Abstract

We present a spatial hybrid discrete-continuum modelling framework for the interaction dynamics between tumour cells and cytotoxic T cells, which play a pivotal role in the immune response against tumours. In this framework, tumour cells and T cells are modelled as individual agents while chemokines that drive the chemotactic movement of T cells towards the tumour are modelled as a continuum. We formally derive the continuum counterpart of this model, which is given by a coupled system that comprises an integro-differential equation for the density of tumour cells, a partial differential equation for the density of T cells, and a partial differential equation for the concentration of chemokines. We report on computational results of the hybrid model and show that there is an excellent quantitative agreement between them and numerical solutions of the corresponding continuum model. These results shed light on the mechanisms that underlie the emergence of different levels of infiltration of T cells into the tumour and elucidate how T-cell infiltration shapes anti-tumour immune response. Moreover, to present a proof of concept for the idea that, exploiting the computational efficiency of the continuum model, extensive numerical simulations could be carried out, we investigate the impact of T-cell infiltration on the response of tumour cells to different types of anti-cancer immunotherapy.

1 Introduction

1.1 Biological background

Understanding the cellular processes that underlie the early stages of tumour development and tumour-immune interaction is important to guide the design of effective treatments, especially immunotherapy [7, 8, 26, 60]. Experimental and clinical evidence indicates that the immune system plays a critical role in the prevention and eradication of tumours, by detecting immunogenic tumour cells through mutational or abnormally expressed genes and mounting an adaptive immune response [16]. In particular, specific immune cells, such as cytotoxic T cells, are activated in secondary lymphoid organs draining the tumour site. Then, these T cells migrate to the tumour micro-environment (TME) in an attempt to eliminate the tumour [8, 56].

However, a myriad of immunosuppressive strategies, the so-called immune checkpoints, help tumour cells acquiring features that allow them to evade immune detection, which may ultimately result in tumour escape. One important route towards this escape is created as tumour cells hijack the regulatory pathways of the immune system to suppress its functionality [61]. The programmed cell death protein-1 (PD1) and its ligand PD-L1 are amongst these inhibitory pathways [28, 32]. Under protracted immune stress, PD-L1 expression can be induced on tumour cells, leading to T cell exhaustion and resistance to anti-tumour immune action in many cancers, such as melanoma [64, 72] and non-small cell lung cancer (NSCLC) [55]. Moreover, the engagement of various oncogenic pathways results in the expression of cytokines and chemokines that mediate the exclusion of T cells from the TME [36] or, alternatively, the repression of factors that facilitate T cell trafficking and infiltration into the tumour [64]. In this context, the design of immune checkpoint therapies which target regulatory pathways in T cells to enhance anti-tumour immune responses may be beneficial to the treatment of multiple types of cancer [28, 36, 62].

The observation that type, density and location of immune cells within the tumour may be associated with prognosis in different types of cancer led to the development of the ‘immunoscore’ as a prognostic marker in cancer patients [5, 19, 20, 21]. The immunoscore provides a score that increases with the density of CD8+ and CD3+ T cells both in the centre and at the margin of the tumour. CD3 is a protein complex and T cell co-receptor that is involved in activating both cytotoxic T cells (CD8+ naive T cells) and T helper cells (CD4+ naive T cells), and it is therefore the common antigen used to identify both CD4+ and CD8+ T cells. In this vein, a new immune-based, rather than a cancer-based, classification of tumours that relies on the immunoscore has been proposed in [20], where the authors have classified tumours in four categories. The “hot” category comprises tumours which are highly infiltrated by T cells and thus have a high immunoscore. The category “altered-immunosuppressed” is for tumours with a small amount of infiltrated T cells. Tumours in the “altered-excluded” category are characterised by two different regions: their margin is T cell-infiltrated while the centre is not. Tumours in these two categories have an intermediate immunoscore. Finally, “cold” tumours have a low immunoscore and are often associated with a poor response to immunotherapies, since T cells are absent both in the centre of the tumour and at its margin.

1.2 Mathematical modelling background

Mathematical models can support a better understanding of the interaction dynamics between tumour cells and immune cells [18, 27, 51, 73]. Incorporating in these models the effects of therapeutic strategies that boost anti-tumour immune response can help predicting the success of cancer treatment protocols, including immunotherapy protocols.

Mechanistic dynamical-system models formulated as ordinary differential equations (ODEs) [1, 4, 11, 25, 39, 41, 40, 43, 46, 65, 73] or integro-differential equations (IDEs) [3, 17, 38, 45] have been developed to investigate the interaction dynamics between tumour and immune cells

in various scenarios, including immunotherapy. However, these models often rely on the assumption that cells are well-mixed and, therefore, do not take into account spatial dynamics of tumour and immune cells. As a result, partial differential equation (PDE) models to study the spatio-temporal dynamics of tumour-immune interactions have also been developed – see for example [2, 6].

Deterministic continuum models are amenable to both analytical and numerical approaches, which allow for a more in-depth theoretical understanding of the underlying cellular dynamics. However, they make it more difficult to incorporate the finer details of dynamical interactions between tumour cells and T cells. Moreover, they cannot easily capture the emergence of population-level phenomena that are driven by stochastic fluctuations in single-cell biophysical properties, which are relevant in the regime of low cellular densities [44]. Hence, one ideally wants to derive these models as the appropriate limit of stochastic discrete (i.e. individual-based) models of the interaction dynamics between tumour cells and T cells. A number of stochastic discrete models [14, 47, 48] and hybrid discrete-continuum models [37, 52, 42] have also been used to study the interaction dynamics between tumour and immune cells. In contrast to continuum models, these discrete models track the dynamics of single cells, thus permitting the representation of single cell-scale mechanisms, and account for possible stochastic fluctuations in single-cell biophysical properties. Integrating the results of computational simulations of stochastic discrete models with the results of analysis and numerical simulation of their deterministic continuum counterparts makes it possible to identify more clearly the validity domain of the results obtained, thus leading to more robust biological insights. As a consequence, the derivation of continuum models for the dynamics of cell populations from underlying hybrid models has become an active research field – see, for instance, [10, 12, 13, 34].

1.3 Contents of the article

In this article, we develop a spatial hybrid discrete-continuum model for the interaction dynamics between tumour cells and immune cells. In this framework, a stochastic individual-based model tracking the dynamics of single tumour cells and immune cells is coupled with a balance equation for the concentration of chemokines (e.g. CXCL9/10) which are secreted by tumour cells and drive the chemotactic movement of immune cells towards the tumour [19, 24]. While being aware of the fact that a variety of different types of cells and molecules take part in the immune response against tumours, here we focus on cytotoxic T cells only, since they are the immune agents that are most commonly stimulated by immunotherapies [30, 68].

In this model, cell dynamics are governed by a set of rules that result in a discrete-time branching random walk on a regular lattice [31]. Using methods similar to those we have previously employed in [3, 9, 49], we formally derive the deterministic continuum counterpart of the hybrid model, which is given by a coupled system that comprises an IDE for the density of tumour cells, a PDE for the density of T cells, and a PDE for the concentration of chemokines. We report on computational results of the hybrid model and show that there is an excellent quantitative agreement between them and numerical solutions of the corresponding continuum model. These results shed light on the mechanisms that underlie the emergence of different levels of infiltration of T cells into the tumour and elucidate how T-cell infiltration shapes anti-tumour immune response. Moreover, to present a proof of concept for the idea that, exploiting the computational efficiency of the continuum model, extensive numerical simulations could be carried out to identify possible targets to improve the efficacy of anti-cancer therapy, we investigate the impact of T-cell infiltration on the dynamics of tumour cells under parameter settings which provide a simplified representation of the action of different types of immunotherapy.

The article is organised as follows. In Section 2, the hybrid discrete-continuum model is introduced. In Section 3, the deterministic continuum counterpart of this model is presented (a formal derivation is provided in Appendix A). In Section 4, computational results of the

hybrid model are discussed and integrated with numerical solutions of the continuum model. In Section 5, biological implications of the main findings of this study are summarised and directions for future research are outlined.

2 Hybrid discrete-continuum model

In our model, each cell is seen as an agent that occupies a position on a lattice, while the concentration of chemokines, to which we will refer as “chemoattractant” in the remainder of the article, is described by a discrete, non-negative function. Each tumour cell can proliferate or die at certain rates. In the vein of [6, 42, 48], here we focus on tumours in the early stages of development (*i.e.* small pre-angiogenic tumours) and, therefore, we neglect the effects of the movement of tumour cells. As similarly done in [6], we let the chemoattractant be secreted by tumour cells and undergo both natural decay and linear diffusion. T cells enter the spatial domain where the tumour is located through blood vessels at a rate that is proportional to the total amount of chemoattractant. Upon entering the domain, T cells undergo undirected, random movement and chemotactic movement towards regions of higher concentration of the chemoattractant (*i.e.* cells migrate towards the tumour), and exert a cytotoxic action against tumour cells.

For ease of presentation, we let the cells and the chemoattractant be distributed across a d -dimensional domain Ω , with $d = 1$ or $d = 2$. In particular, we consider the case where the spatial domain is represented by the set $\Omega := [0, \ell]^d$, with $\ell \in \mathbb{R}_+$, where \mathbb{R}_+ is the set of positive real numbers not including zero. The position of the cells and the molecules of chemoattractant at time $t \in [0, t_f] \subset \mathbb{R}_+$ is modelled by the variable $x \in [0, \ell]$ when $d = 1$ and by the vector $\mathbf{x} = (x, y) \in [0, \ell]^2$ when $d = 2$.

We discretise the time variable t and the space variables x and y , respectively, as $t_k = k\tau$, $x_i = i\chi$ and $y_j = j\chi$, with $k \in \mathbb{N}_0$ and $(i, j) \in [0, \mathcal{N}]^2 \subset \mathbb{N}_0^2$, where \mathbb{N}_0 is the set of natural numbers including zero. Here, $\tau \in \mathbb{R}_+$ and $\chi \in \mathbb{R}_+$ are the time- and space-step, respectively, and $\mathcal{N} := 1 + \lceil \frac{\ell}{\chi} \rceil$, where $\lceil \cdot \rceil$ denotes the ceiling function. We will use the notation $\mathbf{i} \equiv i$ and $\mathbf{x}_i \equiv x_i$ when $d = 1$, and $\mathbf{i} \equiv (i, j)$ and $\mathbf{x}_i \equiv (x_i, y_j)$ when $d = 2$.

We denote by n_i^k the density of tumour cells, which is defined as the number of tumour cells at position \mathbf{x}_i and at time t_k , $N_i^k \in \mathbb{N}_0$, divided by the size of a lattice site, that is

$$n_i^k \equiv n(\mathbf{x}_i, t_k) := \frac{N_i^k}{\chi^d}. \quad (2.1)$$

Furthermore, we denote by c_i^k the density of T cells, which is defined as the number of T cells at position \mathbf{x}_i and at time t_k , $C_i^k \in \mathbb{N}_0$, divided by the size of a lattice site, that is

$$c_i^k \equiv c(\mathbf{x}_i, t_k) := \frac{C_i^k}{\chi^d}. \quad (2.2)$$

Finally, the concentration of chemoattractant on the lattice site \mathbf{i} and at time-step k is modelled by the discrete, non-negative function $\phi_i^k \equiv \phi(\mathbf{x}_i, t_k)$.

In the mathematical framework of our model, the quantity

$$I^k \equiv I(t_k) := \frac{|\Omega_c|}{|\Omega_{\text{tum}}|} I_{\Omega_c}(t_k) + \frac{|\Omega_m|}{|\Omega_{\text{tum}}|} I_{\Omega_m}(t_k) \quad (2.3)$$

provides a possible simplified measure of the immunoscore I at time t_k . In (2.3), $I_{\Omega_c} \in \mathbb{N}_0$ is the number of T cells within the set $\Omega_c \subset \Omega$ defined as the ‘centre of the tumour’, $I_{\Omega_m} \in \mathbb{N}_0$ is the number of T cells within the set $\Omega_m \subset \Omega$ defined as the ‘margin of the tumour’, and

$\Omega_{\text{tum}} := \Omega_c \cup \Omega_m$ is the whole region occupied by the tumour. Here, $|\cdot|$ is the measure of the set (\cdot) . Given the initial distribution of tumour cells, we define (cf. Fig. 1)

$$\Omega_c := \{\mathbf{x}_i \in \Omega : \|\mathbf{x}_i - \mathbf{x}_{\text{cm}}\|_d < R\} \quad \text{and} \quad I_{\Omega_c}(t_k) := \sum_i c_i^k \chi^d \mathbb{1}_{\Omega_c}(\mathbf{x}_i) \quad (2.4)$$

while

$$\Omega_m := \Omega_{\text{tum}} \setminus \Omega_c \quad \text{and} \quad I_{\Omega_m}(t_k) := \sum_i c_i^k \chi^d \mathbb{1}_{\Omega_m}(\mathbf{x}_i). \quad (2.5)$$

Here, $\mathbf{x}_{\text{cm}} \in \Omega$ is the initial centre of mass of the tumour, which is computed as

$$\mathbf{x}_{\text{cm}} = \frac{1}{\rho_n^0} \sum_i n_i^0 \chi^d \mathbf{x}_i, \quad (2.6)$$

where ρ_n^0 is the initial number of tumour cells. Moreover, $\mathbb{1}_{\Omega_m}$ and $\mathbb{1}_{\Omega_c}$ are the indicator functions of the sets Ω_m and Ω_c , respectively. Note that, in the definition of sets Ω_c and Ω_m , we are supposing that the radius R is fixed and, therefore, the two sets do not change over time. This is coherent with the fact that, as mentioned earlier, tumour-cell movement is neglected.

Abstracting from the ‘immunoscore’-based classification of tumours recalled in Section 1, throughout the article we will classify different tumour scenarios depending on the value of I at the end of numerical simulations, *i.e.* the quantity

$$I^f \equiv I(t_f) = \frac{|\Omega_c|}{|\Omega_{\text{tum}}|} I_{\Omega_c}(t_f) + \frac{|\Omega_m|}{|\Omega_{\text{tum}}|} I_{\Omega_m}(t_f). \quad (2.7)$$

In particular, along the lines of [19], scenarios for which the value of I^f is low will be classified as ‘cold tumour scenarios’; scenarios with an intermediate value of I^f will be classified as ‘altered tumour scenarios’, which will then be further classified as ‘altered-immunosuppressed tumour scenarios’ or ‘altered-excluded tumour scenarios’ based on the distribution of T cells at the centre and margin of the tumour; finally, scenarios characterised by a high value of I^f will be classified as ‘hot tumour scenarios’. This tumour classification is illustrated by the schematics presented in Fig. 1.

The strategies used to model the dynamics of the cells and the chemoattractant when $d = 1$ are described in detail in the following subsections, and are also schematically illustrated in Fig. 2. Analogous strategies are used in the case where $d = 2$.

In the remainder of the article, when necessary, the subscripts n , c and ϕ will be used to identify the parameters and functions related to the dynamics of tumour cells, T cells and chemoattractant, respectively.

2.1 Dynamics of tumour cells

We consider a scenario where tumour cells proliferate (*i.e.* undergo cell division) and die due to intra-tumour competition as well as to the cytotoxic action of T cells. We assume that a dividing tumour cell is replaced by two identical cells that are placed on the same lattice site as their parent, while a dying cell is removed from the system.

2.1.1 Tumour cell proliferation and death induced by intra-tumour competition

At every time-step k , we allow tumour cells to undergo cell division with probability

$$\tau \alpha_n > 0, \quad (2.8)$$

where $\alpha_n \in \mathbb{R}_+^*$ represents the rate of tumour cell proliferation.

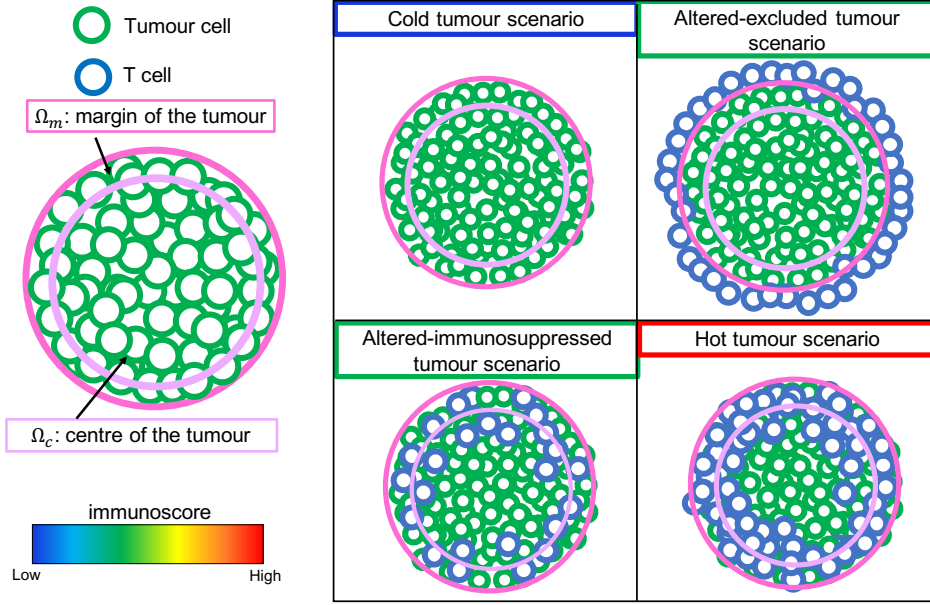

Figure 1: **Schematics describing the classification of cold, altered-excluded, altered-immunosuppressed and hot tumour scenarios based on the immunoscore.** In the mathematical framework of our model we classify different tumour scenarios depending on the value of the immunoscore at the end of numerical simulations, *i.e.* the quantity defined via (2.7). The immunoscore is here defined as a weighted sum of the number of T cells in the centre of the tumour and the number of T cells at the margin of the tumour. In more detail, along the lines of [19], scenarios for which the value of the immunoscore is low will be classified as ‘cold tumour scenarios’; scenarios with an intermediate value of the immunoscore will be classified as ‘altered tumour scenarios’, which will then be further classified as ‘altered-immunosuppressed tumour scenarios’ or ‘altered-excluded tumour scenarios’ based on the distribution of T cells in the centre and at the margin of the tumour; finally, scenarios characterised by a high value of the immunoscore will be classified as ‘hot tumour scenarios’.

Figure 2: **Schematics summarising the mechanisms and processes included in the hybrid discrete-continuum model.** The governing rules for the dynamics of tumour cells are here represented by green solid arrows, the rules for the dynamics of T cells are represented by blue solid arrows, and the processes underlying the dynamics of the chemoattractant are represented by grey solid arrows. At each time-step t_k , tumour cells divide at rate α_n , die due to intra-tumour competition at rate $\mu_n \rho_n^k$ or die due to the cytotoxic action of T cells at rate $\zeta_n K_i^k$. The quantities ρ_n^k and K_i^k are, respectively, defined via (2.9) and (2.11). Tumour cells also secrete the chemoattractant at rate α_ϕ . The chemoattractant diffuses through the domain at rate β_ϕ and decays at rate κ_ϕ . The influx rate of T cells from blood vessels at position x_i is modelled by $\alpha_c r_i^k$, with r_i^k defined via (2.17). T cells change their position through a combination of undirected, random movement and chemotactic movement in response to the chemoattractant secreted by tumour cells, while tumour cell movement is neglected. Finally, T cells die due to homeostatic regulation mechanisms at rate $\mu_c \rho_c^k$, with ρ_c^k defined via (2.20).

In order to capture the effect of cell death induced by intra-tumour competition, we let tumour cells die at a rate proportional to their number, which is denoted by

$$\rho_n^k \equiv \rho_n(t_k) := \sum_i n_i^k \chi, \quad (2.9)$$

with constant of proportionality $\mu_n \in \mathbb{R}_+^*$. Hence, between the time-step k and the time-step $k+1$, we let a tumour cell die due to intra-tumour competition with probability

$$\tau \mu_n \rho_n^k \geq 0. \quad (2.10)$$

2.1.2 Cytotoxic action of T cells against tumour cells

When T cells are sufficiently close to a tumour cell, they release cytotoxic substances which may lead to the death of the tumour cell [8]. Therefore, building on the modelling strategies proposed in [6], we let a tumour cell die due to the cytotoxic action of T cells at a rate proportional to the number of T cells in a sufficiently close neighbourhood of the tumour cell. This models the fact that T cells can interact with a tumour cell up to a certain distance, and that beyond such a distance the tumour cell can no longer be induced to death. Hence, we introduce $K_i^k \in \mathbb{N}_0$ which represents, at each time-step t_k , the number of T cells that can exert a cytotoxic action against a tumour cell at position x_i . In particular, we define K_i^k as

$$K_i^k \equiv K(x_i, t_k) := \sum_p \eta(x_i, x_p; \theta) c_p^k \chi. \quad (2.11)$$

The function η is defined as follow

$$\eta(x, z; \theta) := \begin{cases} 1 & \text{if } |x - z| \leq \theta \\ 0 & \text{if } |x - z| > \theta \end{cases} \quad \text{for } (x, z; \theta) \in \Omega \times \Omega \times (0, |\Omega|], \quad (2.12)$$

where $|\Omega|$ denotes the size of the set Ω (i.e. $|\Omega| = \ell$ if $\Omega := [0, \ell]$). The quantity K_i^k defined via (2.11) and (2.12) represents the number of T cells within a distance θ of x_i . The parameter $0 < \theta \leq |\Omega|$ regulates the maximum radius of interaction between a tumour cell at position x_i and the T cells in its neighbourhood. Therefore, we define the probability of death of tumour cells at position x_i and time t_k due to the cytotoxic action of T cells as

$$\tau \zeta_n K_i^k \geq 0. \quad (2.13)$$

The parameter $\zeta_n \in \mathbb{R}_+^*$ is linked to the level of efficiency of T cells at eliminating tumour cells. In particular, lower values of ζ_n correspond to scenarios in which this cytotoxic action of T cells is less effective, due for example to a higher expression of PD1 inhibitory receptors and PD-L1 ligands on the surface of T cells and tumour cells [28, 32].

Remark 1. Note that (2.8), (2.10) and (2.13) implicitly require the time-step τ to be sufficiently small that $\tau \alpha_n + \tau (\mu_n \rho_n^k + \zeta_n K_i^k)$ is less than or equal to 1.

2.2 Dynamics of the chemoattractant

We denote by ϕ_i^k the concentration of chemoattractant at position x_i and at time t_k . The dynamic of ϕ_i^k is governed by the following discrete balance equation

$$\phi_i^{k+1} = \phi_i^k + \tau \beta_\phi (\mathcal{L}\phi^k)_i + \tau \alpha_\phi n_i^k - \tau \kappa_\phi \phi_i^k, \quad i \in [1, \mathcal{N} - 1], \quad (2.14)$$

subject to a suitable initial condition and discrete zero-flux boundary conditions, i.e.

$$\phi_0^k = \phi_1^k \quad \text{and} \quad \phi_{\mathcal{N}}^k = \phi_{\mathcal{N}-1}^k. \quad (2.15)$$

In the balance equation (2.14), \mathcal{L} is the second-order central difference operator on the lattice $\{x_i\}_i$, i.e.

$$(\mathcal{L}\phi^k)_i = \frac{1}{\chi^2} (\phi_{i+1}^k + \phi_{i-1}^k - 2\phi_i^k) \quad (2.16)$$

Moreover, the parameter $\beta_\phi \in \mathbb{R}_+^*$ is the diffusion coefficient of the chemoattractant and $\kappa_\phi \in \mathbb{R}_+^*$ is the rate at which the chemoattractant undergoes natural decay. Finally, the parameter $\alpha_\phi \in \mathbb{R}_+^*$ represents the per capita production rate of the chemoattractant by tumour cells. The balance equation (2.14) is simply a standard discretisation of a reaction-diffusion equation of the type that is commonly used to describe the dynamics of molecular species, see for example [50].

2.3 Dynamics of T cells

Following [23], we consider a scenario where T cells are recruited from different sources corresponding to blood vessels that are located in the tissue surrounding the tumour. T cells can change their position according to a combination of undirected, random movement and chemotactic movement, which are regarded as independent processes. Finally, T cells can die at a certain rate due to homeostatic regulation mechanisms, and dying cells are removed from the system. This results in the following rules for the dynamics of T cells.

2.3.1 Inflow and death of T cells

We let $\omega \subset \Omega$ be the set of points in the tissue surrounding the tumour that are occupied by blood vessels, through which new T cells can enter the domain. Since we do not consider the formation of new blood vessels, we assume that ω is given and does not change in time. We denote by r_i^k the term controlling the inflow of T cells from blood vessels, which is defined as

$$r_i^k \equiv r(x_i, t_k) := \phi_{tot}^k \mathbb{1}_\omega(x_i), \quad (2.17)$$

where $\mathbb{1}_\omega$ is the indicator function of the set ω and ϕ_{tot}^k is the total amount of chemoattractant at time t_k , that is,

$$\phi_{tot}^k \equiv \phi_{tot}(t_k) := \sum_i \phi_i^k \chi. \quad (2.18)$$

We then let the influx rate of T cells from blood vessels at position x_i and time t_k be proportional to r_i^k with constant of proportionality $\alpha_c \in \mathbb{R}_+^*$. Hence, between the time-step k and the time-step $k+1$, we let a density of T cells equal to

$$\tau \alpha_c r_i^k \geq 0 \quad (2.19)$$

enter a blood vessel at position x_i .

Finally, we let T cells die due to homeostatic regulation mechanisms. In analogy with the case of tumour cells, we suppose the rate of death of T cells to be proportional to the number of T cells

$$\rho_c^k \equiv \rho_c(t_k) := \sum_i c_i^k \chi, \quad (2.20)$$

with constant of proportionality $\mu_c \in \mathbb{R}_+^*$. Therefore, between the time-step k and the time-step $k+1$, we let a T cell die with probability

$$\tau \mu_c \rho_c^k \geq 0. \quad (2.21)$$

Remark 2. Note that (2.21) implicitly requires the time-step τ to be sufficiently small that the corresponding quantity is less than or equal to 1.

2.3.2 Chemotactic movement of T cells

We now turn to modelling the chemotactic movement of T cells (*i.e.* the movement of T cells up the gradient of the chemoattractant ϕ_i^k). Building on [9], chemotactic movement is here modelled as a biased random walk whereby the movement probabilities depend on the difference between the concentration of chemoattractant at the site occupied by a T cell and the concentration of chemoattractant at the neighbouring sites. To take into account possible reduction in cell motility at high cell densities [58, 63, 70], we incorporate into the model volume-filling effects [59], whereby T cell movement is allowed only to site locations x_i where the total cell density $w_i^k := n_i^k + c_i^k$ is smaller than a threshold value $w_{\max} \in \mathbb{R}_+^*$, which corresponds to a cell tight-packing state. Therefore, we modulate the movement probabilities of T cells by a monotonically decreasing function of the total cell density at the neighbouring sites. Specifically, as similarly done in [71], we define this function as

$$\psi(w_i^k) := \begin{cases} 1 - \frac{w_i^k}{w_{\max}}, & 0 \leq w_i^k \leq w_{\max}, \\ 0, & \text{otherwise.} \end{cases} \quad (2.22)$$

Hence, for a T cell on the lattice site x_i and at time step t_k , we define:

1. the probability of moving to the lattice site x_{i-1} (*i.e.* the probability of moving left) via chemotaxis as

$$q_{Li}^k := \nu \psi(w_{i-1}^k) \left(\frac{\phi_{i-1}^k - \phi_i^k}{2\phi_{\max}} \right)_+ \quad \text{for } i \in [1, \mathcal{N}] \quad \text{and} \quad q_{L0}^k = 0 \quad (2.23)$$

where $(\cdot)_+$ denotes the positive part of (\cdot) and $\phi_{\max} \in \mathbb{R}_+^*$ is the maximum value which can be attained by the concentration of the chemoattractant – see comments below definition (2.25);

2. the probability of moving to the lattice site x_{i+1} (*i.e.* the probability of moving right) via chemotaxis as

$$q_{Ri}^k := \nu \psi(w_{i+1}^k) \left(\frac{\phi_{i+1}^k - \phi_i^k}{2\phi_{\max}} \right)_+ \quad \text{for } i \in [0, \mathcal{N} - 1] \quad \text{and} \quad q_{R\mathcal{N}}^k = 0; \quad (2.24)$$

3. and the probability of not undergoing chemotactic movement as

$$1 - q_{Li}^k - q_{Ri}^k \quad \text{for } i \in [0, \mathcal{N}]. \quad (2.25)$$

Here, the parameter $\nu \in \mathbb{R}_+$, with $0 \leq \nu \leq 1$, is directly proportional to the chemotactic sensitivity of T cells. Dividing by ϕ_{\max} ensures that the values of the quotients in (2.23) and (2.24) are less than or equal to 1.

2.3.3 Undirected, random movement of T cells

To model the effect of undirected, random movement, we allow T cells to update their position according to a random walk with movement probability $\lambda \in \mathbb{R}_+^*$, where $0 < \lambda \leq 1$. In particular, we assume that a T cell on the lattice site x_i can move via undirected, random movement into either the lattice site x_{i-1} or the lattice site x_{i+1} with probability $\frac{\lambda}{2}$. As similarly done in the case of chemotactic movement, in order to capture a possible reduction in T cell motility at higher cell densities [58, 63, 70], we modulate the movement probability by a decreasing function of the density of tumour cells and T cells at the neighbouring sites. In particular, for a T cell on the lattice site i and at the time-step k , we define:

1. the probability of moving to the lattice site $i - 1$ via undirected, random movement as

$$T_{Li}^k := \frac{\lambda}{2} \psi(w_{i-1}^k) \quad \text{for } i \in [1, \mathcal{N}] \quad \text{and} \quad T_{L0}^k = 0; \quad (2.26)$$

2. the probability of moving to the lattice site $i + 1$ via undirected, random movement as

$$T_{Ri}^k := \frac{\lambda}{2} \psi(w_{i+1}^k) \quad \text{for } i \in [0, \mathcal{N} - 1] \quad \text{and} \quad T_{R\mathcal{N}}^k = 0; \quad (2.27)$$

3. and the probability of not undergoing undirected, random movement as

$$1 - T_{Li}^k - T_{Ri}^k \quad \text{for } i \in [0, \mathcal{N}]. \quad (2.28)$$

In (2.26) and (2.27), the modulating function ψ is defined via (2.22).

3 Corresponding continuum model

Letting the time-step $\tau \rightarrow 0$ and the space-step $\chi \rightarrow 0$ in such a way that

$$\frac{\lambda \chi^2}{2d \tau} \rightarrow \beta_c \in \mathbb{R}_+^* \quad \text{and} \quad \frac{\nu \chi^2}{2d \phi_{\max} \tau} \rightarrow \gamma_c \in \mathbb{R}_+^* \quad \text{as } \tau \rightarrow 0, \chi \rightarrow 0, \quad (3.1)$$

using the method employed in [3, 9, 49], it is possible to formally show (see Appendix A) that the deterministic continuum counterpart of the hybrid model described in Section 2 comprises the following coupled IDE-PDE-PDE system for the density of tumour cells, $n(\mathbf{x}, t)$, the density of T cells, $c(\mathbf{x}, t)$ and the chemoattractant concentration, $\phi(\mathbf{x}, t)$

$$\begin{cases} \partial_t n = \alpha_n n - \mu_n \rho_n(t) n - \zeta_n K(\mathbf{x}, t) n \\ \partial_t c - \nabla \cdot [\beta_c \psi(w) \nabla c - \gamma_c \psi(w) c \nabla \phi - \beta_c c \psi'(w) \nabla w] = -\mu_c \rho_c(t) c + \alpha_c r(\mathbf{x}, t) \\ \partial_t \phi - \beta_\phi \Delta \phi = \alpha_\phi n - \kappa_\phi \phi \\ w(\mathbf{x}, t) := n(\mathbf{x}, t) + c(\mathbf{x}, t), \end{cases} \quad (3.2)$$

where the IDE (3.2)₁ is posed on $\Omega \times (0, t_f]$, while the PDEs (3.2)₂ and (3.2)₃ are posed on $\Omega \setminus \partial\Omega \times (0, t_f]$ and are subject to zero-flux boundary conditions on $\partial\Omega$. The IDE-PDE-PDE system (3.2) is complemented with the following definitions

$$K(\mathbf{x}, t) := \int_{\Omega} \eta(\mathbf{x}, \mathbf{x}'; \theta) c(\mathbf{x}', t) d\mathbf{x}', \quad r(\mathbf{x}, t) := \phi_{tot}(t) \mathbb{1}_{\omega}(\mathbf{x})$$

$$\rho_n(t) := \int_{\Omega} n(\mathbf{x}, t) d\mathbf{x}, \quad \rho_c(t) := \int_{\Omega} c(\mathbf{x}, t) d\mathbf{x}, \quad \phi_{tot}(t) := \int_{\Omega} \phi(\mathbf{x}, t) d\mathbf{x}.$$

In system (3.2), $\beta_c \in \mathbb{R}_+^*$ defined via (3.1) is the diffusion coefficient (*i.e.* the motility) of T cells, while $\gamma_c \in \mathbb{R}_+^*$ defined via (3.1) is the chemotactic sensitivity of T cells to the chemoattractant.

Figure 3: **Initial conditions.** Plots of the density of tumour cells $n(x, y, t)$ (panel (a)), the density of T cells $c(x, y, t)$ (panel (b)), and the chemoattractant concentration $\phi(x, y, t)$ (panel (c)) at the initial time of the simulations (*i.e.* at $t = 0$) for the continuum model. Analogous initial conditions are used for the hybrid model.

4 Numerical simulations

In this section, we report on computational results of the hybrid discrete-continuum model along with numerical solutions of the corresponding continuum model given by the IDE-PDE-PDE system (3.2). First, we establish a baseline scenario in which the level of efficiency of T cells at eliminating tumour cells (*i.e.* the parameter ζ_n) is sufficiently high so as to lead to tumour eradication. Then, we reduce the level of T cell efficiency in order to avoid tumour eradication, and we explore the mechanisms that underlie the emergence of different levels of infiltration of T cells into the tumour, which correspond to cold, altered-immunosuppressed, altered-excluded and hot tumour scenarios. In particular, we carry out sensitivity analysis to two parameters that we expect to play a key role in determining the spatial distribution of T cells: the secretion rate of chemoattractant by tumour cells (*i.e.* the parameter α_ϕ) and the threshold value of the total cell density above which T cell movement is impaired (*i.e.* the parameter w_{\max} in definition (2.22)). Finally, exploiting the computational efficiency of the continuum model, we investigate the impact of T-cell infiltration on the dynamics of tumour cells under parameter settings which provide a simplified representation of the action of different types of immunotherapy.

4.1 Set-up of numerical simulations

The hybrid and continuum models are parameterised using parameter values retrieved from the literature, wherever possible. The full list of parameter values and related references are provided in Table 1. For the numerical simulations we report on, we use the 2D spatial domain $\Omega := [0, 1]^2$. Under the parameter choice of Table 1, this is equivalent to considering a square region of a 2D cross-section of a tumour tissue of area 1 cm^2 . Furthermore, to carry out numerical simulations of the hybrid model, we use the space-step $\chi = 0.016 \text{ cm}$ and the time-step $\tau = 1 \times 10^{-4} \text{ days}$. Finally, unless otherwise specified, we choose the final time $t_f = 15 \text{ days}$. All simulations are performed in MATLAB [53].

Initial conditions and blood vessel distribution Fig. 3 displays the initial conditions chosen to carry out numerical simulations. In particular, for the hybrid model we have

$$n_{ij}^0 = 800 \exp[-200(i\chi - x_{11}^*)^2 - 200(j\chi - y_{11}^*)^2], \quad (4.1)$$

$$c_{ij}^0 = 60 \sum_{p=1}^4 \exp[-300(i\chi - x_{2p}^*)^2 - 300(j\chi - y_{2p}^*)^2], \quad (4.2)$$

and

$$\phi_{ij}^0 = 90 \exp[-200(i\chi - x_{11}^*)^2 - 200(j\chi - y_{11}^*)^2], \quad (4.3)$$

with $(x_{11}^*, y_{11}^*) = (0.5, 0.5)$, $(x_{21}^*, y_{21}^*) = (0.26, 0.74)$, $(x_{22}^*, y_{22}^*) = (0.26, 0.26)$, $(x_{23}^*, y_{23}^*) = (0.74, 0.74)$ and $(x_{24}^*, y_{24}^*) = (0.74, 0.26)$. The points where T cells are initially concentrated are the centres of the regions where blood vessels are assumed to be located, that is, the set ω in (2.17) is defined as the union of four balls of small radius and centres (x_{21}^*, y_{21}^*) , (x_{22}^*, y_{22}^*) , (x_{23}^*, y_{23}^*) and (x_{24}^*, y_{24}^*) .

Similarly, for the continuum model we have

$$n(x, y, 0) = 800 \exp[-200(x - x_{11}^*)^2 - 200(y - y_{11}^*)^2], \quad (4.4)$$

$$c(x, y, 0) = 60 \sum_{p=1}^4 \exp[-300(x - x_{2p}^*)^2 - 300(y - y_{2p}^*)^2], \quad (4.5)$$

and

$$\phi(x, y, 0) = 90 \exp[-200(x - x_{11}^*)^2 - 200(y - y_{11}^*)^2]. \quad (4.6)$$

A description of the algorithmic rules that underlie computational simulations of the hybrid model is provided in Appendix B.1, while the methods employed to numerically solve the IDE-PDE-PDE system (3.2), subject to suitable initial conditions and no-flux boundary conditions, are detailed in Appendix B.2.

Given the initial conditions of the two models, we compute the coordinates of the centre of mass of the tumour $(x_{\text{cm}}, y_{\text{cm}}) = (0.5, 0.5)$, and we define the set Ω_c (*i.e.* the ‘centre of the tumour’) via definition (2.4) as

$$\Omega_c := \left\{ \mathbf{x}_i \equiv (x_i, y_i) \in [0, 1]^2 : \sqrt{(x_i - x_{\text{cm}})^2 + (y_i - y_{\text{cm}})^2} < 0.144 \right\}.$$

The set Ω_c corresponds to approximately 65% of the region initially occupied by the tumour and, therefore, the set $\Omega_m = \Omega \setminus \Omega_c$ (*i.e.* the ‘margin of the tumour’) comprises the remaining 35% of the tumour region.

Parameter values Unless otherwise specified, we use the parameter values listed in Table 1. Here, the value of the parameter α_n is consistent with previous measurement and estimation studies on the dynamics of tumour cells by [14], who calculated the estimated proliferation rate of a tumour cell by using the average duplication time of melanoma cells. The values of the diffusion coefficient β_ϕ and decay rate κ_ϕ of the chemoattractant correspond to those used in [15, 54]. Moreover, the range of values of the secretion rate α_ϕ is consistent with the values used in [6]. To explore a wide range of biological situations corresponding to different degrees of immune infiltration, we use an arbitrary range of values for the parameter w_{max} . Moreover, on the basis of the considerations drawn in [9], we define $\phi_{\text{max}} := A w_{\text{max}}$, where $A \in \mathbb{R}_+^*$ is a scaling factor that ensures unit consistency. We verified via preliminary numerical simulations that, under initial conditions (4.3) and (4.6) for the concentration of the chemoattractant, if $A = 1$ then the concentration of chemoattractant remains uniformly smaller than ϕ_{max} for all times. Hence, we set $\phi_{\text{max}} = w_{\text{max}}$ to carry out numerical simulations. Finally, the values of the parameters λ and ν correspond to values of β_c and γ_c that are consistent with those reported in [54] and [6], respectively. Given the values of the parameters β_c and γ_c chosen to carry out numerical simulations of the continuum model, the following definitions are used for the hybrid model

$$\lambda := \beta_c \frac{4\tau}{\chi^2} \quad \text{and} \quad \nu := \gamma_c \frac{4\phi_{\text{max}}\tau}{\chi^2}$$

so that conditions (3.1) are met.

Table 1: Model parameters and related values used in numerical simulations.

Phenotype	Description	Value & Units	Reference
Domain	Space-step in the x and y direction	$\chi = 0.016 [cm]$	
	Time-step	$\tau = 10^{-4} [days]$	
	Final time	$t_f = 15 [days]$	
Tumour cells	Cell density at position \mathbf{x}	$n(\mathbf{x}, t) \geq 0 [cells/cm^2]$	
	Initial number	$\rho_n(0) = 45228 [cells]$	
	Proliferation rate	$\alpha_n = 1.5 [1/days]$	[14]
	Rate of death due to competition between tumour cells	$\mu_n = 1.25 \times 10^{-5} [1/(days cells)]$	
	Level of efficiency of T cells	$\zeta_n \in [0.001, 1] [1/(days cells)]$	
	Radius of interaction between tumour cells and T cells	$\theta = 3 \times 0.016 [cm]$	
T cells	Cell density at position \mathbf{x}	$c(\mathbf{x}, t) \geq 0 [cells/cm^2]$	
	Initial number	$\rho_c(0) = 8960 [cells]$	
	Prop. const. for influx rate	$\alpha_c = 6 [cells/(cm^2 days mol)]$	
	Chemotactic sensitivity (hybrid model)	$\nu = \gamma_c \frac{4\phi_{\max}\tau}{\chi^2}$	
	Chemotactic coefficient (continuum model)	$\gamma_c = 10 [cm^2/(days mol)]$	[6]
	Random movement prob. (hybrid model)	$\lambda = \beta_c \frac{4\tau}{\chi^2}$	
	Diffusion coefficient (continuum model)	$\beta_c = 1 \times 10^{-3} [cm^2/days]$	[54]
	Total cell density above which T cell movement is impaired	$w_{\max} = [0.74 \times 10^5, 8.88 \times 10^5] [cells/cm^2]$	
	Rate of death due to competition between T cells	$\mu_c = 6 \times 10^{-6} [1/(days cells)]$	
Chemoattr.	Concentration at position \mathbf{x}	$\phi(\mathbf{x}, t) \geq 0 [mol/cm^2]$	
	Total amount	$\phi_{tot}(t) \geq 0 [mol]$	
	Diffusion coefficient	$\beta_\phi = 10^{-1} [cm^2/day]$	[54]
	Secretion rate	$\alpha_\phi \in [0.001, 1.5] [mol/(cells days)]$	[6]
	Decay rate	$\kappa_\phi = 2 [1/days]$	[15]
	Maximum concentration	$\phi_{\max} = Aw_{\max}$, with $A = 1 [mol/cm^2]$	

Figure 4: **Baseline scenario: evolution of the numbers of tumour cells and T cells, and the total amount of chemoattractant.** Plots of the time evolution of the number of tumour cells $\rho_n(t)$, the number of T cells $\rho_c(t)$, and the total amount of chemoattractant $\phi_{tot}(t)$ (in the inset) of the hybrid model (solid, coloured lines) and the continuum model (dotted, black lines) for a choice of parameters that results in the eradication of the tumour. Here, $\zeta_n = 0.004$ and all the other parameters are as in Table 1 with $\alpha_\phi = 1.5$ and $w_{\max} = 2.96 \times 10^5$. The results from the hybrid model correspond to the average over three simulations and the related variance is displayed by the coloured areas surrounding the curves.

4.2 Baseline scenario corresponding to tumour eradication

As mentioned earlier, we first establish a baseline scenario where the parameter ζ_n is high enough so that T cells are able to eradicate the tumour. The plots in Fig. 4 and Fig. 5 summarise the results of simulations of the hybrid and continuum models obtained under this scenario.

After initial growth, the number of tumour cells decreases steadily over time until tumour cells are completely eliminated (*cf.* Fig. 4). The chemoattractant produced by tumour cells triggers the inflow of T cells through blood vessels and the movement of T cells towards the tumour (*cf.* Fig. 5). Since the value of ζ_n is sufficiently large, once T cells are close enough to tumour cells they start eliminating them until eradication (*cf.* Fig. 5). When the number of tumour cells decreases, the total amount of chemoattractant decays as well, thus triggering a reduction in the inflow of T cells, which initiates a decrease in the number of T cells (*cf.* Fig. 4).

Both Fig. 4 and Fig. 5 indicate that there is an excellent quantitative agreement between numerical solutions of the continuum model (3.2) and the results of numerical simulations of the hybrid model.

4.3 Emergence of hot, altered and cold tumour scenarios

We now consider a lower value of the parameter ζ_n in order to explore biological scenarios in which the cytotoxic action of T cells is less effective, for example due to high expression of PD1 inhibitory receptors and PD-L1 ligands on the surface of T cells and tumour cells. As mentioned

Figure 5: **Baseline scenario: evolution of the spatial distributions of cells over time.** Panels (a)-(d)-(g) display the plots of the density of tumour cells $n(x, y, t)$ and panels (b)-(e)-(h) display the plots of the density of T cells $c(x, y, t)$ of the continuum model at three successive time instants – *i.e.* $t = 1$, $t = 4$, and $t = 15$. The pink dashed lines highlight the 1D cross-section corresponding to $y = 0.5$. Panels (c)-(f)-(i) display the corresponding side on view plot of the densities of tumour cells $n(x, y, t)$ and T cells $c(x, y, t)$ of the hybrid model (solid, coloured lines) and continuum model (dotted, black lines) (*i.e.* at $y = 0.5$ and $t = 1$, $t = 4$, and $t = 15$). Here, $\zeta_n = 0.004$ and all the other parameters are as in Table 1 with $\alpha_\phi = 1.5$ and $w_{\max} = 2.96 \times 10^5$. The results from the hybrid model correspond to the average over three simulations and the related variance is displayed by the coloured areas surrounding the curves.

earlier, we wish to investigate how the spatial distribution of T cells within the tumour varies depending on the value of the parameters α_ϕ and w_{\max} . Therefore, we perform numerical simulations holding all parameters constant but considering different combinations of α_ϕ and w_{\max} . For each pair of values considered, we stored the resulting dynamics of the densities of tumour cells and T cells along with the dynamics of the corresponding cell numbers, and the final value of the immunoscore computed via (2.7). The results obtained are summarised by the heat maps in Fig. 6 and the plots in Figs. 7-11.

Low immunoscore and emergence of cold tumour scenarios As shown by the blue regions on the left side of the two heat maps of Fig. 6, for sufficiently small values of α_ϕ , the immunoscore is relatively low independently of the value of w_{\max} . This is due to the small con-

Figure 6: **Immunoscore**. The heat map in panel (a) displays the value of the immunoscore computed via (2.7) at the end of numerical simulations of the hybrid model for different combinations of α_ϕ and w_{\max} . For each given value of α_ϕ and w_{\max} , the values of the other parameters are as in Table 1, with $\zeta_n = 0.00012$. This heat map matches with the corresponding heat map obtained for the continuum model, which is displayed in panel (b). Sample dynamics of the numbers and densities of tumour cells and T cells for the values of parameters α_ϕ and w_{\max} corresponding to the dotted pink squares 1-4 are displayed in the plots of Fig. 7 and Figs. 8-11, respectively.

centration of chemoattractant present in the domain, which poses limitations to the inflow and movement of T cells towards the tumour. Hence, in the framework of our model, this parameter range corresponds to the emergence of cold tumour scenarios.

Sample dynamics of the numbers and densities of tumour cells and T cells for the values of α_ϕ and w_{\max} corresponding to the dotted pink square 1 in Fig. 6 are displayed in the plots in Fig. 7(a) and Fig. 8. As shown by Fig. 7(a), for sufficiently small values of α_ϕ , the total amount of chemoattractant in the domain is too small to trigger a sufficiently high inflow of T cells that can compensate for the loss caused by T cell death. As a result, the number of T cells decreases over time. Moreover, there is a shallow gradient of the chemoattractant, which results in a slow movement of T cells towards the tumour. As a result, as shown by Fig. 8(b)-(c), at the end of simulations, the density of T cells around the tumour is almost zero and T cells are still very much concentrated in the proximity of the blood vessels (*i.e.* their entry points).

Intermediate immunoscore and emergence of altered tumour scenarios The light blue regions of the heat maps of Fig. 6 indicate that there are two possible parameter ranges giving rise to an intermediate immunoscore. The first one corresponds to intermediate values of α_ϕ along with intermediate to large values of w_{\max} , while the second one corresponds to larger values of α_ϕ along with small values of w_{\max} . In the framework of our model, altered tumour scenarios emerge under these parameter ranges.

Sample dynamics of the numbers and densities of tumour cells and T cells for the values of α_ϕ and w_{\max} corresponding to the dotted pink squares 2 and 3 in Fig. 6 are displayed in the plots in Fig. 7(b)-(c), Fig. 9 and Fig. 10. The results of Fig. 7(b)-(c) show that increasing the value of α_ϕ leads to a progressive increase in the total amount of chemoattractant. This in turn results in an increased inflow of T cells and facilitates the movement of T cells towards the tumour. The spatial distribution of T cells within the tumour varies depending on the value of w_{\max} . Fig. 9 shows that smaller values of w_{\max} lead to an accumulation of T cells at the margin of the tumour, which corresponds to an altered-excluded tumour scenario. On the other hand,

Figure 7: **Sample dynamics of the numbers of tumour cells and T cells in hot, altered-immunosuppressed, altered-excluded and cold tumour scenarios.** Time evolution of the number of tumour cells $\rho_n(t)$, the number of T cells $\rho_c(t)$, and the total amount of chemoattractant $\phi_{tot}(t)$ (in the insets) of the hybrid model (solid, coloured lines) and the continuum model (dotted, black lines) for values of α_ϕ and w_{max} corresponding to the dotted pink squares 1-4 of Fig. 6. Sufficiently low values of α_ϕ lead to the emergence of cold tumour scenarios (panel (a)); intermediate values of α_ϕ and sufficiently high values of w_{max} lead to the emergence of altered-immunosuppressed tumour scenarios (panel (b)); intermediate values of α_ϕ and sufficiently small values of w_{max} lead to the emergence of altered-excluded tumour scenarios (panel (c)); and sufficiently high values of α_ϕ and w_{max} lead to the emergence of hot tumour scenarios (panel (d)). To obtain these results, we used the values of the parameters α_ϕ and w_{max} corresponding to the dotted pink squares 1 (panel (a)), 3 (panel (b)), 2 (panel (c)), and 4 (panel (d)) of Fig. 6. All the other parameters are as in Table 1, with $\zeta_n = 0.00012$. The results from the hybrid model correspond to the average over three simulations and the related variance is displayed by the coloured areas surrounding the curves.

larger values of w_{max} promote the infiltration of T cells into the tumour and lead to an altered-immunosuppressed tumour scenario (see Fig. 10).

Figure 8: **Sample spatial distributions of cells in cold tumour scenarios.** Panels (a) and (b) display, respectively, the densities of tumour cells $n(x, y, t)$ and T cells $c(x, y, t)$ of the continuum model at the end of numerical simulations (*i.e.* at $t = 15$) for a choice of parameters that results in the emergence of a cold tumour scenario (*cf.* dotted pink square 1 in Fig. 6). The pink dashed line highlights the 1D cross-section corresponding to $y = 0.5$. Panel (c) displays the corresponding side on view plot of the densities of tumour cells $n(x, y, t)$ and T cells $c(x, y, t)$ of the hybrid model (solid, coloured lines) and continuum model (dotted, black lines) (*i.e.* at $y = 0.5$ and $t = 15$). Here, $\zeta_n = 0.00012$, $\alpha_\phi = 0.0015$, $w_{\max} = 2.96 \times 10^5$, and all the other parameters are as in Table 1. The results from the hybrid model correspond to the average over three simulations and the related variance is displayed by the coloured areas surrounding the curves.

High immunoscore and emergence of hot tumour scenarios Finally, as shown by the red regions on the bottom-right side of Fig. 6, for large values of α_ϕ and w_{\max} , the value of the immunoscore is relatively high. In the framework of our model, this parameter range corresponds to the emergence of hot tumour scenarios.

Sample dynamics of the numbers and densities of tumour cells and T cells for the values of α_ϕ and w_{\max} corresponding to the dotted pink square 4 in Fig. 6 are displayed in the plots in Fig. 7(d) and Fig. 11. When α_ϕ is high enough, the larger amount of chemoattractant promotes the inflow of a larger number of T cells (see Fig. 7(d)). Moreover, Fig. 11 shows that, similarly to the altered-immunosuppressed tumour scenario, larger values of w_{\max} facilitate the infiltration of T cells into the tumour. As the number of infiltrated T cells is larger than in the previous scenarios, the immune action is slightly more efficient and thus leads to a slightly decreased number of tumour cells (see Fig. 7).

Remark 3. Although the specific colours of the regions of the heat maps in Fig. 6 can vary according to the values of the other parameters of the model, the behaviours of the spatial distributions of T cells and tumour cells in the case of hot, altered-immunosuppressed, altered-excluded and cold tumour scenarios remain qualitatively similar to those shown in Figs. 8-11. Moreover, the heat maps in Fig. 6, as well as the plots in Fig. 7 and Figs. 8(c)-11(c) demonstrate that there is an excellent agreement between numerical simulations of the hybrid and continuum models. This testifies to the robustness of the computational results presented here and the biological insight that they provide.

4.4 Immunotherapy effects

The results presented in the previous subsection summarise how scenarios corresponding to different levels of T-cell infiltration into the tumour can emerge under different combinations

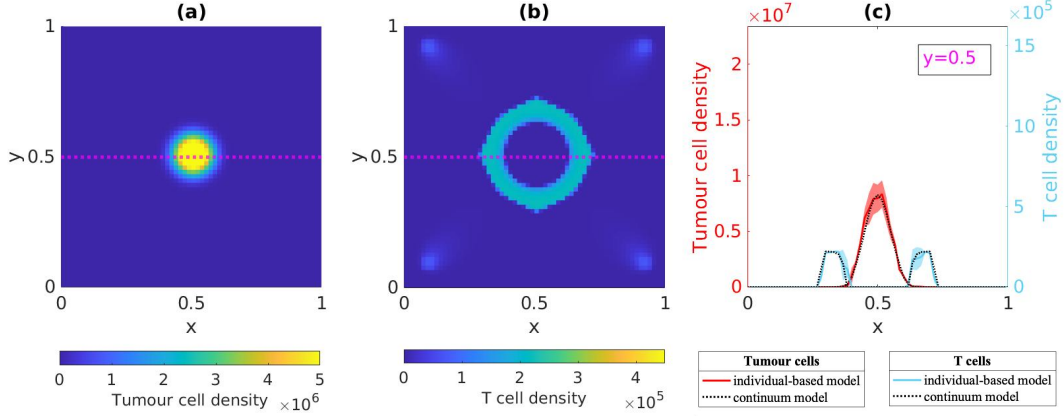

Figure 9: **Sample spatial distributions of cells in altered-excluded tumour scenarios.** Panels (a) and (b) display, respectively, the densities of tumour cells $n(x, y, t)$ and T cells $c(x, y, t)$ of the continuum model at the end of numerical simulations (*i.e.* at $t = 15$) for a choice of parameters that results in the emergence of a altered-excluded tumour scenario (*cf.* dotted pink square 2 in Fig. 6). The pink dashed line highlights the 1D cross-section corresponding to $y = 0.5$. Panel (c) displays the corresponding side on view plot of the densities of tumour cells $n(x, y, t)$ and T cells $c(x, y, t)$ of the hybrid model (solid, coloured lines) and continuum model (dotted, black lines) (*i.e.* at $y = 0.5$ and $t = 15$). Here, $\zeta_n = 0.00012$, $\alpha_\phi = 0.15$, $w_{\max} = 2.22 \times 10^5$, and all the other parameters are as in Table 1. The results from the hybrid model correspond to the average over three simulations and the related variance is displayed by the coloured areas surrounding the curves.

of the values of the parameters α_ϕ and w_{\max} . We now investigate possible outcomes of immunotherapy in these different scenarios.

In order to do this, we consider the same parameter settings used for the numerical simulations of Fig. 6, but we allow the level of efficiency of T cells at eliminating tumour cells to be higher (*i.e.* we increase the value of ζ_n). This corresponds to a biological scenario in which the tumour is treated with anti-PD1 monotherapy, which restores immune efficacy [67]. We also investigate the effects of coupling anti-PD1 therapy with two other therapies. First we explore the effects of anti-PD1 therapy in combination with another immune checkpoint therapy, *i.e.* the anti CTLA-4 therapy [69]. To do so, we perform numerical simulations defining all parameters as in the case of the anti-PD1 therapy but increasing the influx rate of T cells through blood vessels (*i.e.* the value of the parameter α_c). Then, we explore the effects of combining anti-PD1 therapy with chemotherapy, which inhibits tumour cell division, inflames the TME with tumour antigens, and boosts the activation of T cells [19]. To do so, we perform numerical simulations defining all parameters as in the scenario of the anti-PD1 therapy but decreasing the proliferation rate of tumour cells (*i.e.* the value of the parameter α_n) and increasing the influx rate of T cells through blood vessels (*i.e.* the value of the parameter α_c). The results obtained are displayed in Fig. 12, which shows a comparison between the numbers of tumour cells at the end of numerical simulation in the scenario “without treatment” (*i.e.* with the parameter values considered in Section 4.3) and the three aforementioned scenarios in which the effects of different therapeutic protocols are considered.

Exploiting the excellent quantitative agreement between the results of numerical simulations of the hybrid and continuum models presented in the previous subsections, here we carry out the numerical simulations of the continuum model only, since they require computational times much smaller than those that would be required by the numerical exploration of the corresponding hybrid model. To obtain the results presented in this subsection, we carried out

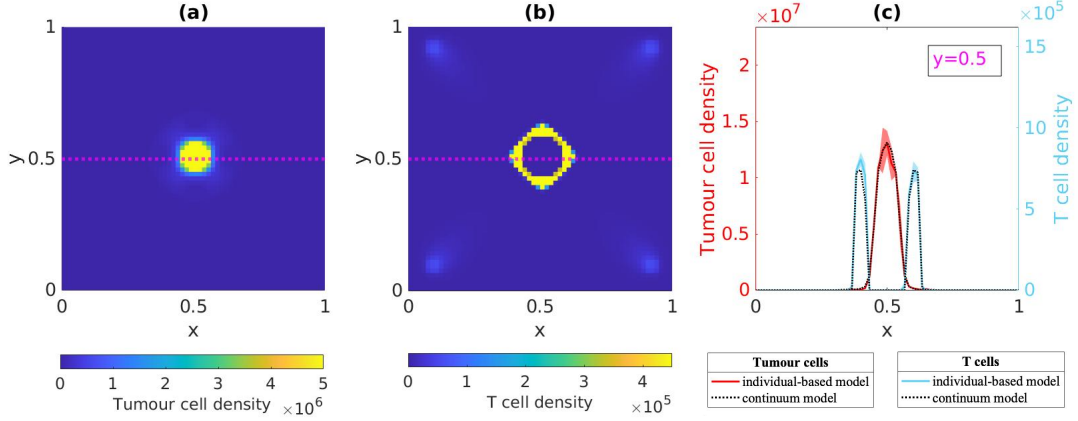

Figure 10: **Sample spatial distributions of cells in altered-immunosuppressed tumour scenarios.** Panels (a) and (b) display, respectively, the densities of tumour cells $n(x, y, t)$ and T cells $c(x, y, t)$ of the continuum model at the end of numerical simulations (*i.e.* at $t = 15$) for a choice of parameters that results in the emergence of a altered-immunosuppressed tumour scenario (*cf.* dotted pink square 3 in Fig. 6). The pink dashed line highlights the 1D cross-section corresponding to $y = 0.5$. Panel (c) displays the corresponding side on view plot of the densities of tumour cells $n(x, y, t)$ and T cells $c(x, y, t)$ of the hybrid model (solid, coloured lines) and continuum model (dotted, black lines) (*i.e.* at $y = 0.5$ and $t = 15$). Here, $\zeta_n = 0.00012$, $\alpha_\phi = 0.15$, $w_{\max} = 8.88 \times 10^5$, and all the other parameters are as in Table 1. The results from the hybrid model correspond to the average over three simulations and the related variance is displayed by the coloured areas surrounding the curves.

numerical simulations by using a final time corresponding to 10 days (*i.e.* $t_f = 10$).

Anti-PD1 monotherapy Fig. 12(b) displays the number of tumour cells at the end of numerical simulations of the continuum model for parameter settings corresponding to anti-PD1 monotherapy (*i.e.* when only the value of ζ_n is increased). Comparing these results with those displayed in Fig. 12(a), we see that, in general, for the same values of parameters α_ϕ and w_{\max} , increasing the value of ζ_n leads to a decrease in the number of tumour cells at the end of simulations. However, when the value of α_ϕ is too small (*i.e.* in cold tumour scenarios) or when the value of w_{\max} is too small (*i.e.* in altered-excluded tumour scenarios), increasing ζ_n has no benefit on the action of T cells against tumour cells. Finally, when the values of α_ϕ and w_{\max} are sufficiently large (*i.e.* in hot tumour scenarios) anti-PD1 monotherapy is more effective.

Anti-PD1-CTLA4 dual therapy Fig. 12(c) displays the number of tumour cells at the end of numerical simulations of the continuum model for parameter settings corresponding to anti-PD1-CTLA4 dual therapy (*i.e.* when both the value of ζ_n and the value of α_c are increased). Comparing these results with those displayed in Fig. 12(b), we see that increasing the value of α_c along with the value of ζ_n improves immune efficacy only when the values of α_ϕ and w_{\max} are large enough (*i.e.* in hot tumour scenarios). Moreover, for intermediate values of α_ϕ (*i.e.* in altered-immunosuppressed tumour scenarios), increasing the value of α_c slightly decreases the number of tumour cells at the end of simulations. Finally, when the values of α_ϕ or w_{\max} are too small, increasing α_c has no benefit on the action of T cells against tumour cells.

Chemotherapy combined with anti-PD1 therapy Fig. 12(d) displays the number of tumour cells at the end of numerical simulations of the continuum model for parameter settings corre-

Figure 11: **Sample spatial distributions of cells in hot tumour scenarios.** Panels (a) and (b) display, respectively, the density of tumour cells $n(x, y, t)$ and T cells $c(x, y, t)$ of the continuum model at the end of numerical simulations (*i.e.* at $t = 15$) for a choice of parameters that results in the emergence of a hot tumour scenario (*cf.* dotted pink square 4 in Fig. 6). The pink dashed line highlights the 1D cross-section corresponding to $y = 0.5$. Panel (c) displays the corresponding side on view plot of the densities of tumour cells $n(x, y, t)$ and T cells $c(x, y, t)$ of the hybrid model (solid, coloured lines) and continuum model (dotted, black lines) (*i.e.* at $y = 0.5$ and $t = 15$). Here, $\zeta_n = 0.00012$, $\alpha_\phi = 1.5$, $w_{\max} = 8.88 \times 10^5$, and all the other parameters are as in Table 1. The results from the hybrid model correspond to the average over three simulations and the related variance is displayed by the coloured areas surrounding the curves.

sponding to chemotherapy in combination with anti-PD1 therapy (*i.e.* when the value of α_n is decreased and the values of ζ_n and α_c are increased). Compared to the other heat maps of Fig. 12, these results show that the number of tumour cells decreases even for small values of α_ϕ or w_{\max} . Moreover, when the values of α_ϕ or w_{\max} are small (*i.e.* in cold and altered-excluded tumour scenarios), the numbers of tumour cells at the end of simulations are similar. On the other hand, from intermediate to large values of α_ϕ and w_{\max} , the numbers of tumour cells at the end of simulation decrease as the values of these two parameters increase. As expected, the larger the values of α_ϕ and w_{\max} (*i.e.* the “hotter” the tumour scenario considered), the more effective the combined action of chemotherapy and anti-PD1 therapy.

Figure 12: **Immunotherapy effects.** Comparison between the numbers of tumour cells $\rho_n(t)$ at the end of simulations (*i.e.* at $t = 10$) of the continuum model for different values of α_ϕ and w_{\max} without therapy (panel (a)) and when the effects of different immunotherapies are incorporated by considering different values of the parameters ζ_n , α_c and α_n (panel (b)-(d)). In panel (a), $\zeta_n = 0.00012$ and the values of the other parameters are as in Table 1. In panel (b), $\zeta_n = 0.001$ and the values of the other parameters are as in Table 1. In panel (c), $\zeta_n = 0.001$, $\alpha_c = 12$ and the values of the other parameters are as in Table 1. In panel (d), $\zeta_n = 0.001$, $\alpha_c = 12$, $\alpha_n = 0.75$ and the values of the other parameters are as in Table 1.

5 Discussion and research perspectives

5.1 Discussion

The results that we have presented demonstrate that the level of efficiency of T cells at eliminating tumour cells (*i.e.* the parameter ζ_n) plays a key role in tumour-immune competition. In fact, when the value of ζ_n is large enough, our results indicate that tumour eradication can occur, while lower values of ζ_n may result in tumour cell survival. This is consistent with experimental and clinical data which point to a key role of immune check-points in immunosuppressing T-cell responses. In fact, the presence of immunosuppressive components in the TME, such as PD1 inhibitory receptors and PD-L1 ligands, decreases the efficiency of T cells at eliminating tumour cells, and can ultimately result in tumour escape [30, 68].

Moreover, our numerical results indicate that when tumour eradication does not occur (*i.e.* when the value of ζ_n is sufficiently small), the secretion rate of the chemoattractant by tumour cells (*i.e.* the parameter α_ϕ) and the threshold value of the total cell density above which T cell movement is impaired (*i.e.* the parameter w_{\max}) have a strong impact on the level of infiltration of T cells into the tumour, and different combinations of the values of these parameters bring about the emergence of four immune-based tumour scenarios. Hot tumour scenarios emerge

for high values of α_ϕ and w_{\max} , and are characterised by a large number of T cells in the centre of the tumour. By displaying a high degree of T cell infiltration, these tumour scenarios provide a fertile ground for immune checkpoint therapies. Altered tumour scenarios emerge for intermediate values of α_ϕ , and reflect the intrinsic ability of the immune system to effectively mount a T-cell-mediated immune response and the ability of tumour cells to partially escape such a response. This can either be due to an insufficient number of infiltrated T cells (the immunosuppressed tumour scenarios, which emerge for intermediate to large values of w_{\max}) or to the presence of physical barriers that hinder T cell infiltration (the excluded tumour scenarios, which emerge for small values of w_{\max}). Finally, cold tumour scenarios emerge for sufficiently small values of α_ϕ and w_{\max} . These tumour scenarios are characterised by an insufficient number of T cells both in the centre of the tumour and at its margin, and are invariably associated with poor prognosis.

We also explored how the outcomes of different immunotherapy protocols can vary in such immune-based tumour scenarios. In particular, our results suggest that increasing the level of efficiency of T cells (*i.e.* the value of the parameter ζ_n), which is associated to the effects of anti-PD1 monotherapy, is not sufficient for treating all types of tumour scenarios, and it is particularly ineffective in altered-excluded and cold tumour scenarios. This finding is coherent with experimental observations indicating that anti-PD1 monotherapy is effective only in the context of hot or altered-immunosuppressed tumours, as a certain number of T cells is already infiltrated into the tumour [19].

Moreover, the results of our model indicate that, in these two categories of tumours, increasing both the level of efficiency of T cells and their influx rate (*i.e.* the value of the parameters ζ_n and α_c), which are associated with the combined effects of anti-PD1 and anti-CTLA4 therapy, may lead to a better therapeutic outcome. This conclusion is also supported by experimental work showing that anti-PD1-CTLA4 dual therapy may be successful in treating advanced-stage melanoma [74], renal-cell carcinoma [57] and non-small-cell lung cancer (NSCLC) [29], resulting in regulatory approval. However, our results suggest that prognosis in altered-excluded and cold tumour scenarios may not benefit from the combined effects of these two immune checkpoint inhibitors. Nevertheless, our results indicate that therapeutic strategies promoting the infiltration of T cells could turn altered-excluded tumours into altered-immunosuppressed or hot tumours, helping to decrease the resistance of tumours to the combination of anti-PD1 and anti-CTLA4 therapy. This finding is coherent with experimental observations suggesting that a synergistic effect can be achieved by combining anti-angiogenic therapies, which act on vascular abnormalities facilitating T-cell infiltration, with immune checkpoint therapies [66].

Finally, the outputs of our model suggest that increasing both the level of efficiency of T cells and their influx rate through blood vessels (*i.e.* the values of the parameters ζ_n and α_c) and decreasing the proliferation rate of tumour cells (*i.e.* the parameter α_n), which may represent the combination of anti-PD1 therapy with chemotherapy, a stronger immune response may be induced. In fact, a proposed approach to overcome the lack of a pre-existing immune response consists in combining a priming therapy that enhances T cell responses (such as chemotherapy) with the removal of co-inhibitory signals (through approaches such as immune checkpoint therapies) [19]. For example, the success of the combination of anti-PD1 therapy with chemotherapy in metastatic NSCLC has demonstrated the strength of this dual approach [22].

5.2 Research perspectives

We conclude with an outlook on possible extensions of the present work. While here we focused on the role of the secretion rate of the chemoattractant by tumour cells and the threshold value of the total cell density above which T cell movement is impaired, it would be interesting to investigate how other model parameters (*e.g.* the chemotactic sensitivity of T cells) may affect the level of infiltration of T cells into the tumour. Carrying out a more extensive exploration of the model parameter space would ultimately allow more robust biological conclusions to be

drawn.

Moreover, our hybrid modelling framework for the spatial dynamics of tumour cells and cytotoxic T cells, along with the formal derivation of the corresponding continuum model, can be developed further in several ways. For instance, a key factor of the immune response is that T cells express a unique repertoire of T cell receptors (TCRs) [16], and are capable of detecting and eliminating tumour cells by recognising specific cancer-associated antigens. The model presented here does not include this aspect, but it could easily be extended to do so by introducing, for instance, a variable representing the antigens expressed by tumour cells and the TCR expressed by T cells. This would make it possible to take explicitly into account the effects of both spatial and antigen-specific interactions between tumour cells and T cells, as similarly done in [35, 42, 47, 48], and then study the effects of antigen presentation or intra-tumour heterogeneity on immune surveillance.

Only a simplified representation of the action of different types of immunotherapy was considered in this work, but it would be important to carry out a more detailed study of the impact of T-cell infiltration on the dynamics of tumour cells under different immunotherapeutic protocols. In particular, by using optimal control methods for the continuum model, we could investigate the best delivery schedule of therapeutic agents (*i.e.* the best delivery times and dosages) that make it possible to minimise the number of tumour cells at the end of the treatment and achieve the best therapeutic outcomes [33]. These are all lines of research that we will be pursuing in the near future.

Appendices

A Formal derivation of the continuum model

Building on the methods employed in [9], we carry out a formal derivation of the deterministic continuum model given by the IDE-PDE-PDE system (3.2) for $d = 1$. Similar methods can be used in the case where $d = 2$.

A.1 Formal derivation of the IDE for the density of tumour cells $n(x, t)$

When tumour cell dynamics are governed by the rules described in Sections 2.1.1 and 2.1.2, considering $i \in [0, \mathcal{N}]$, between time-steps k and $k + 1$ the principle of mass balance gives the following difference equation for the tumour cell density n_i^k :

$$n_i^{k+1} = \left[2\tau\alpha_n + 1 - \tau(\alpha_n + \zeta_n K_i^k + \mu_n \rho_n^k) \right] n_i^k. \quad (\text{A.1})$$

Using the fact that the following relations hold for τ and χ sufficiently small

$$t_k \approx t, \quad t_{k+1} \approx t + \tau, \quad x_i \approx x, \quad x_{i\pm 1} \approx x \pm \chi, \quad (\text{A.2})$$

$$n_i^k \approx n(x, t), \quad n_i^{k+1} \approx n(x, t + \tau), \quad c_i^k \approx c(x, t), \quad (\text{A.3})$$

$$\rho_n^k \approx \rho_n(t) := \int_{\Omega} n(x, t) dx, \quad K_i^k \approx K(x, t) := \int_{\Omega} \eta(x, x'; \theta) c(x', t) dx', \quad (\text{A.4})$$

where the function η is defined via (2.12), equation (A.1) can be formally rewritten in the approximate form

$$n(x, t + \tau) - n(x, t) = \tau(\alpha_n - \zeta_n K(x, t) - \mu_n \rho_n(t)) n(x, t). \quad (\text{A.5})$$

If, in addition, the function $n(x, t)$ is continuously differentiable with respect to the variable t , starting from equation (A.5), and letting the time-step $\tau \rightarrow 0$, one formally obtains the following IDE for the tumour cell density $n(x, t)$:

$$\partial_t n(x, t) = \alpha_n n(x, t) - \mu_n \rho_n(t) n(x, t) - \zeta_n K(x, t) n(x, t) \quad (x, t) \in \Omega \times (0, t_f].$$

A.2 Formal derivation of the PDE for the density of T cells $c(x, t)$

When T cell dynamics are governed by the rules described in Section 2.3, considering $i \in [1, \mathcal{N} - 1]$, between time-steps k and $k + 1$ the principle of mass balance gives the following difference equation for the T cell density c_i^k :

$$\begin{aligned} c_i^{k+1} &= c_i^k (1 - \tau \mu_c \rho_c^k) + \tau \alpha_c r_i^k \\ &+ \frac{\lambda}{2} \psi(w_i^k) (c_{i+1}^k + c_{i-1}^k) \\ &- \frac{\lambda}{2} (\psi(w_{i-1}^k) + \psi(w_{i+1}^k)) c_i^k \\ &+ \frac{\nu}{2\phi_{\max}} \psi(w_i^k) \left[(\phi_i^k - \phi_{i-1}^k)_+ c_{i-1}^k \right] \\ &+ \frac{\nu}{2\phi_{\max}} \psi(w_i^k) \left[(\phi_i^k - \phi_{i+1}^k)_+ c_{i+1}^k \right] \\ &- \frac{\nu}{2\phi_{\max}} \psi(w_{i+1}^k) \left[(\phi_{i+1}^k - \phi_i^k)_+ c_i^k \right] \\ &- \frac{\nu}{2\phi_{\max}} \psi(w_{i-1}^k) \left[(\phi_{i-1}^k - \phi_i^k)_+ c_i^k \right]. \end{aligned} \quad (\text{A.6})$$

Using the fact that relations (A.2)-(A.4) and the following relations

$$c_i^k \approx c(x, t), \quad c_{i\pm 1}^k \approx c(x \pm \chi), \quad \rho_c^k \approx \rho_c(t) := \int_{\Omega} c(x, t) dx,$$

$$\begin{aligned} \phi_i^k &\approx \phi(x, t), \quad \phi_i^{k+1} \approx \phi(x, t + \tau), \quad \phi_{i\pm 1}^k \approx \phi(x \pm \chi), \\ w_i^k &\approx w(x, t), \quad \text{with } w(x, t) = n(x, t) + c(x, t), \quad w_{i\pm 1}^k \approx w(x \pm \chi), \end{aligned}$$

$$r_i^k \approx r(x, t) := \phi_{tot}(t) \mathbb{1}_\omega(x), \text{ with } \phi_{tot}(t) := \int_{\Omega} \phi(x, t) dx$$

hold for τ and χ sufficiently small, equation (A.6) can be formally rewritten in the approximate form

$$\begin{aligned} c(x, t + \tau) = & c(x, t)(1 - \tau \mu_c \rho_c(t)) + \tau \alpha_c r(x, t) \\ & + \frac{\lambda}{2} \psi(w(x, t)) \left(c(x + \chi, t) + c(x - \chi, t) \right) \\ & - \frac{\lambda}{2} \left(\psi(w(x - \chi, t)) + \psi(w(x + \chi, t)) \right) c(x, t) \\ & + \frac{\nu}{2\phi_{\max}} \psi(w(x, t)) \left[\left(\phi(x, t) - \phi(x - \chi, t) \right)_+ c(x - \chi, t) \right] \\ & + \frac{\nu}{2\phi_{\max}} \psi(w(x, t)) \left[\left(\phi(x, t) - \phi(x + \chi, t) \right)_+ c(x + \chi, t) \right] \\ & - \frac{\nu}{2\phi_{\max}} \psi(w(x + \chi, t)) \left[\left(\phi(x + \chi, t) - \phi(x, t) \right)_+ c(x, t) \right] \\ & - \frac{\nu}{2\phi_{\max}} \psi(w(x - \chi, t)) \left[\left(\phi(x - \chi, t) - \phi(x, t) \right)_+ c(x, t) \right]. \end{aligned}$$

Building on the methods employed in [9], letting $\tau \rightarrow 0$ and $\chi \rightarrow 0$ in such a way that

$$\frac{\lambda \chi^2}{2 \tau} \rightarrow \beta_c \in \mathbb{R}_*^+ \quad \text{and} \quad \frac{\nu}{2\phi_{\max}} \frac{\chi^2}{\tau} \rightarrow \gamma_c \in \mathbb{R}_*^+ \quad \text{as } \tau \rightarrow 0, \chi \rightarrow 0,$$

after a little algebra, considering $(x, t) \in \Omega \setminus \partial\Omega \times (0, t_f]$, we find

$$\partial_t c - \partial_x \left[\beta_c \psi(w) \partial_x c - \gamma_c \psi(w) c \partial_x \phi - \beta_c c \psi'(w) \partial_x w \right] = -\mu_c \rho_c(t) c + \alpha_c r$$

where ψ is given by (2.22) and $w := n + c$. Moreover, zero-flux boundary conditions easily follow from the fact that T-cell moves that require moving out of the spatial domain are not allowed.

A.3 Formal derivation of the balance equation for the chemoattractant concentration $\phi(x, t)$

The formal derivation of the balance equation for the chemoattractant concentration $\phi(x, t)$ is obtained using the methods employed in [9].

B Details of numerical simulations

The numerical simulations of our hybrid and continuum models are carried out on a two-dimensional domain and are performed in MATLAB.

B.1 Details of numerical simulations of the hybrid model

The flowchart in Fig. 13 illustrates the general computational procedure to carry out simulations of the hybrid model in one-dimensional settings, while the flowchart in Fig. 14 provides further details of the computational procedure to simulate cell dynamics in one-dimensional settings. Analogous strategies are used in two-dimensional settings. All random numbers mentioned in Fig. 14 are real numbers drawn from the standard uniform distribution on the interval $(0, 1)$, which in our case are obtained using the built-in MATLAB function RAND.

As summarised by Fig. 14, at any time-step, each T cell undergoes a three-phase process: Phase A) undirected, random movement according to the probabilities defined via (2.26) and (2.27); Phase B) chemotaxis according to the probabilities defined via (2.23) and (2.24); Phase

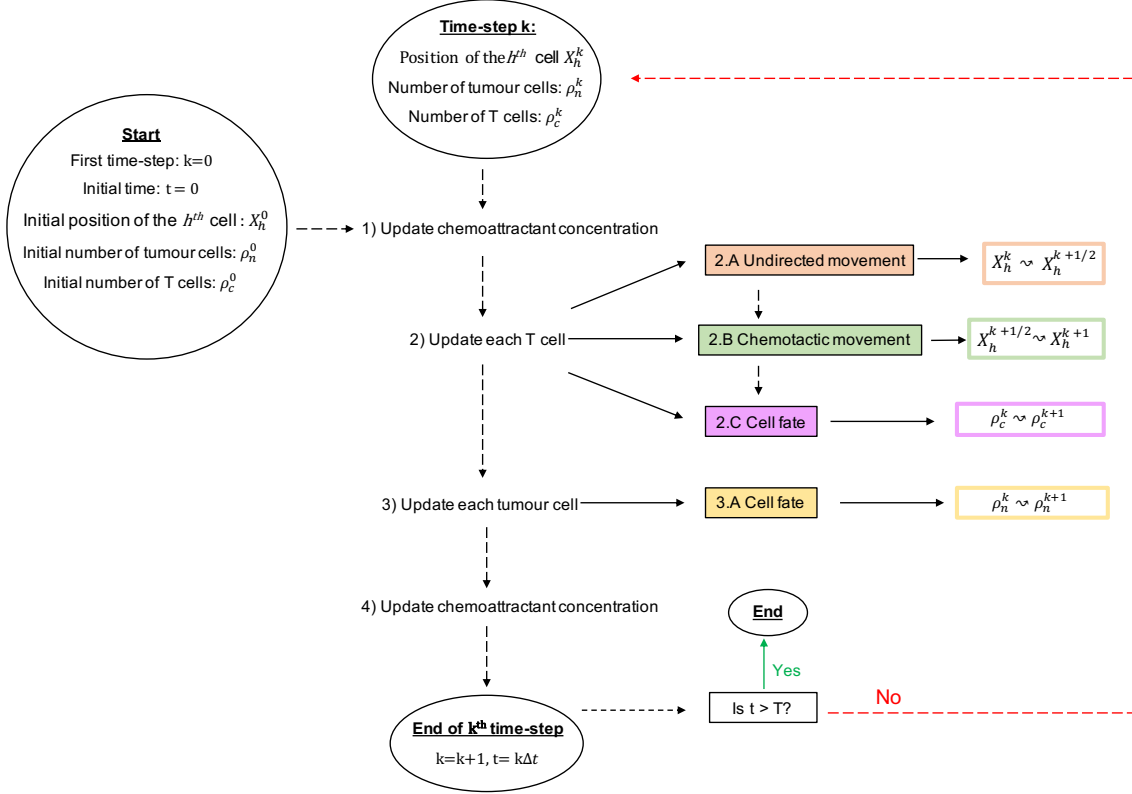

Figure 13: Flowchart illustrating the computational procedure to simulate the hybrid model in one-dimensional settings. A detailed summary of steps 2) and 3) is provided by the flowchart in Fig. 14. A similar procedure is used in two-dimensional settings.

C) death according to the probabilities defined via (2.17) and (2.21). We let then each tumour cell proliferate with the probability defined via (2.8), die due to intra-tumour competition with the probability defined via (2.10), or die due to immune action with the probability defined via (2.13). Finally, the tumour cell density at every lattice site is computed via (2.1) and inserted into (2.14) in order to update the concentration of the chemoattractant.

In a two-dimensional setting, the positions of the single T cells are updated following a procedure analogous to that illustrated in Figs. 13 and 14, with the only differences being that: T cells are allowed to move up and down as well; the concentration of the chemoattractant is updated through the two-dimensional analogue of (2.14), where the operator \mathcal{L} is defined as the finite-difference Laplacian on a two-dimensional regular lattice of step χ ; the tumour and T cell densities are respectively computed via (2.1) and (2.2).

B.2 Details of numerical simulations of the continuum model

To construct numerical solutions of the IDE-PDE-PDE system (3.2), we use a uniform discretisation consisting of $N^2 = 3721$ points of the square $\Omega := [0, 1]^2$ as the computational domain of the independent variable $\mathbf{x} \equiv (x, y)$ (i.e. $(x_i, y_j) = (i\Delta x, j\Delta x)$ with $\Delta x = 0.016$ and $i, j = 0, \dots, N$). Moreover, we choose the time step $\Delta t = 10^{-4}$ and, unless stated otherwise, we perform numerical simulations for 15×10^4 time-steps (i.e. the final time of simulations is $t_f = 15$).

The method for constructing numerical solutions of the IDE-PDE-PDE system (3.2) is based on a finite difference scheme whereby the discretised dependent variables are

$$n_{i,j}^k := n(x_i, y_j, t_k), \quad c_{i,j}^k := c(x_i, y_j, t_k) \quad \text{and} \quad \phi_{i,j}^k := \phi(x_i, y_j, t_k).$$

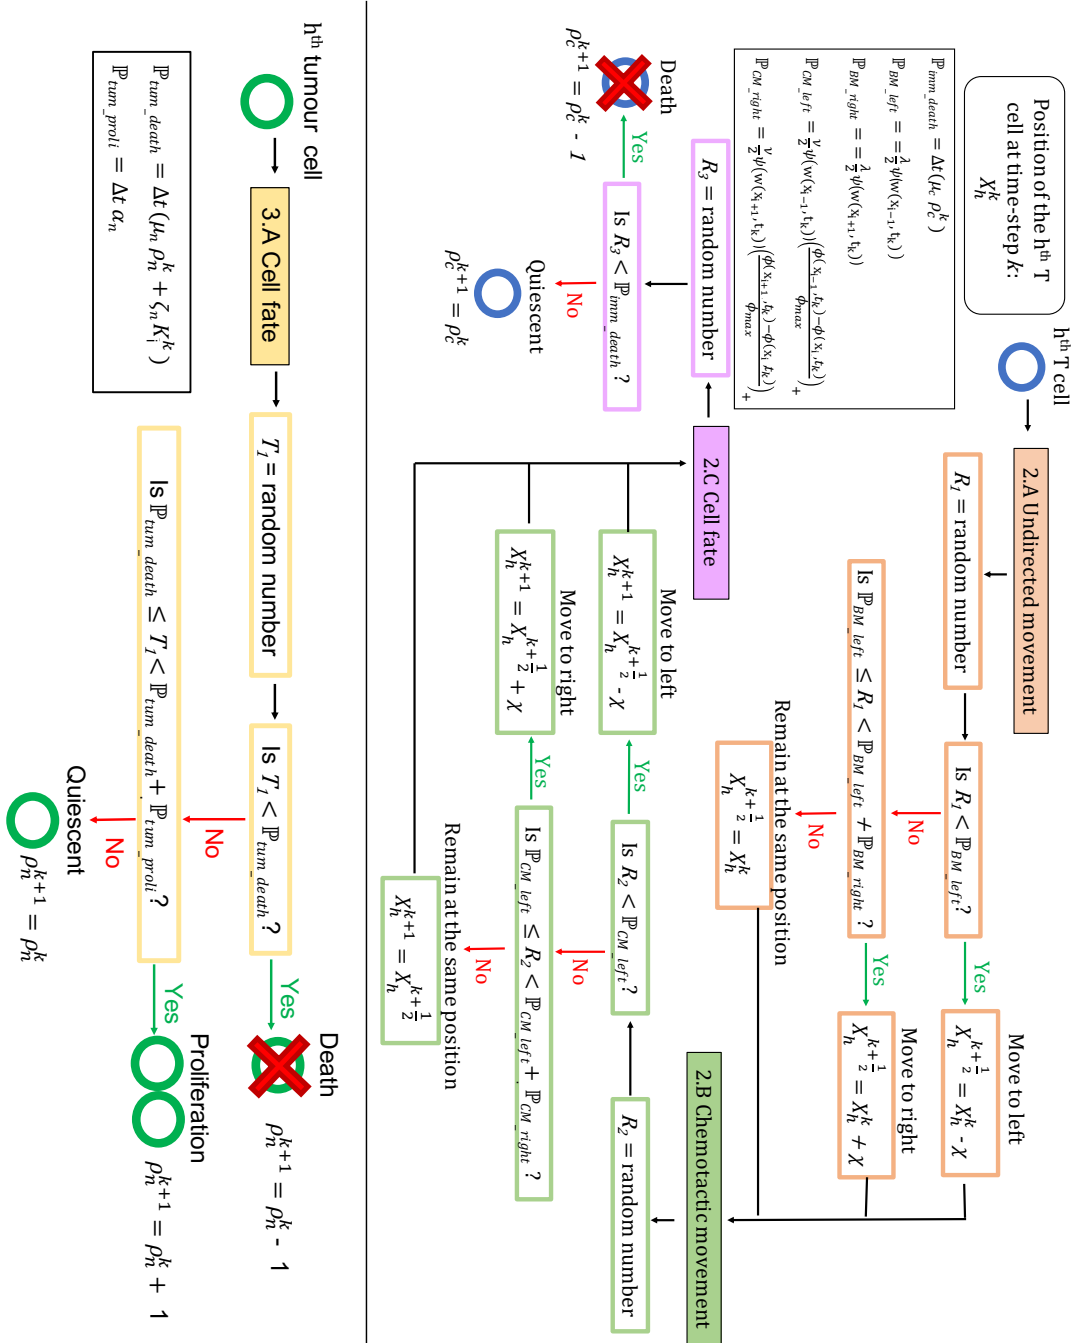

Figure 14: Flowchart illustrating the detailed computational procedure followed to update the positions of every T cell, as well as the fate of each tumour cell and T cell in one-dimensional settings. Analogous strategies are used in two-dimensional domains.

We solve numerically the IDE (3.2)₁ for n and the PDE (3.2)₃ for ϕ using the following schemes

$$\frac{n_{i,j}^{k+1} - n_{i,j}^k}{\Delta t} = \left(\alpha_n - \mu_n \rho_n^k - \zeta_n K_{i,j}^k \right) n_{i,j}^k \quad i, j = 0, \dots, N,$$

and

$$\begin{aligned} \frac{\phi_{i,j}^{k+1} - \phi_{i,j}^k}{\Delta t} = & \beta_\phi \frac{\phi_{i-1,j}^k + \phi_{i+1,j}^k - 2\phi_{i,j}^k}{(\Delta x)^2} + \beta_\phi \frac{\phi_{i,j-1}^k + \phi_{i,j+1}^k - 2\phi_{i,j}^k}{(\Delta x)^2} \\ & + \alpha_\phi n_{i,j}^k - \kappa_\phi \phi_{i,j}^k, \quad i, j = 1, \dots, N-1, \end{aligned}$$

and impose zero-flux boundary conditions for ϕ by letting

$$\phi_{0,j}^{k+1} = \phi_{1,j}^{k+1} \quad \text{and} \quad \phi_{N,j}^{k+1} = \phi_{N-1,j}^{k+1}, \quad j = 0, \dots, N$$

$$\phi_{i,0}^{k+1} = \phi_{i,1}^{k+1} \quad \text{and} \quad \phi_{i,N}^{k+1} = \phi_{i,N-1}^{k+1}, \quad i = 0, \dots, N$$

Moreover, we solve numerically the PDE (3.2)₂ for c using the following explicit scheme, which is the same as the one used in [9],

$$\frac{c_{i,j}^{k+1} - c_{i,j}^k}{\Delta t} - \frac{F_{i+\frac{1}{2},j}^k + F_{i-\frac{1}{2},j}^k}{\Delta x} - \frac{F_{i,j+\frac{1}{2}}^k + F_{i,j-\frac{1}{2}}^k}{\Delta x} = r(\phi_{i,j}^k) - \mu_c \rho_c^k c_{i,j}^k$$

for $i, j = 0, \dots, N$, where

$$\begin{aligned} F_{i+\frac{1}{2},j}^k &:= \beta_c \psi(w_{i+\frac{1}{2},j}^k) \frac{c_{i+1,j}^k - c_{i,j}^k}{\Delta x} - \beta_c c_{i+\frac{1}{2},j}^k \psi'(w_{i+\frac{1}{2},j}^k) \frac{w_{i+1,j}^k - w_{i,j}^k}{\Delta x} \\ &\quad - b_{i+\frac{1}{2},j}^{k,+} c_{i,j}^k \psi(w_{i+1,j}^k) + b_{i+\frac{1}{2},j}^{k,-} c_{i+1,j}^k \psi(w_{i,j}^k), \quad i = 0, \dots, N-1, \quad j = 0, \dots, N, \\ F_{i,j+\frac{1}{2}}^k &:= \beta_c \psi(w_{i,j+\frac{1}{2}}^k) \frac{c_{i,j+1}^k - c_{i,j}^k}{\Delta x} - \beta_c c_{i,j+\frac{1}{2}}^k \psi'(w_{i,j+\frac{1}{2}}^k) \frac{w_{i,j+1}^k - w_{i,j}^k}{\Delta x} \\ &\quad - b_{i,j+\frac{1}{2}}^{k,+} c_{i,j}^k \psi(w_{i,j+1}^k) + b_{i,j+\frac{1}{2}}^{k,-} c_{i,j+1}^k \psi(w_{i,j}^k), \quad i = 0, \dots, N, \quad j = 0, \dots, N-1, \end{aligned}$$

with

$$\begin{aligned} w_{i+\frac{1}{2},j}^k &:= \frac{w_{i+1,j}^k + w_{i,j}^k}{2}, \quad w_{i,j+\frac{1}{2}}^k := \frac{w_{i,j+1}^k + w_{i,j}^k}{2}, \\ c_{i+\frac{1}{2},j}^k &:= \frac{c_{i+1,j}^k + c_{i,j}^k}{2}, \quad c_{i,j+\frac{1}{2}}^k := \frac{c_{i,j+1}^k + c_{i,j}^k}{2}, \\ b_{i+\frac{1}{2},j}^k &:= \gamma_c \frac{\phi_{i+1,j}^k - \phi_{i,j}^k}{\Delta x}, \quad b_{i+\frac{1}{2},j}^{k,+} = \max\left(0, b_{i+\frac{1}{2},j}^k\right), \quad b_{i+\frac{1}{2},j}^{k,-} = \max\left(0, -b_{i+\frac{1}{2},j}^k\right) \end{aligned}$$

and

$$b_{i,j+\frac{1}{2}}^k := \gamma_c \frac{\phi_{i,j+1}^k - \phi_{i,j}^k}{\Delta x}, \quad b_{i,j+\frac{1}{2}}^{k,+} = \max\left(0, b_{i,j+\frac{1}{2}}^k\right), \quad b_{i,j+\frac{1}{2}}^{k,-} = \max\left(0, -b_{i,j+\frac{1}{2}}^k\right)$$

The discrete fluxes $F_{i-\frac{1}{2},j}^k$ for $i = 1, \dots, N, j = 0, \dots, N$ and $F_{i,j-\frac{1}{2}}^k$ for $i = 0, \dots, N, j = 1, \dots, N$ are defined in an analogous way, and we impose zero-flux boundary conditions by using the definitions

$$F_{0-\frac{1}{2},j}^k := 0 \quad \text{and} \quad F_{N+\frac{1}{2},j}^k := 0, \quad \text{for} \quad j = 0, \dots, N,$$

$$F_{i,0-\frac{1}{2}}^k := 0 \quad \text{and} \quad F_{i,N+\frac{1}{2}}^k := 0, \quad \text{for} \quad i = 0, \dots, N.$$
