $\eta_{oil}$   
 169 and the apparent emulsion viscosity  $\eta_{emul}$ , and  $K_1$ ,  $K_2$ ,  $K_3$ , and  $K_4$  are free adjustable model parameters to be  
 170 fitted with experimental data.  $R_{eq}$  is the equivalent radius of colliding drops of diameter  $L$  and  $L'$ , defined as:  
 171  $R_{eq} = 2/(2/L + 2/L')$ . Although the interfacial tension  $\sigma$  in Eq. (9) is dynamic for an oil-in-water emulsion as it  
 172 varies according to local flow conditions (Anton, 2013), it is here assumed constant and equal to 10 mN/m as in the  
 173 work of Dubbelboer et al. (2016) and verified in previous studies (Ferrari et al., 2023, 2022). In Eq. (9),  $\text{Ca}$  is the

174 capillary number, defined as:

$$Ca = \frac{\eta_{emul} \dot{\gamma} L}{2\sigma}, \quad (10)$$

175 where  $\eta_{emul}$  is the apparent emulsion viscosity and  $\dot{\gamma}$  is the local shear rate.

176 The high shear rates developed inside the mixer tend to stretch the oil droplets and droplet breakage is assumed to  
 177 follow the capillary instability mechanism. This means that, when the ratio of the viscous stress acting on the drops to  
 178 the interfacial tension force, i.e.  $Ca$ , exceeds a critical value, i.e. the critical capillary number  $Ca_{cr}$ , a mother droplet  
 179 breaks into two or more daughter droplets, depending on the form of the daughter-size distribution function  $\beta(L|L')$ .  
 180 The critical capillary number  $Ca_{cr}$  determines the stability of the droplet and depends on the ratio between the viscosity  
 181 of the disperse and continuous phases,  $\lambda$ , and on the type of flow inside a specific geometry (Bentley and Leal, 1986;  
 182 Frungieri and Briesen, 2023). Its expression can usually be derived from experiments and in this work, we used two  
 183 empirical correlations. The first one refers to the case of pure shear flow (i.e. mixing index,  $\alpha$ , equal to 0.5) (Debruijn,  
 184 1991) as the result of single droplet breakup experiments between two concentric cylinders:

$$\log_{10} Ca_{cr} = -0.506 - 0.0994 \log_{10} \lambda + 0.124 (\log_{10} \lambda)^2 - \frac{0.115}{\log_{10} \lambda - 0.611}. \quad (11)$$

185 It is worth mentioning that this expression is valid for  $\lambda < 4$ , as for  $\lambda > 4$  the critical capillary number tends to infinity,  
 186 implying that for  $\lambda > 4$  pure shear flow is not effective in breaking the droplets. The second one refers to the case of  
 187 flows with an elongational component (i.e.  $0.5 < \alpha \leq 1.0$ ) and reads as follows (Bentley and Leal, 1986):

$$Ca_{cr} = \frac{0.14 \lambda^{-1/6}}{\alpha^{1/2}}, \quad (12)$$

188 Figure 1 reports the dependency of the critical Capillary number versus the viscosity ratio for two values of the mixing  
 189 index, namely pure shear flow,  $\alpha = 0.5$ , and pure elongational flow  $\alpha = 1.0$ . As it is seen, for every reported value  
 190 of the viscosity ratio  $\lambda$ , the critical Capillary number for pure elongational flow is smaller than for pure shear flow,  
 191 indicating that flows with an elongational component are more effective in breaking droplets. This is particularly true  
 192 for highly viscous disperse phases, where  $\lambda > 4$ . In these cases in fact the critical Capillary number for pure shear  
 193 flows is practically infinitely large, implying that pure shear flow cannot break the droplets, no matter how intense is  
 194 the shear rate. When  $\lambda > 4$  only an elongational component can reduce the drop size.

195 As far as the viscosity ratio,  $\lambda = \eta_d/\eta_c$ , is concerned, this is usually evaluated as the ratio between the dispersed and  
 196 continuous phase viscosity. It is however very common, in the case of dense emulsions, to use the apparent emulsion  
 197 viscosity  $\eta_{emul}$  instead of the continuous phase viscosity  $\eta_c$ , as in high disperse phase emulsions, droplets perceive a

198 surrounding continuous phase with the emulsion viscosity (Jansen et al., 2001; Maindarkar et al., 2014). This is also  
 199 consistent with simulating the flow field in the device by using the pseudo-single phase approach.

200 The coalescence kernel  $C(L, L')$  in Eq. (9) is incorporated in the model since colliding drops may coalesce despite  
 201 the cone mill is designed to promote droplet breakage (Maindarkar et al., 2014, 2012). The coalescence kernel which  
 202 depends on colliding drops of diameter  $L$  and  $L'$  appears in the PBE (Eq. (7)), thus affecting the evolution and the  
 203 final shape of the DSD. The coalescence rate is determined by the product of the frequency of droplet collisions and  
 204 the probability that a collision event will produce coalescence. The collision frequency depends on the local flow  
 205 field (Klink et al., 2011), and the coalescence probability depends on the capillary number  $Ca$  and the viscosity ratio  
 206  $\lambda$  (Chesters, 1991). Further details about the expressions of kernels used in this work can be found in the literature  
 207 (Dubbelboer, 2016; Dubbelboer et al., 2016; Maindarkar et al., 2014). As it can be seen from Eqs. (9) to (12), the  
 208 coalescence and the breakage kernels are calculated as functions of the local shear rate  $\dot{\gamma}$  and of the local apparent  
 209 emulsion viscosity  $\eta_{emul}$ , both resulting from solving the flow field.

210 Regarding the daughter-size distribution  $\beta(L|L')$ , it states the size distribution of daughter droplets originating  
 211 from a mother droplet after a breakage event. Here a beta function is employed (Laakkonen et al., 2006):

$$\beta(L, L') = 180 \left( \frac{L^2}{L'^3} \right) \left( \frac{L^3}{L'^3} \right)^2 \left( 1 - \frac{L^3}{L'^3} \right)^2, \quad (13)$$

212 where  $L$  and  $L'$  are the sizes of the daughter and mother droplets. Equation (13) assumes that two droplets are formed  
 213 from a mother and that symmetric breakage is the most likely event. It is important to remind here that the choice of the  
 214 daughter-size distribution function has a large impact on the final DSD (Dubbelboer, 2016; Dubbelboer et al., 2016;  
 215 Maindarkar et al., 2014), but much less on the mean Sauter diameter (Gao et al., 2016), used to evaluate the evolution  
 216 of the DSD in this work. Therefore, the form of the daughter-size distribution function is of secondary importance  
 217 here.

### 218 3. Numerical details

219 As already mentioned, we simulated the last step of the mayonnaise production process, i.e., the cone mill mixer,  
 220 by using CFD and PBM as described in Section 2. The information about the experiments is taken from the work of  
 221 Dubbelboer (2016); Dubbelboer et al. (2016). More in detail, three types of mayonnaise were prepared with different  
 222 concentrations of soybean oil (0.65, 0.70, 0.75 kg/kg), whose density  $\rho_d$  and viscosity  $\eta_d$  are respectively equal to 917  
 223 kg/m<sup>3</sup> and 50 mPa · s (Maindarkar et al., 2014). Before pumping it into the cone mill, the mayonnaise is characterized  
 224 by a coarse DSD, whose shape only depends on the initial oil content. After the continuous mixing process into the

225 cone mill, the desired product structure is obtained, i.e. the final DSD is reached. Upstream and downstream DSD  
226 measurements are available in the literature for model validation.

227 Each one of these three types of mayonnaise was processed under the three different operating conditions reported  
228 in Table 1. The last three columns report the corresponding Reynolds numbers for the intermediate soybean oil  
229 concentration (0.70 kg/kg). As it can be seen, only for experiment 1 the Reynolds number in the gap section exceeds the  
230 critical Reynolds number (also corresponding to the highest Taylor number), highlighting for this operating condition  
231 the presence of Taylor vortices (Li et al., 2010, 2014) (see Section 4.1).

232 A sketch of the cone mill mixer, together with its 2D and 3D representations, is reported in Figure 2. It consists of a  
233 solid conical frustum rotor, which rotates clockwise inside a slightly larger stator of the same shape. This configuration  
234 forms a small gap in which the emulsion flows from the top to the bottom of the cone mill. The chambers before and  
235 after the small gap ensure a homogeneous composition of the emulsion but their role in determining the final DSD is  
236 not fully clear (Dubbelboer, 2016; Dubbelboer et al., 2016; Lupieri et al., 2021). This is why we considered different  
237 geometries for the simulations, including 2D and 3D representations of the gap region, with and without the pre- and  
238 post-mixing chambers. Finally, it is worth mentioning that the pilot scale apparatus (manufactured by IKA) employed  
239 in experimental measurements has a more complex geometry, but the representation reported in Fig. 2 is a reasonable  
240 compromise between computational costs and accuracy (Dubbelboer, 2016).

241 All the simulations were performed with the open-source CFD software OpenFOAM (version 6.0). In order to  
242 evaluate the flow field, the SRFSimpleFoam solver is employed, which is a steady-state solver for incompressible  
243 flows in a single rotating frame. This solver adopts the SIMPLE algorithm for the solution of velocity and pressure  
244 coupling. The viscosity model of the emulsion described in Section 2.1 is implemented as an add-on library.

245 In order to properly describe the flow field in the cone mill a grid independence study has been conducted. The six  
246 different grids described in Table 2 were tested. These six grids refer to the 2D geometry limited to the gap, without pre-  
247 and post-mixing chambers. The Table reports the grid resolution along the axial and radial directions, the total number  
248 of cells, the resulting number of Taylor vortices, and the volume-averaged shear rate. Only the fine resolution of Grids  
249 4, 5, and 6 makes it possible to properly describe the flow field, both in terms of the number of Taylor vortices and  
250 volume-averaged shear rate. Similar information is reported in Fig. 3 where a contour plot of the shear rate is reported  
251 for Experiment 1 and an oil concentration of 0.65 kg/kg for Grid 1 and Grid 4. As it is seen the vortex structures emerge  
252 and are correctly described only at the second grid resolution. Moreover, for the six grid resolutions of Table 2, Fig. 4  
253 reports the volume probability density distributions (PDF) of the values of pressure  $p$  normalized with respect to the  
254 atmospheric pressure  $p_{atm}$ , relative viscosity  $\eta_r$ , and shear rate  $\dot{\gamma}$  normalized with respect to the nominal shear rate  $\dot{\gamma}_n$   
255 calculated as the rotor maximal tip velocity divided by the gap size. As it can be seen, the finer the grid resolution  
256 the better defined the shape of the distributions. Therefore, all subsequent results refer to a grid resolution of at least

257  $25 \times 360$  cells in the gap, corresponding to Grid 4 (red highlighted curves in Fig. 4), as a compromise between result  
258 accuracy and computational cost.

259 The PBM is solved by means of the QMOM with a three node quadrature, meaning that the first six moments  
260 of the DSD are transported. Although in general the evolution of the DSD has an effect on the emulsion viscosity  
261 (Barnes, 1994), the rheology model here implemented depends only on the disperse phase volume fraction and not on  
262 the oil droplets size. Therefore the hydrodynamics of the emulsion does not depend on the DSD (see Section 2.1). As a  
263 consequence, in all simulations at first, only the governing equations of SRFSimpleFoam are solved, in order to obtain  
264 a steady-state flow field information. Then, the variables linking CFD and PBM together, i.e. viscosity and velocity  
265 fields (see Section 2.2), are transferred to the PBM model. As mentioned, in this work two approaches are used; for a  
266 limited number of cases, the viscosity and velocity field are transferred to the modified scalarTransportFoam in order to  
267 solve the PBM, within the CFD code but assuming the flow field was frozen. Further details about this implementation  
268 can be found in our previous works (Boccardo et al., 2019; Buffo et al., 2013, 2016b; Passalacqua et al., 2018). Here,  
269 the six moments are considered as scalars and their transport equations are incorporated in the scalarTransportFoam  
270 module of OpenFOAM that provides a solver for steady or transient transport equation for a single passive scalar,  
271 obtaining a modified solver for the solution of the six equations simultaneously. The coalescence and breakage kernels  
272 described in Section 2.2 are used to evaluate the droplet coalescence and breakage rates. Alternatively, the shear rate,  
273  $\dot{\gamma}$ , and the mixing index,  $\alpha$ , within the cone mill are extracted and the PBM is solved in a simplified form as described  
274 in previous works (De Bona et al., 2016).

275 An overview of the numerical schemes and of the boundary conditions used in this work can be found in Table  
276 3. Regarding inlet boundary conditions, the zero gradient condition is set for the pressure, whereas for the velocity an  
277 inlet constant profile is imposed, whose value is calculated from the inlet mass flow rate corresponding to experiments  
278 reported in Table 1. The values of inlet moments (and consequentially the inlet  $d_{32}$  value) are calculated from the  
279 experimentally measured inlet DSD.

## 280 4. Results and discussion

281 In this section, the most significant results of the simulations performed will be presented. First, the flow field of  
282 the emulsion inside the mixer is shown, then, the results of the PBM simulations are also discussed and compared with  
283 experimental data.

### 284 4.1. Flow field results

285 It is interesting to compare the CFD results obtained with the 2D and 3D geometries with the pre- and post-mixing  
286 chambers. Figure 5 reports this comparison in terms of the axial velocity across the gap for three different axial positions

287 (inlet, center, and outlet) for one operating condition, namely experiment no. 1 of Tab. 1. As it is seen, no significant  
288 difference is observed between the 2D and the 3D predictions, probably due to the intrinsic axial symmetry of the cone  
289 mill. For this reason from now on only 2D results will be presented and discussed. Figs. 6 and 7 qualitatively represent  
290 the flow field developed within the cone mill. The streaklines for one operating condition are reported in Fig. 6. As it is  
291 seen two large laminar recirculation zones are identified in the pre- and post-mixing chambers. Such a secondary flow  
292 pattern is due to the sudden presence of a very narrow gap between the top and bottom chambers. This is correctly  
293 reproduced as in the work of Lupieri et al. (2021), where its effect was extensively discussed. Moreover, similar results  
294 were obtained in terms of pressure change within the cone mill compared to those of the work of Lupieri et al. (2021),  
295 where the same emulsion was modeled with a two-phase approach, thus showing the validity of the pseudo-single  
296 phase assumption employed here.

297 As expected, the CFD simulations show a high velocity gradient due to the high rotational speed, in particular, the  
298 highest velocity corresponds to the tip velocity of the rotor, as it can be seen in Fig. 7, which shows the contour plot of  
299 the velocity magnitude in a magnified longitudinal section of the cone mill with oil concentration equal to 0.70 kg/kg  
300 (70 wt%) and at operating conditions corresponding to experiment no. 1.

301 Since the rotational speed of the rotor is considerably higher than the inlet fluid velocity, the tangential component  
302 of velocity is larger than the axial and radial one and the contour plot of the tangential velocity is very similar to the  
303 one reported in Fig. 7. Moreover, the contour plot shows that the tangential velocity has a linear profile along the gap,  
304 with the maximum value at the rotor wall and the minimum one at the stator wall, like in a Couette flow.

305 Although the main velocity component is the tangential one, it is more interesting to observe the trend of the axial  
306 component of the emulsion velocity ( $z$ -component). Figure 8 reports the axial velocity profiles versus the normalized  
307 distance from the rotor wall at half height of the cone mill, with oil concentration equal to 0.70 kg/kg (70 wt%), and for  
308 different operating conditions (see Table 1). In experiments no. 2 and 3 the axial velocity presents a parabolic profile, in  
309 which the maximum value depends on the inlet flow rate. It is worth reminding here that the fluid flow enters where the  
310 cone mill has the smaller radius (top) and exits where it has the larger one (bottom) (see Figure 2), explaining the reason  
311 for the negative values of velocity. Experiment no. 1 presents a different shape of the axial velocity. Close to the rotor  
312 wall, the axial velocity points downward, while its direction is opposite close to the stator wall. Therefore, the presence  
313 of such backflow suggests that a large vortex appears for this operating condition, extending over the entire height of  
314 the cone mill. This situation has already been observed in previous works, performed with null axial flow (Li et al.,  
315 2010, 2014). For a better understanding of the fluid flow, Reynolds numbers in the gap section (defined in Equation (1))  
316 are calculated for the same conditions of the Figure 8, and the results are summarized in Table 1. For experiment no. 1,  
317  $Re$  is higher than  $Re_c$  (equal to 132 (Noui-Mehidi et al., 2005)), at which value the flow starts to become unstable and  
318 the first large Taylor vortex appears. Although it has been shown experimentally that the axial flow has a stabilizing

319 effect on the formation of instabilities, increasing the value of  $Re_c$  (Giordano et al., 1998), Reynolds numbers (and,  
 320 correspondingly, Taylor numbers) shown in Table 1, for experiment no. 1, is high enough to justify the axial velocity  
 321 trends shown in Figure 8 and to imply the presence of a large vortex filling the entire height of the cone mill gap. Table  
 322 1 also reports the Reynolds numbers in the pre- and post-chambers of the cone mill. These values indicate that the  
 323 Reynolds number is low enough to consider the flow regime laminar within the whole cone mill, despite the change in  
 324 the characteristic length dimension due to the cone mill geometry. This can be justified by looking at Figure 9, showing  
 325 the contour plots of the kinematic emulsion viscosity corresponding to the cases of Table 1. As it can be seen, the local  
 326 viscosity in pre- and post-mixing zones is one or two orders of magnitude higher than that in the gap section. This is  
 327 related to the shear-thinning behavior of the modeled emulsion (Eq. (2)) since pre- and post-mixing zones experienced  
 328 much lower shear rates compared to those in the gap region.

329 At last, it is interesting to discuss the predictions for the shear rate, the mixing index, and the corresponding  
 330 Capillary number. Figure 10 reports the contour plots for the ratio between the Capillary number and the critical  
 331 Capillary number, calculated by using the emulsion viscosity and Eq. (11), and the viscosity of the continuous phase  
 332 and Eq. (12), as well as the mixing index for Experiments no. 1 and 3 and an oil concentration of 0.70 kg/kg. Closer  
 333 observation of Fig. 10 highlights that most of the breakage occurs in the gap, where the Capillary number is larger  
 334 than its critical value, due to pure shear, namely  $\alpha \approx 0.5$ . Larger values of the mixing index, namely  $\alpha \approx 1$ , are  
 335 observed in the pre- and post-mixing chambers, where however the shear rate is not large enough to ensure a value of  
 336 the Capillary number greater than its critical value. This is also confirmed by the results reported in Fig. 11, where the  
 337 volume distribution of shear rate and mixing index across the cone mill are reported for the three investigated operating  
 338 conditions. As it can be seen, the highest shear rates ( $\gamma \geq 10^3$  1/s) are observed in regions characterized by a mixing  
 339 index approximately equal to 0.5. We can therefore conclude that, although elongational flow, generally more effective  
 340 in breaking droplets, is observed in the pre- and post-mixing chambers, most of the droplet breakup occurs within the  
 341 cone mill gap due to pure shear.

## 342 4.2. PBM results

343 As already mentioned, the high rotational speed of the cone mill mixer develops a high-shear rate inside a narrow  
 344 gap, in order to obtain the final product with the desired features.

345 Figure 12 reports the trend of the number of the oil droplets per unit volume, corresponding to the moment of  
 346 order zero of the DSD, and the oil volume fraction, proportional to the moment of order three of the DSD, along the  
 347 normalized distance from the middle point of the inlet to the middle point of the outlet of the cone mill mixer for  
 348 different oil concentrations. Since the oil concentration does not change due to droplet coalescence and breakage, the  
 349 third-order moment, which is proportional to the oil volume fraction, remains constant along the gap and is equal to

350 the corresponding values of different types of mayonnaise, as reported in a previous work (Dubbelboer et al., 2016).  
351 On the other hand, the number of oil droplets per unit volume (the moment of order zero) increases, meaning that  
352 droplets break moving through the mixer since the total oil amount is constant. In addition, it is important to note that  
353 the number of oil droplets is larger for higher oil concentrations.

354 The evolution of the DSD is reported in terms of the mean Sauter diameter  $d_{32}$ , calculated as the ratio between the  
355 third and second-order moments. Thanks to the link between PBM and CFD, as described in Section 2.2, it is possible  
356 to highlight the influence of the flow field, and in particular the high shear rates and the axial velocity, on the trend  
357 of  $d_{32}$ . Figure 13 reports the contour plot of  $d_{32}$  along a longitudinal section of the cone mill with oil concentration  
358 equal to 0.70 kg/kg (70 wt%) for experiments no. 1 and 3. As it can be seen,  $d_{32}$  decreases along the flow direction,  
359 since droplets undergo breakage induced by the high shear rates inside the mixer. These trends exactly reproduce what  
360 is expected from experimental observations (Dubbelboer, 2016; Dubbelboer et al., 2016). The insets in Figure 13 are  
361 magnified sections of the cone mill that show in detail how the flow field, and in particular the axial velocity, influences  
362  $d_{32}$  trends. For experiment n. 3, the  $d_{32}$  presents a parabolic profile along the gap width, with the higher value at the  
363 center of the gap and the lower at the walls, similar to the respective axial component of velocity (see Figure 8). For  
364 experiment n. 1, the situation is different from experiment n. 3. In this case, it is represented very clearly how the  
365 flow field can influence the local DSD. As it is reported in Section 4.1 and Figure 8, the presence of Taylor instability  
366 inside the mixer leads to a particular shape of the velocity profile. Therefore, the link between CFD and PBM is able  
367 to show that the oil droplets are bigger close to the rotor and smaller close to the stator. The average outlet values of  
368  $d_{32}$  shown in Figure 13 are equal to  $7.1 \mu\text{m}$  for case no. 3 and  $5.4 \mu\text{m}$  for case no. 1, whereas the experimental ones  
369 are respectively  $7.7 \mu\text{m}$  and  $6.6 \mu\text{m}$  (Dubbelboer et al., 2016), with a relative error under 20%. These outcomes are  
370 obtained by suitably adjusting the free parameters that appear in coalescence and breakage kernels, through a trial and  
371 error procedure, and more details on this are given below. It is important to point out that the results reported here have  
372 illustrative purposes, to show the capabilities of the CFD-PBM approach. Achieving a unique and generic set of free  
373 parameters that matches all the experimental data, using optimization and uncertainty quantification techniques, will  
374 be the scope of future works.

375 As just mentioned the predictions of the PBM are highly affected by the values of the model parameters appearing  
376 in the coalescence kernel,  $K_1$  and  $K_2$ , and the breakage kernel,  $K_3$  and  $K_4$ . Due to the semi-empirical nature of these  
377 kernels and the many approximations adopted in their derivation, their values cannot be predicted by the theory but  
378 have to be fitted with experiments. An example of the influence of the model parameters on the final predictions can be  
379 found in Table 4. As expected by increasing  $K_1$  coalescence becomes more important and the mean Sauter diameter  
380 increases, and conversely by increasing  $K_3$  or  $K_4$  breakup becomes more important and the mean Sauter diameter  
381 decreases.

382 In order to optimize the model parameters  $K_1$ ,  $K_2$ ,  $K_3$ , and  $K_4$  the PBM, solved in the simplified form described in  
383 our previous work (De Bona et al., 2016), has been coupled with the covariance matrix adaptation evolution strategy  
384 (CMA-ES) algorithm (Hansen, 2006). The algorithm minimized the normalized distance between the predicted mean  
385 Sauter diameter and the corresponding experimental values, resulting in the final predictions reported in Table 5. The  
386 optimization was performed with the PBM implemented in its simplified form, rather than with the full CFD-PBM  
387 due to the computational costs associated with the full CFD-PBM which are prohibitive for these applications. As it  
388 can be seen from Table 5, the comparison is satisfactory as the PBM is capable of capturing the most important trends  
389 for the investigated operating conditions. The same approach was used to conduct further analysis of the individual  
390 and combined effect of the type of flow on the resulting drop size. Fig. 14 shows the comparison between the outlet  
391 experimental Sauter mean diameter values and the predicted ones for different operating conditions and mayonnaise  
392 types when droplet breakage occurs due to the simple shear, elongational flow, and the combination of both of them,  
393 respectively. As can be seen, the comparison is acceptable in the case of pure shear flow. On the other hand, the  
394 prediction is unsatisfactory when the elongational flow is only responsible for droplet breakage. However, the best  
395 results are obtained when both types of flow are taken into account (Table 5). This confirms again that simple shear  
396 flow is the most effective in droplet breakage inside the cone mill, but the combination of both shear and elongational  
397 flow gives the best predictions in terms of drop size. It is also important to point out here that the discrepancies in the  
398 results shown in the middle plot of Figure 14 are potentially due to the fact that elongational rheology is not taken into  
399 account in this work although its implementation and effect may be hard to achieve. Therefore, its study can be the  
400 object of future investigations for similar emulsions.

## 401 5. Conclusions

402 In this work, we presented a modeling approach for food emulsion production in a high-shear mixer. A flow field  
403 analysis performed with CFD shows that recognizable patterns for the investigated geometry are in agreement with  
404 previous experimental works. In particular, the tangential component of the emulsion velocity shows a Couette flow,  
405 whereas the axial velocity trends depend on Reynolds number: for  $Re < Re_c$ , a Poiseuille flow develops inside the gap  
406 of the mixer, but above  $Re_c$  the first instability appears and backflow occurs. Thanks to the coupling between CFD and  
407 PBM, demonstrated with two approaches, it is possible to obtain a better understanding of the flow influence on the  
408 evolution of the droplet size distribution. In particular, the role of the type of flow, elongational versus pure shear, on  
409 droplet breakage and the role of the pre- and post-mixing chambers in the cone mill have been elucidated, although the  
410 emulsion elongational rheology was not taken into account here. This model accounts for both the coalescence and the  
411 breakage of the oil droplets, which depend in turn on the local flow conditions. From the evaluation of the mean oil  
412 droplet diameter, the simulations are able to show that the breaking of the oil droplets promoted by the high shear rates

413 prevails over the coalescence phenomenon, reproducing correctly the experimental data. As a powerful and convenient  
414 method for such kind of applications, QMOM is employed for the solution of the population balance equation, taking  
415 into account the actual hydrodynamics of the emulsion in order to provide a more accurate prediction of the droplet  
416 size distribution.

417 The results presented here will also serve as the basis for future extension of this work in several directions. First, an  
418 optimization procedure will be employed in order to identify an accurate and generic set of kernel constants reproducing  
419 the available experimental data. Then, these simulations can be included in a more general multi-scale framework  
420 in which the effect of the DSD on the emulsion viscosity can be taken into account via detailed interface-tracking  
421 simulations, in which the rheology of the whole emulsion is one of the possible outcomes, and the interfacial tension  
422 can be directly computed with the help of atomistic techniques, such as molecular dynamics or dissipative particle  
423 dynamics. Other aspects should also be taken into consideration when modeling the food emulsion preparation, such  
424 as a more complex geometry of the rotor-stator mixer, a better definition of the coalescence and breakage functions  
425 for highly concentrated emulsion, or the inclusion of the surfactant adsorption mechanism on the oil/water interface  
426 during droplet formation.

**Figure 1:** Dependency of the critical Capillary number versus the viscosity ratio for pure shear flow (black line  $\alpha = 0.5$ ) and pure elongational flow (red line  $\alpha = 1.0$ ).

**Table 1**

Design of experimental test cases from the work of Dubbelboer (2016); Dubbelboer et al. (2016) and corresponding Reynolds numbers computed in pre-chamber, gap, and post-chambers of the cone mill at oil concentration equal to 0.70 kg/kg (70 wt%).

Experiment no.	Rotor speed (rpm)	Gap (mm)	Inlet mass flow rate (kg/h)	$Re_{pre}$	$Re_{gap}$	$Re_{post}$
1	6039	0.624	31	12.9	140.0	$> Re_c$ 212.5
2	6784	0.208	15	12.3	61.2	393.4
3	3170	0.624	64	3.7	64.6	50.1

**Table 2**

Grid independence study on a 2D geometry without pre- and post-mixing chambers for Experiment n. 1 and for a dispersed phase concentration of 0.65 kg/kg.

	Grid 1	Grid 2	Grid 3	Grid 4	Grid 5	Grid 6
Number of cells along the radial direction	10	15	20	25	30	35
Number of cells along the axial direction	150	220	285	360	430	500
Total number of cells	1500	3300	5700	9000	12900	17500
Number of Taylor vortices	3	16	19	21	21	21
Volume-averaged shear rate (1/s)	28991	29733	30339	30540	30605	30758

Figure 2: Sketch of the cone mill mixer (right) and corresponding 3D (left) and 2D (center) representations.

Figure 3: Contour plots of the shear rate reported for Experiment 1 and an oil concentration of 0.65 kg/kg for Grid 1 (left) and Grid 4 (right).

**Figure 4:** Volume probability density distributions (PDF) of the values of normalized pressure  $p$ , relative viscosity  $\eta_r$ , and normalized shear rate  $\dot{\gamma}$  for different grid resolutions of the gap section for Experiment 1 and for a dispersed phase concentration of 0.65 kg/kg.

**Table 3**

Numerical schemes and boundary conditions used in the simulations.

Variable	Scheme	Boundary condition			
		Rotor wall	Stator wall	Inlet	Outlet
Pressure	Second-order central scheme	Zero gradient	Zero gradient	Zero gradient	Fixed value
Fluid velocity	Bounded second-order upwind	Rotor speed	No-slip	Constant profile	Zero gradient
Moments	Bounded first-order upwind	Zero gradient	Zero gradient	Fixed value	Zero gradient

**Figure 5:** Axial velocity across the gap (normalized distance from the rotating wall) at the gap inlet, center, and outlet, as predicted by 2D and 3D simulations for experiment no. 1 and for a dispersed phase concentration of 0.70 kg/kg.

**Figure 6:** Streaklines for experiment no. 1 and for a dispersed phase concentration of 0.65 kg/kg

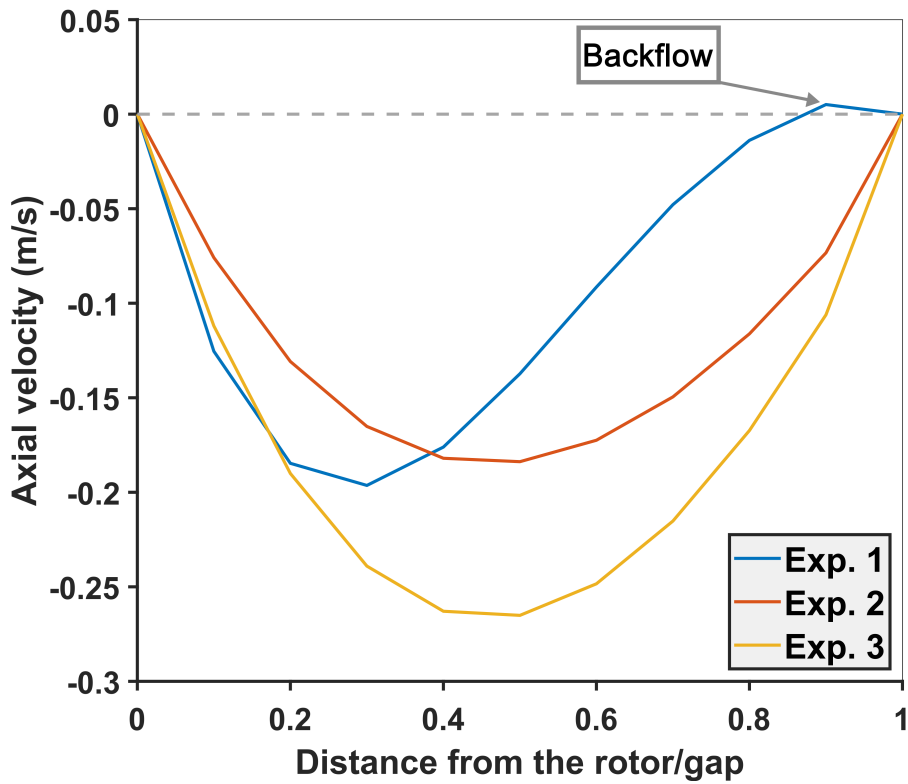

**Figure 7:** Contour plot of the velocity magnitude in a magnified longitudinal section of the cone mill with oil concentration equal to 0.70 kg/kg (70 wt%) and at operating conditions corresponding to experiment no. 1 (see Table 1).

**Table 4**

Comparison between PBM predictions and experimental measurements for the mean Sauter diameter for experiments no. 1 and 3 for different values of the coalescence kernel constants,  $K_1$  and  $K_2$ , and the breakage kernel constants,  $K_3$  and  $K_4$ .

Experiment	$K_1$	$K_2$	$K_3$	$K_4$	$d_{32}^{Model}(\mu\text{m})$	$d_{32}^{Exp}(\mu\text{m})$
no. 1	$1 \times 10^{-6}$	$1.077 \times 10^2$	$2.154 \times 10^{-4}$	$1.744 \times 10^{-3}$	6.9	6.6
	$2.154 \times 10^{-4}$	$1.498 \times 10^{-6}$	$4.642 \times 10^{-2}$	2.684	3.6	
	$1 \times 10^1$	$1.077 \times 10^2$	$2.154 \times 10^{-4}$	2.684	23.7	
no. 3	$1 \times 10^{-6}$	$1.077 \times 10^2$	$2.154 \times 10^{-4}$	$1.744 \times 10^{-3}$	29.1	7.7
	$2.154 \times 10^{-4}$	$1.498 \times 10^{-6}$	$4.642 \times 10^{-2}$	2.684	6.7	
	$1 \times 10^1$	$1.077 \times 10^2$	$2.154 \times 10^{-4}$	2.684	32.0	

**Figure 8:** Axial velocity profiles versus the normalized distance from the rotor wall at half height of the cone mill with oil concentration equal to 0.70 kg/kg (70 wt%) and for different operating conditions (see Table 1).

**Table 5**

The final comparison between the mean Sauter diameter predicted by the PBM and measured experimentally for experiments no. 1, 2, and 3 and for the three dispersed phase concentrations investigated in this work.

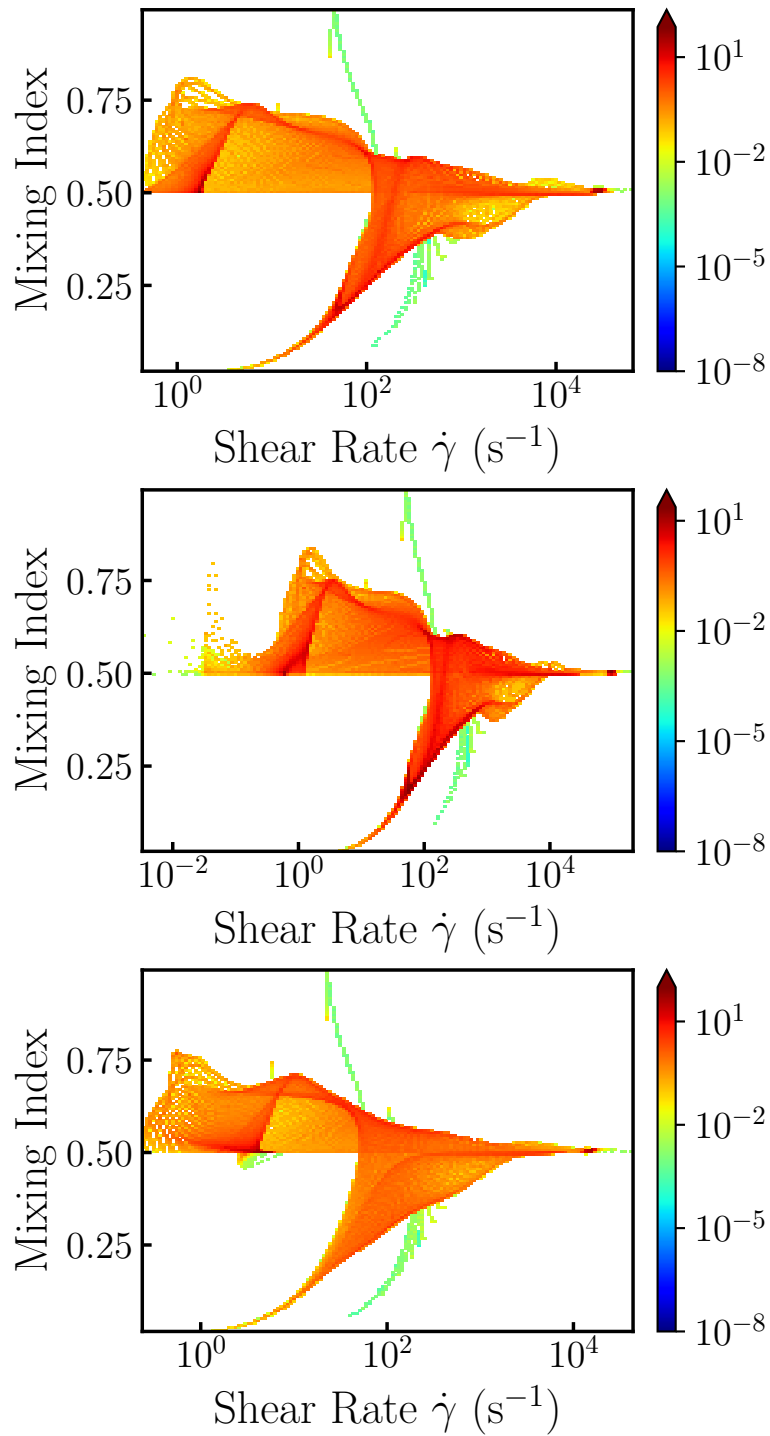

Exp.	Mayonnaise 1 (0.65 kg/kg)		Mayonnaise 2 (0.70 kg/kg)		Mayonnaise 3 (0.75 kg/kg)	
	exp. data [ $\mu\text{m}$ ]	model pred. [ $\mu\text{m}$ ]	exp. data [ $\mu\text{m}$ ]	model pred. [ $\mu\text{m}$ ]	exp. data [ $\mu\text{m}$ ]	model pred. [ $\mu\text{m}$ ]
1	7.206	9.530	6.587	5.180	4.647	3.180
2	8.787	9.250	5.844	4.780	4.815	2.950
3	12.364	11.99	7.713	6.130	6.063	3.830

**Figure 9:** Contour plots of the emulsion apparent kinematic viscosity  $\nu_{emul}$  corresponding to experiment no. 1 (left), 2 (center), and 3 (right) of Table 1 at an oil concentration equal to 0.70 kg/kg.

**Figure 10:** Contour plots for the ratio between the Capillary number and the critical Capillary number calculated by using the emulsion viscosity and Eq. (11) (left) and the continuous phase viscosity and Eq. (12) (center), and the mixing index  $\alpha$  (right) for Experiment no. 1 (top) and no. 3 (bottom) and an oil concentration of 0.70 kg/kg.

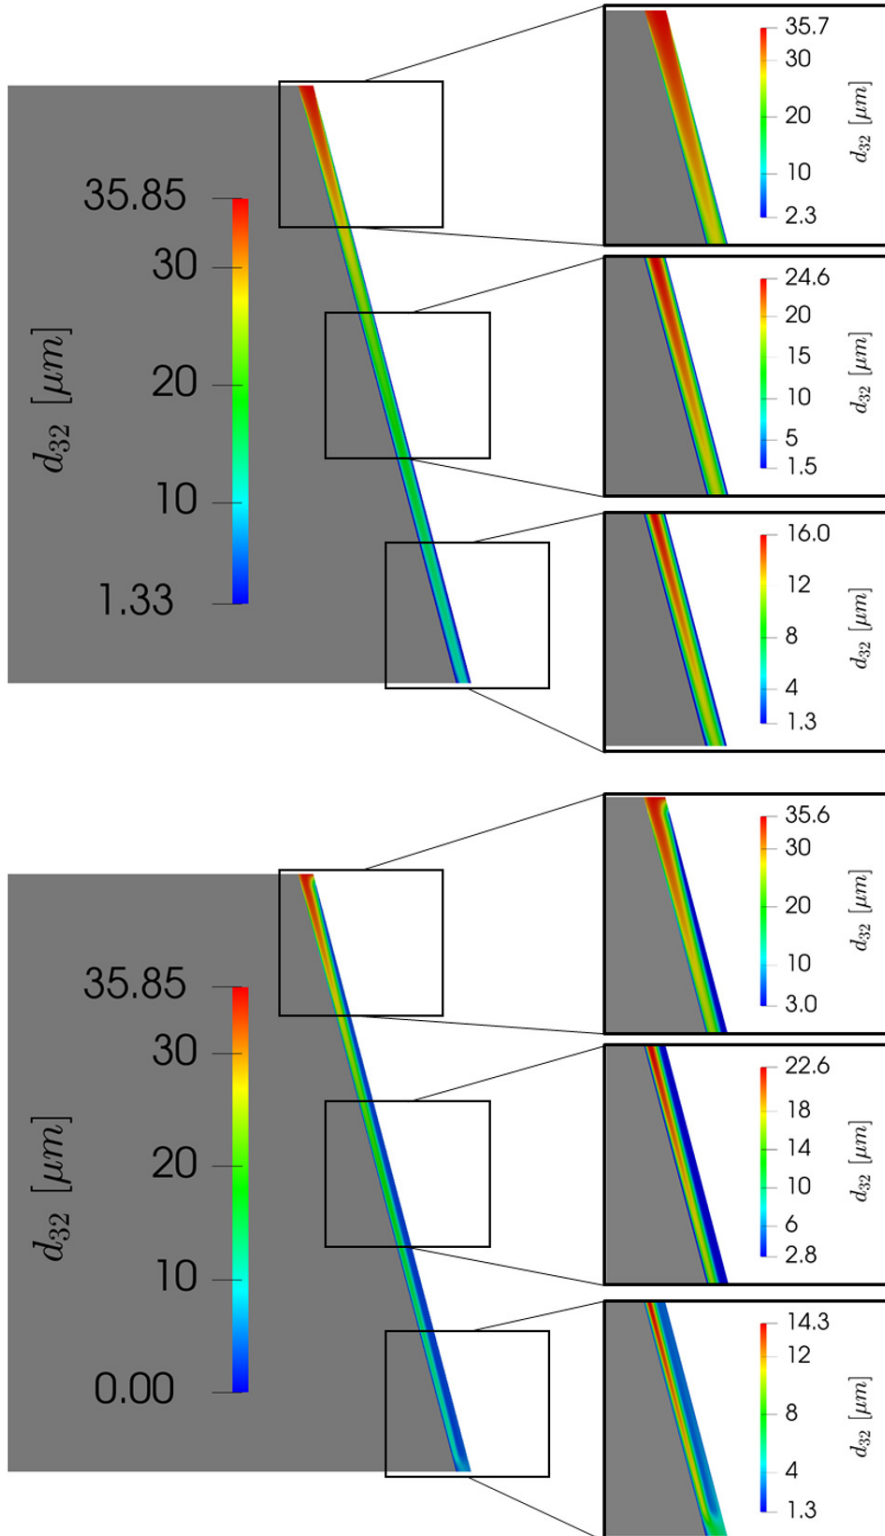

**Figure 11:** Volume distribution of mixing index (-) and shear rate (1/s) for operating conditions corresponding to experiment no. 1 (top), no. 2 (middle), and no. 3 (bottom) and an oil concentration of 0.70 kg/kg.

**Figure 12:** The trend of the number of oil droplets per unit volume ( $M_0$ , top) and oil volume fraction ( $\pi/6M_3$ , bottom) along the normalized distance from the middle point of the inlet to the middle point of the outlet of the cone mill mixer, for oil concentrations equal to 0.65 kg/kg (blue line), 0.70 kg/kg (green line), and 0.75 kg/kg (red line) in the experiment n.3 (see Table 1).

**Figure 13:** Contour plots of the mean Sauter diameter  $d_{32}$  of oil droplets along a longitudinal section of the cone mill with oil concentration equal to 0.70 kg/kg (70 wt%) for the experiments n. 3 (top) and n. 1 (bottom) (see Table 1). Insets are magnified gap sections.

**Figure 14:** Comparison between the outlet experimental Sauter mean diameter values and the predicted ones for Experiments no. 1, 2, and 3 (circle, triangle, and square symbols, respectively) and oil content of 0.65 kg/kg, 0.70 kg/kg, and 0.75 kg/kg (blue, green, and red symbols, respectively) when droplet breakage occurs due to the simple shear (top), elongational flow (middle), and the combination of both of them (bottom).
