Supporting Information

**ABSTRACT:** Charge/energy separation across interfaces of plasmonic materials is vital for minimizing plasmonic losses and enhancing their performance in photochemical and optoelectronic applications. While heterostructures combining plasmonic two-dimensional transition metal carbides/nitrides (MXenes) and semiconducting transition metal dichalcogenides (TMDs) hold significant potential, the mechanisms governing plasmon-induced carrier dynamics at these interfaces remain elusive. Here, we uncover a distinctive secondary excitation phenomenon and an ultrafast charge/energy transfer process in heterostructure films composed of macro-scale  $\text{Ti}_3\text{C}_2\text{T}_x$  and  $\text{MoS}_2$  films. Using Rayleigh–Bénard convection and Marangoni effect-induced self-assembly, we fabricate large-scale (square centimeters)  $\text{Ti}_3\text{C}_2\text{T}_x$  and  $\text{MoS}_2$  films composed of edge-connected monolayer nanoflakes. These films are flexibly stacked in a controlled sequence to form macroscopic heterostructures, enabling the investigation and manipulation of excited-state dynamics using transient absorption and optical pump-terahertz probe spectroscopy. In the  $\text{Ti}_3\text{C}_2\text{T}_x\text{-MoS}_2$  heterostructure, we observe a secondary excitation in  $\text{MoS}_2$  driven by the surface plasmon resonance of  $\text{Ti}_3\text{C}_2\text{T}_x$ . This phenomenon, with a characteristic rise time constant of  $\sim 70$  ps, is likely facilitated by acoustic phonon recycling across the interface. Further interfacial thermal transport engineering—achieved by tailoring the sequence and combination of interfaces in trilayer heterostructures—allows extending the characteristic time to  $\sim 175$  ps. Furthermore, we identify a sub-150 fs ultrafast charge/energy transfer process from  $\text{Ti}_3\text{C}_2\text{T}_x$  to  $\text{MoS}_2$ . The transfer efficiency is strongly dependent on the excitation photon energy, resulting in amplified photoconductivity in  $\text{MoS}_2$  by up to  $\sim 180\%$  under 3.10 eV excitation. These insights are crucial for developing plasmonic MXene-based heterostructures, paving the way for advancements in photochemical and optoelectronic applications.

## INTRODUCTION

Plasmonic materials are well-known for their ability to confine photoenergy through surface plasmon resonances or localized surface plasmon resonance, making them highly promising for applications in photochemical reactions and optoelectronic devices.<sup>1–3</sup> Recently, emerging two-dimensional (2D) transition metal carbides/nitrides (i.e., MXenes with  $\text{Ti}_3\text{C}_2\text{T}_x$  as the representative case) have been revealed with a wide array of surface plasmon (SP) modes across the visible, near-infrared, and mid-infrared wavelengths.<sup>4–6</sup> Typically, MXenes are synthesized by selectively etching atomic layers from their MAX precursors, sharing the general formula of  $\text{M}_{n+1}\text{X}_n\text{T}_x$  (M represents a transition metal, X denotes C and/or N, and  $\text{T}_x$  refers to surface terminations).<sup>7</sup> They exhibit remarkable structural diversity, including variations in M and X elements, atomic layer numbers, in-plane and out-of-plane ordering, solid solution lattices, and abundant surface chemistries.<sup>7–9</sup> This structural diversity offers a vast playground for SP engineering,<sup>10,11</sup> positioning MXenes as a unique class of plasmonic

materials with diverse applications. For instance, plasmon-induced thermalization and hot-electron injection in the visible and near-infrared region have been shown to significantly enhance the electrocatalytic activity of MXenes in the hydrogen evolution reaction across a broad pH range, boosting the catalytic performance by more than 5-fold.<sup>12</sup> Moreover,  $\text{Mo}_2\text{CT}_x$  MXene-based plasmonic photodetectors demonstrated high responsivity (up to  $9 \text{ A W}^{-1}$ ) and detectivity ( $\approx 5 \times 10^{11}$  Jones), outperforming many other 2D materials due to intrinsic plasmon-assisted hot carrier generation.<sup>13</sup>

However, plasmon-generated hot carriers face rapid kinetic energy dissipation as lattice heat, which significantly limits their

(d) Schematic showing an ultrafast charge/energy transfer from  $\text{Ti}_3\text{C}_2\text{T}_x$  to  $\text{MoS}_2$ , followed by a secondary excitation in  $\text{MoS}_2$  driven by the SP excitation of  $\text{Ti}_3\text{C}_2\text{T}_x$ .

effectiveness in potential applications.<sup>14</sup> In MXenes, this dissipation pathway has been proposed to involve multiple energy conversion processes, including direct plasmon-phonon coupling, nonthermal electron-phonon coupling after Landau damping, and thermal electron-phonon coupling following electron thermalization.<sup>15</sup> Time-resolved spectroscopy and ultrafast electron diffraction have provided important insights into ultrafast hot carrier-lattice relaxation in MXenes, observing carrier-phonon scattering within 100 fs<sup>15,16</sup> and excited lattice vibrations within approximately 230 fs,<sup>17</sup> respectively. Constructing an interface that enables ultrafast charge separation and energy transfer represents a promising pathway to manipulate plasmon-vibration interactions and mitigate plasmonic losses. In this context, heterostructures comprising MXenes and semiconducting transition metal dichalcogenides (TMDs) are of great interest owing to the intimate contact at the 2D-2D interfaces and the strong light-matter interactions in TMDs.<sup>18</sup> As a classic example, hybrid  $\text{Ti}_3\text{C}_2\text{T}_x/\text{MoS}_2$  plasmonic photodetectors have demonstrated greatly enhanced performance, achieving a 150-fold increase in detectivity compared to pristine  $\text{MoS}_2$ , reaching  $2.33 \times 10^{12}$  Jones under 635 nm illumination.<sup>19</sup> Nevertheless, the fundamental interfacial charge/energy dynamics in MXene-TMD heterostructures, essential for guiding future interface optimization, has remained elusive. A major challenge arises from the limited size of flake-stacked MXene-TMD interfaces, as the top-down etching-delamination synthesis limits MXene nanoflakes to the micrometer range,<sup>20</sup> restricting direct probing of interfacial dynamics via conventional spectroscopic methods. Alternatively, heterostructures formed through solution processing or

coating techniques may compromise interface control, introducing extrinsic properties and interferences that impede an understanding of the intrinsic properties.

In this study, we employ  $\text{Ti}_3\text{C}_2\text{T}_x$  and  $\text{MoS}_2$  as model materials to construct macro-scale heterostructure films, uncovering a unique secondary excitation mechanism and an ultrafast charge/energy transfer process within the heterostructure. Specifically, we fabricate individual  $\text{Ti}_3\text{C}_2\text{T}_x$  and  $\text{MoS}_2$  films composed of edge-connected monolayer nanoflakes with macroscopically continuous areas (up to square centimeters) by leveraging Rayleigh-Bénard convection and Marangoni effect-induced self-assembly (Figure 1a).<sup>21,22</sup> The flexible stacking of these films allows the construction of macro-scale heterostructure films with tunable configurations (Figure 1b), enabling direct detection and control of excited-state dynamics through transient absorption spectroscopy and optical pump-terahertz (THz) probe spectroscopy (Figure 1c). In a bilayer  $\text{Ti}_3\text{C}_2\text{T}_x$ - $\text{MoS}_2$  heterostructure film (denoted HS-TM), we discover an intriguing secondary excitation of  $\text{MoS}_2$  under 1.55 eV excitation, where the SP resonance of  $\text{Ti}_3\text{C}_2\text{T}_x$  dominates the interfacial dynamics. This phenomenon is explained by acoustic phonon recycling with a characteristic time of  $\sim 70$  ps, where heat generated in  $\text{Ti}_3\text{C}_2\text{T}_x$  transfers to  $\text{MoS}_2$  and activates electronic excitation (Figure 1d). We also construct trilayer heterostructure films with configurations of  $\text{Ti}_3\text{C}_2\text{T}_x$ - $\text{MoS}_2$ - $\text{Ti}_3\text{C}_2\text{T}_x$  (denoted HS-TMT) and  $\text{Ti}_3\text{C}_2\text{T}_x$ - $\text{Ti}_3\text{C}_2\text{T}_x$ - $\text{MoS}_2$  (HS-TTM), demonstrating how interface engineering influences interfacial thermal transport and extends the excited-state lifetime in  $\text{MoS}_2$ . Notably, HS-TTM shows a long-lived excited-state lifetime exceeding 800

ps, significantly longer than the  $\text{MoS}_2$  film (92 ps), HS-TM (341 ps), and HS-TMT (550 ps). Additionally, we unveil that the ultrafast charge/energy transfer from  $\text{Ti}_3\text{C}_2\text{T}_x$  to  $\text{MoS}_2$  occurs within 150 fs. This transfer exhibits a strong dependence on the excitation photon energy, with interband transition (IBT) excitation of  $\text{Ti}_3\text{C}_2\text{T}_x$  amplifying the photoconductivity of HS-TM by up to  $\sim 180\%$  compared to individual  $\text{MoS}_2$  under an equivalent absorbed photon density.

## RESULTS AND DISCUSSION

### Preparation of $\text{Ti}_3\text{C}_2\text{T}_x$ - $\text{MoS}_2$ Heterostructure Films.

We first adopted a self-assembly approach to fabricate individual macro-scale  $\text{Ti}_3\text{C}_2\text{T}_x$  and  $\text{MoS}_2$  films using their respective nanoflakes. Aqueous dispersions of  $\text{Ti}_3\text{C}_2\text{T}_x$  nanoflakes (Figure S1) and  $\text{MoS}_2$  nanoflakes (Figure S2) were prepared and diluted in glass beakers. Ethyl acetate was then added dropwise to the surface of each dispersion, inducing Rayleigh-Bénard convection during evaporation. This con-

vection, combined with the high surface tension of water, compactly assembled the nanoflakes on the water surface due to the Marangoni effect, forming continuous films that covered the whole liquid surface.<sup>21,22</sup> Using this method, we achieved continuous  $\text{Ti}_3\text{C}_2\text{T}_x$  and  $\text{MoS}_2$  films with areas extending up to square centimeters. These films can be easily transferred onto any desired substrates including but not limited to silicon or quartz plates via a “fishing” step for further processing. Optical microscopy images verify the macroscopic homogeneity of both films (Figure S3). Atomic force microscopy (AFM) images reveal that both  $\text{Ti}_3\text{C}_2\text{T}_x$  (Figure 2a) and  $\text{MoS}_2$  (Figure 2b) films consist predominantly of monolayer flakes with slight overlap at the edges of adjacent flakes, achieving nanoflake coverage of 89.3 and 95.3%, respectively (Figure S4). These individual films can be easily stacked to create macro-scale, face-to-face  $\text{Ti}_3\text{C}_2\text{T}_x$ - $\text{MoS}_2$  heterostructure films, where the underlying  $\text{Ti}_3\text{C}_2\text{T}_x$  film maintains good coverage and morphological stability (Figure S5). To demonstrate the

(h) Schematic illustrating the mechanism governing the secondary excitation in the Ti<sub>3</sub>C<sub>2</sub>T<sub>x</sub>-MoS<sub>2</sub> heterostructure.

robustness and ease of this process, we created a multilayer heterostructure film by alternately stacking four  $\text{Ti}_3\text{C}_2\text{T}_x$  layers and three  $\text{MoS}_2$  layers, resulting in a clearly visible layered architecture (Figure S6).

Our emphasis then shifted to HS-TM, which was obtained by stacking a single  $\text{MoS}_2$  layer onto a  $\text{Ti}_3\text{C}_2\text{T}_x$  layer (Figures 2c and S7). All films were annealed at 300 °C under an Ar atmosphere to eliminate residual solvent moisture and ensure the complete transition of  $\text{MoS}_2$  to the semiconducting 2H phase (Figures S8 and S9).<sup>23</sup> Both  $\text{MoS}_2$  and  $\text{Ti}_3\text{C}_2\text{T}_x$  films show good chemical and morphological stability after thermal treatment (Figures S9 and S10). Raman spectra unveiled a redshift in the  $E_{2g}^1$  phonon mode of  $\text{MoS}_2$  (from 385.2  $\text{cm}^{-1}$  in the  $\text{MoS}_2$  film to 384.4  $\text{cm}^{-1}$  in HS-TM), which can be attributed to stacking-induced changes in intralayer bonding and/or Coulombic interlayer interactions (Figure 2d).<sup>24</sup> Besides, grazing-incidence wide-angle X-ray scattering (GIWAXS) revealed interfacial interactions in HS-TM, evidenced by a shift of the (100) diffraction compared to  $\text{MoS}_2$ . This suggests an in-plane expansion of the lattice of the heterostructure compared to the individual materials possibly due to lattice matching (Figure S11).

We collected steady-state ultraviolet–visible–near-infrared (UV–vis–NIR) absorption spectra for the  $\text{Ti}_3\text{C}_2\text{T}_x$  film,  $\text{MoS}_2$  film, and HS-TM (Figure 2e). The  $\text{Ti}_3\text{C}_2\text{T}_x$  film exhibited a broad peak centered around 800 nm, characteristic of its transversal SP mode,<sup>5,11</sup> along with two ultraviolet peaks at approximately 260 and 325 nm, corresponding to its IBTs.<sup>11,25</sup> Meanwhile, the  $\text{MoS}_2$  film showed the characteristic A exciton (667 nm), B exciton (611 nm), and C exciton (430 nm) peaks associated with 2H-phase  $\text{MoS}_2$ . A subresonant absorption tail was also observed, attributed to the presence of atomic defects.<sup>26,27</sup> Moreover, the spectrum of HS-TM retained all the characteristic absorption peaks of the individual  $\text{Ti}_3\text{C}_2\text{T}_x$  and  $\text{MoS}_2$  films. The superposition of the spectra of  $\text{Ti}_3\text{C}_2\text{T}_x$  and  $\text{MoS}_2$  in equal proportions (i.e.,  $1 \times \text{Ti}_3\text{C}_2\text{T}_x + 1 \times \text{MoS}_2$ ) closely matches the spectrum of HS-TM. Figure 2f compares the photoluminescence (PL) spectra of the three films under 488 nm excitation. The  $\text{MoS}_2$  film displayed evident peaks at 660 nm (1.88 eV) and 613 nm (2.02 eV), corresponding to the radiative emissions of A and B excitons of 2H-phase  $\text{MoS}_2$ , respectively. In HS-TM, a redshift in exciton resonances, along with reduced PL intensity, was observed. This behavior can be attributed to two factors: (1) changes in Coulomb interactions potentially induced by alterations in the dielectric environment or strong screening effects by the free carriers in MXenes,<sup>28</sup> or (2) the presence of ultrafast interfacial processes.<sup>29</sup> The band structure evolution of  $\text{MoS}_2$  in the  $\text{Ti}_3\text{C}_2\text{T}_x$ - $\text{MoS}_2$  heterostructure was further corroborated by density functional theory calculations, suggesting a potential transition from a direct to an indirect bandgap (Figure S12).

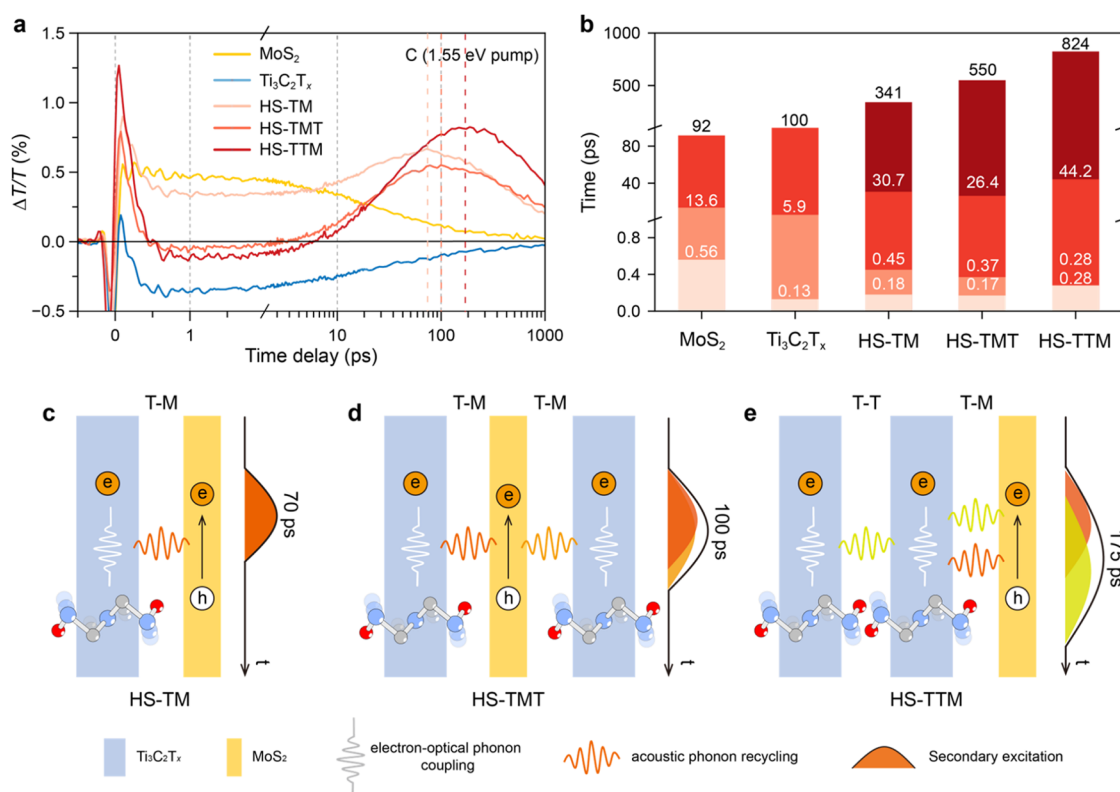

Furthermore, ultraviolet photoelectron spectroscopy (UPS) was conducted to assess the band alignment of  $\text{Ti}_3\text{C}_2\text{T}_x$  and  $\text{MoS}_2$  (Figure 2g). The  $\text{Ti}_3\text{C}_2\text{T}_x$  film showed a secondary electron cutoff energy ( $E_{\text{cutoff}}$ ) of  $\sim 16.58$  eV, from which its work function ( $W_F$ ) was estimated as  $\sim 4.64$  eV by subtracting the He I excitation energy (21.22 eV). For the  $\text{MoS}_2$  film, the  $E_{\text{cutoff}}$  was measured at  $\sim 16.66$  eV, corresponding to a  $W_F$  of  $\sim 4.56$  eV. The valence band maximum ( $E_v$ ) of  $\text{MoS}_2$  was found to be around 1.29 eV below the Fermi level ( $E_F$ ). Given its bandgap of  $\sim 1.88$  eV,  $E_F$  resides close to the conduction band minimum ( $E_c$ ), indicating the n-type nature of the  $\text{MoS}_2$  film, presumably originating from sulfur vacancies.<sup>30,31</sup> The  $W_F$

of HS-TM was measured to be approximately 4.56 eV, similar to the  $\text{MoS}_2$  film. However, the energy difference between  $E_v$  and  $E_F$  narrowed to  $\sim 1.20$  eV in HS-TM. These results indicate that both  $E_v$  and  $E_c$  of  $\text{MoS}_2$  in the heterostructure shift toward the vacuum energy level compared to the individual  $\text{MoS}_2$  film (as illustrated in Figure 2h), revealing strong interactions between  $\text{Ti}_3\text{C}_2\text{T}_x$  and  $\text{MoS}_2$ . Although the  $E_F$  of  $\text{MoS}_2$  in the heterostructure shows minimal change compared to the  $\text{MoS}_2$  film, its position relative to  $E_v$  is closer, suggesting electron transfer from  $\text{MoS}_2$  to  $\text{Ti}_3\text{C}_2\text{T}_x$ . This electronic doping effect, narrowing the gap between  $E_F$  and  $E_v$ , was further corroborated by Mo 3d and S 2p X-ray photoelectron spectroscopy (XPS) spectra, which showed lowered binding energies in HS-TM (Figure S9).<sup>32,33</sup>

### Secondary Excitation and Prolonged Excited States.

The macro-scale heterostructure films enable direct probing of their electronic excitations using transient absorption (TA) spectroscopy. We first employed a 1.55 eV (800 nm) optical pump pulse to activate the SP excitation of  $\text{Ti}_3\text{C}_2\text{T}_x$  and investigated the excited-state dynamics of the  $\text{Ti}_3\text{C}_2\text{T}_x$  film, the  $\text{MoS}_2$  film, and HS-TM. Transient differential transmittance (TDT) spectra were retrieved by measuring the differential transmission signals with and without photoexcitation ( $\Delta T/T = [T_{\text{with pump}} - T_{\text{w/oupump}}]/T_{\text{w/oupump}}$ ). As exhibited in Figure 3a, the  $\text{MoS}_2$  film exhibits a characteristic optical response following optical excitations mediated by defects. In this process, optical excitations via defect states (see static absorption in Figure 2e) promote trapped electrons (holes) from defect states to the conduction (valence) band of  $\text{MoS}_2$ .<sup>26,27</sup> This electronic occupation enhances the screening effect, causing simultaneous renormalization of the electronic gap and excitonic binding energy, which tend to compensate for each other.<sup>34</sup> This many-body effect results in the simultaneous bleaching of the A exciton (660 nm), B exciton (616 nm) and C exciton (436 nm) peaks of  $\text{MoS}_2$ . Additionally, this effect is reflected by a red-shifted photo-induced absorption (PIA-1 (494 nm) and PIA-2 (684 nm)) within 0.5 ps, followed by blue-shifted excitonic transitions. In contrast, the TDT spectrum of the  $\text{Ti}_3\text{C}_2\text{T}_x$  film displays a bleaching peak at  $\sim 424$  nm and a PIA band covering the entire spectrum at 100 fs, which later evolves into a broad PIA band with a maximum near 500 nm (Figure 3b). This behavior aligns with a thermalization scenario in which hot carriers with an undefined electronic distribution rapidly evolve into thermalized carriers following the Fermi–Dirac distribution.<sup>35</sup>

The TDT spectra of HS-TM are characterized by apparent excitonic peaks associated with  $\text{MoS}_2$ , along with more pronounced PIA bands resulting from the combined response of both  $\text{MoS}_2$  and  $\text{Ti}_3\text{C}_2\text{T}_x$  (Figure 3c). Intriguingly, the C exciton bleaching shows an initial intensity decay within the first 1 ps, followed by a remarkable “turnaround” feature characterized by sustained growth lasting up to 70 ps (Figure 3d). This “turnaround” feature symbolizes secondary excitation of  $\text{MoS}_2$  in HS-TM, leading to a prolonged excited-state lifetime, contrasting with the monotonic decay observed in the  $\text{MoS}_2$  film. Of note, the kinetics and spectral features of HS-TM are distinctly different from the individual signals of the  $\text{MoS}_2$  film and the  $\text{Ti}_3\text{C}_2\text{T}_x$  film, as well as their superposition (i.e.,  $1 \times \text{MoS}_2 + 1 \times \text{Ti}_3\text{C}_2\text{T}_x$ ) (Figures 3d and S13), indicating that the negative background generated by the PIA of  $\text{Ti}_3\text{C}_2\text{T}_x$  is not the reason for the observed “turnaround” feature in HS-TM. Likewise, the kinetics curve of PIA-1 in HS-TM also displayed a “turnaround” feature, with an onset at 8 ps

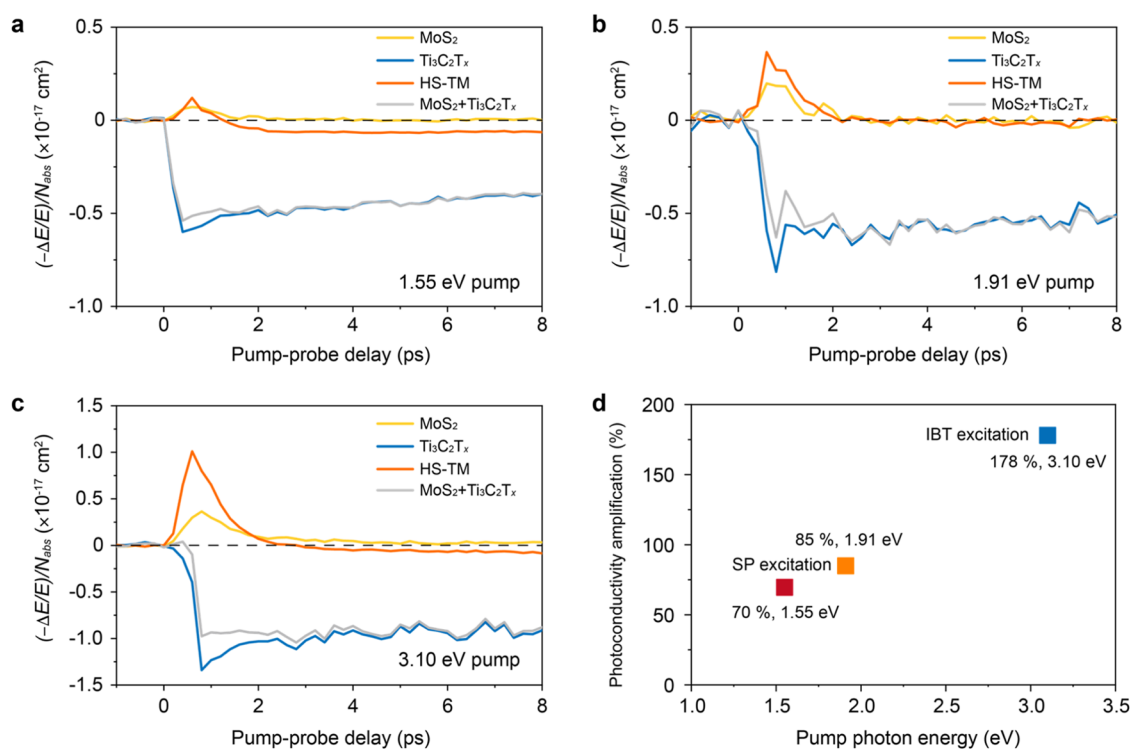

**Figure 4.** Interface-manipulated dynamics. (a) TA kinetics probed at 436 nm (C exciton bleaching) under excitation at 1.55 eV, and (b) the corresponding exponentially fitted time constants. Schematics illustrating the mechanisms governing the interfacial thermal conductivity in (c) HS-TM, (d) HS-TMT, and (e) HS-TTM. The contribution of each Ti<sub>3</sub>C<sub>2</sub>T<sub>x</sub> layer to the secondary excitation of MoS<sub>2</sub> was schematically deconvoluted and illustrated using different colors.

(Figure S14). This feature is in stark contrast with the monotonic decay of the negative signals observed in both the MoS<sub>2</sub> film and the Ti<sub>3</sub>C<sub>2</sub>T<sub>x</sub> film after 10 ps. To further explore this “turnaround” feature, pump fluence-dependent experiments were performed. The normalized dynamics curves of PIA-1 revealed that the signal decay within the first 2 ps was associated with the pump fluence (Figure 3e). The oscillation feature, agreeing well with the previous observation in Ti<sub>3</sub>C<sub>2</sub>T<sub>x</sub> (Figure S15), was attributed to direct energy transfer from nonthermal electrons to out-of-plane A<sub>1g</sub> (~60 fs) and in-plane E<sub>g</sub> coherent phonons (1–2 ps) following SP excitation and Landau damping.<sup>15</sup> This observation suggests that the onset of the “turnaround” feature follows or overlaps electron–phonon coupling.

Previous spectroscopic studies have shown that ultrafast photoexcitation can transiently heat the electron bath of Ti<sub>3</sub>C<sub>2</sub>T<sub>x</sub>, followed by ultrafast subps carrier–lattice relaxation driven by efficient electron–phonon interactions in Ti<sub>3</sub>C<sub>2</sub>T<sub>x</sub>.<sup>15,16</sup> Moreover, considering the time scale of electron/energy transfer of Ti<sub>3</sub>C<sub>2</sub>T<sub>x</sub>,<sup>36</sup> direct nonthermal electron transfer occurs within 50 fs, while nonthermal energy transfer via interface scattering takes place within 125 fs. Additionally, thermal electron transfer following electron–electron scattering emerges around 75 fs and peaks at approximately 125 fs. Consequently, the hot carrier injection scenario cannot adequately account for the observed “turnaround” feature in HS-TM happening in tens of ps following light excitations. Here we attribute this “turnaround” feature to an acoustic phonon recycling process (see follow-up details). In this process, after optical phonon emission and optical-

acoustic phonon coupling, the acoustic phonons populated in Ti<sub>3</sub>C<sub>2</sub>T<sub>x</sub> can transfer energy to MoS<sub>2</sub> via thermal excitation,<sup>37–39</sup> likely by promoting electrons from shallow defect states into the conduction band. A similar phenomenon was observed in graphene–WS<sub>2</sub> heterostructures, where acoustic phonon recycling occurred with a characteristic time exceeding 100 ps.<sup>39</sup>

To further investigate the proposed acoustic phonon recycling process, pump-photon-energy dependent TA measurements were performed using optical pumps at 1.91 eV (650 nm) and 3.10 eV (400 nm). The 1.91 eV excitation matches well with the excitonic resonance in MoS<sub>2</sub>, while the SP excitation of Ti<sub>3</sub>C<sub>2</sub>T<sub>x</sub> is relatively weak compared to the 1.55 eV excitation (Figure S16). Under 1.91 eV excitation, the kinetics curve of HS-TM depicted only a slightly prolonged excited-state lifetime compared to the MoS<sub>2</sub> film, without displaying the pronounced “turnaround” feature (Figure 3f). In contrast, the 3.10 eV excitation induced both the IBT excitation of Ti<sub>3</sub>C<sub>2</sub>T<sub>x</sub> and the above-bandgap excitation of MoS<sub>2</sub> (Figure S17). At the C exciton bleaching, the kinetics were primarily influenced by the behavior of MoS<sub>2</sub>, with the “turnaround” feature and extended excited-state lifetime being less prominent (Figure 3g). Considering that Ti<sub>3</sub>C<sub>2</sub>T<sub>x</sub> exhibits similar acoustic phonon conditions following nonthermal electron–vibration coupling and optical phonon decay, regardless of the pump excitation wavelength,<sup>15,40,41</sup> the observed variation in the significance of the “turnaround” phenomenon likely stems from differences in the excited-state populations of MoS<sub>2</sub> under different photon energies. Specifically, below-bandgap, defect-assisted excitation gener-

**Figure 5.** Ultrafast interfacial charge/energy transfer probed by THz spectroscopy. (a–c) THz photoconductivity dynamics normalized by absorbed photon density of the MoS<sub>2</sub> film, the Ti<sub>3</sub>C<sub>2</sub>T<sub>x</sub> film, HS-TM, and the superimposed responses of the MoS<sub>2</sub> film and the Ti<sub>3</sub>C<sub>2</sub>T<sub>x</sub> film under (a) 1.55 eV, (b) 1.91 eV, and (c) 3.10 eV excitations. (d) Comparison of photoconductivity enhancement under different excitations.

ates a significantly lower excited-state population than resonant or above-bandgap excitation. This results in a larger proportion of unoccupied electronic states, which facilitates electronic transitions driven by acoustic phonon recycling, thereby enhancing the prominence of the secondary excitation feature (Figure 3h).

**Interface-Manipulated Dynamics.** With the tunable stacking configurations of the macro-scale Ti<sub>3</sub>C<sub>2</sub>T<sub>x</sub> and MoS<sub>2</sub> films, we further constructed trilayer heterostructure films with varying stacking orders, namely HS-TMT and HS-TTM. In the TDT spectra obtained using 1.55 eV optical pump (Figure S18), we observed that adding an additional layer of Ti<sub>3</sub>C<sub>2</sub>T<sub>x</sub> did not qualitatively alter the dominant optical response of MoS<sub>2</sub> in HS-TMT and HS-TTM. However, we detected an enhanced negative background due to the Ti<sub>3</sub>C<sub>2</sub>T<sub>x</sub> layers, which was particularly pronounced in HS-TTM. This effect can be attributed to the increased SP effect from the additional layer of Ti<sub>3</sub>C<sub>2</sub>T<sub>x</sub>.<sup>11</sup> Moreover, the apparent “turnaround” feature, marked by a prolonged and sustained increase, was observed for the C exciton bleaching of MoS<sub>2</sub> in both HS-TMT (~100 ps) and HS-TTM (~175 ps) (Figure 4a). To gain deeper understanding of the transformation of excited states in these films, we performed multiexponential fitting of the C exciton kinetics, using a phenomenological model based on eq 1, where  $A_i$  and  $\tau_i$  denote the fractional amplitude and decay constant, respectively. Figure 4b illustrates the kinetics decay components for all films under 1.55 eV excitation. Three decay components were identified for the MoS<sub>2</sub> film, including a fast component ( $\tau_1 \sim 560$  fs) typically associated with charge trapping, an intermediate component ( $\tau_2 \sim 13.6$  ps) related to exciton–phonon scattering and exciton–exciton annihilation, and a slow component ( $\tau_3 \sim 92$  ps) corresponding to exciton recombination.<sup>42</sup> Meanwhile, kinetics fitting of the Ti<sub>3</sub>C<sub>2</sub>T<sub>x</sub>

film revealed three decay components, including a rapid component ( $\tau_1 \sim 130$  fs) attributed to electron thermalization (electron–electron scattering), a subsequent electron cooling (electron–phonon scattering) process ( $\tau_2 \sim 6$  ps), and a phonon diffusion process determined by the thermal boundary resistance between Ti<sub>3</sub>C<sub>2</sub>T<sub>x</sub> and the substrate ( $\tau_3 \sim 100$  ps).<sup>6,41</sup> The decay behavior of all three heterostructure films (HS-TM, HS-TMT, and HS-TTM) was more complex than that of the individual MoS<sub>2</sub> film and the Ti<sub>3</sub>C<sub>2</sub>T<sub>x</sub> film, with each exhibiting four decay components. Notably, the long-lived process, attributed to exciton recombination in MoS<sub>2</sub>,<sup>42</sup> displayed significantly extended time constants in the heterostructure films. In HS-TM, the time constant increased to 341 ps, compared to 92 ps in the MoS<sub>2</sub> film. This duration was further extended to 550 ps in HS-TMT and reached 824 ps in HS-TTM.

$$\Delta T/T(t) = \sum A_i \exp(-t/\tau_i) \quad (1)$$

In addition, we conducted the TA measurements on HS-TMT and HS-TTM using 1.91 and 3.10 eV pump lights (Figure S19). Under 1.91 eV excitation, the “turnaround” feature in the C exciton kinetics became weakened but remained discernible across all heterostructure films (Figure S20). The long-lived process exhibited an especially extended time constant in HS-TTM, reaching 858 ps. Under 3.10 eV excitation, the “turnaround” feature was nearly absent across all heterostructure films, and the long-lived process did not exhibit a significantly increased time constant or any discernible pattern (Figure S21). These observations further confirm that the “turnaround” feature and the prolonged excited-state lifetime are closely linked to the differences in the excited-state populations of MoS<sub>2</sub>.

To further explore the distinct time constants associated with the “turnaround” feature in the three heterostructure films, we analyzed the pump fluence-dependent dynamics of the C exciton and PIA-1 in HS-TM. The differential transmittance signals at the “turnaround” for both the C exciton and PIA-1 displayed a linear relationship with varying pump fluence and maintained a constant characteristic time (Figure S22). This finding indicates that the fraction of energy transferred to the MoS<sub>2</sub> lattice is governed by the heat capacity of each component and the thermal conductance at the interface, rather than by the pump fluence itself. Therefore, we attribute the variations in acoustic phonon recycling across the three heterostructure films to differences in thermal conductance at the interfaces. Compared to HS-TM (Figure 4c), an additional layer of Ti<sub>3</sub>C<sub>2</sub>T<sub>x</sub> in HS-TMT delivers more heat to MoS<sub>2</sub> while simultaneously offering better insulation, leading to a prolonged characteristic time of ~100 ps (Figure 4d). HS-TTM, which has a Ti<sub>3</sub>C<sub>2</sub>T<sub>x</sub>-Ti<sub>3</sub>C<sub>2</sub>T<sub>x</sub> interface and a Ti<sub>3</sub>C<sub>2</sub>T<sub>x</sub>-MoS<sub>2</sub> interface, exhibits more pronounced differences (Figure 4e). Thermal transport across the Ti<sub>3</sub>C<sub>2</sub>T<sub>x</sub>-Ti<sub>3</sub>C<sub>2</sub>T<sub>x</sub> interface is less efficient than that across the Ti<sub>3</sub>C<sub>2</sub>T<sub>x</sub>-MoS<sub>2</sub> interface. This reduced efficiency at the Ti<sub>3</sub>C<sub>2</sub>T<sub>x</sub>-Ti<sub>3</sub>C<sub>2</sub>T<sub>x</sub> interface likely contributes to the longer time constant (~175 ps) observed for HS-TTM (i.e., “tertiary excitation”). Overall, our findings suggest that interfacial engineering through multilayer stacking can effectively modulate the interfacial thermal transport efficiency and affect the time duration of the acoustic phonon recycling process. Such modulation could extend the lifetime of excited states, offering potential benefits for carrier extraction in the related applications.

**Ultrafast Charge/Energy Transfer.** In the TA spectra of HS-TM, clear intensity variations within the first 1 ps suggest rapid charge/energy transfer at the Ti<sub>3</sub>C<sub>2</sub>T<sub>x</sub>-MoS<sub>2</sub> interface. However, overlapping spectral signals from Ti<sub>3</sub>C<sub>2</sub>T<sub>x</sub> and MoS<sub>2</sub> complicate the direct extraction of this process. In this context, optical pump-THz probe (OPTP) spectroscopy provides complementary insights by measuring transient conductivity changes via the pump-induced relative change in the transmitted THz electrical field ( $-\Delta E/E = [E_{\text{with pump}} - E_{\text{w/ opump}}]/E_{\text{w/ opump}}$ ).<sup>43,44</sup> Figure 5a compares the photoconductivity dynamics normalized by absorbed photon density ( $(-\Delta E/E)/N_{\text{abs}}$ ) for the Ti<sub>3</sub>C<sub>2</sub>T<sub>x</sub> film, the MoS<sub>2</sub> film, and HS-TM under 1.55 eV excitation. The Ti<sub>3</sub>C<sub>2</sub>T<sub>x</sub> film showed a long-lived negative photoconductivity following SP excitation, indicative of heating effects typically observed in metallic systems.<sup>45</sup> Sub-bandgap excitation at 1.55 eV, below the A exciton resonance of MoS<sub>2</sub> at 1.88 eV, led to positive photoconductivity in MoS<sub>2</sub>, attributed to defect-assisted free carrier generation.<sup>43</sup> The resulting photoconductivity decayed rapidly within 2 ps due to the recapture of transient free carriers into in-gap defect states. Intriguingly, HS-TM under 1.55 eV excitation displayed a transient positive photoconductivity that reversed to negative within 2 ps, followed by a long-lived negative photoconductivity plateau persisting for over 10 ps. This dynamic feature deviates from a simple, linearly superimposed response of individual MoS<sub>2</sub> and Ti<sub>3</sub>C<sub>2</sub>T<sub>x</sub> films, indicating the involvement of interfacial processes in HS-TM. The suppression of negative photoconductivity originating from hot carriers in Ti<sub>3</sub>C<sub>2</sub>T<sub>x</sub>, combined with the amplification of positive photoconductivity associated with free carriers in MoS<sub>2</sub>, point to efficient charge/energy transfer from Ti<sub>3</sub>C<sub>2</sub>T<sub>x</sub> to MoS<sub>2</sub>. Furthermore, the

instantaneous changes in both TA and THz photoconductivity dynamics of HS-TM, compared to the individual components, suggest that the charge/energy transfer occurs in an ultrafast manner, faster than the instrument response (~150 fs). Otherwise, HS-TM would exhibit similar TA and THz dynamics with the superimposed responses of individual MoS<sub>2</sub> and Ti<sub>3</sub>C<sub>2</sub>T<sub>x</sub> films at the initial stage. The ultrafast charge/energy transfer from Ti<sub>3</sub>C<sub>2</sub>T<sub>x</sub> to MoS<sub>2</sub> enhances the maximum positive photoconductivity of HS-TM, which is dominated by free carriers in MoS<sub>2</sub>, compared to the MoS<sub>2</sub> film under an equivalent absorbed photon density and identical pump wavelength. To quantify this enhancement resulting from the ultrafast interfacial charge/energy flow from Ti<sub>3</sub>C<sub>2</sub>T<sub>x</sub> to MoS<sub>2</sub>, we defined the photoconductivity amplification ratio,  $\eta$  (%), of HS-TM based on eq 2, where  $[(-\Delta E/E)/N_{\text{abs}}]_{\text{HS-TM(max)}}$  and  $[(-\Delta E/E)/N_{\text{abs}}]_{\text{MoS}_2(\text{max})}$  represent the maximum photoconductivity per absorbed photon density for HS-TM and the MoS<sub>2</sub> film, respectively. Based on this definition, the  $\eta$  of HS-TM under 1.55 eV excitation is estimated to be ~70%.

$$\eta = \frac{[(-\Delta E/E)/N_{\text{abs}}]_{\text{HS-TM(max)}} - [(-\Delta E/E)/N_{\text{abs}}]_{\text{MoS}_2(\text{max})}}{[(-\Delta E/E)/N_{\text{abs}}]_{\text{MoS}_2(\text{max})}} \times 100\% \quad (2)$$

To gain further insights into the interfacial charge/energy transfer mechanism, we performed pump-wavelength-dependent OPTP measurement at 1.91 eV (Figure 5b) and 3.10 eV (Figure 5c). In both cases, HS-TM retained the characteristic dynamic features observed under 1.55 eV excitation, namely, suppressed negative photoconductivity compared to Ti<sub>3</sub>C<sub>2</sub>T<sub>x</sub> and enhanced positive photoconductivity relative to MoS<sub>2</sub>. This consistency indicates that the interfacial charge/energy flow is directed from Ti<sub>3</sub>C<sub>2</sub>T<sub>x</sub> to MoS<sub>2</sub> across all employed pump-photon energies. Notably, the photoconductivity amplification increased with higher excitation photon energy, rising from ~70% at 1.55 eV to ~85% at 1.91 eV and reaching ~180% at 3.10 eV (Figure 5d). This trend suggests that the interfacial charge/energy transfer efficiency increases as the excitation photon energy rises. Such behavior is consistent with the previously reported hot carrier transfer scenario: the excess kinetic energy of hot carriers facilitates interfacial charge separation processes, leading to enhanced transfer efficiency with increasing the pump photon energy.<sup>46,47</sup> The involvement of hot carriers in ultrafast charge/energy transfer has also been recently observed at the MXene/dye molecule interfaces, including the direct transfer of nonthermalized electrons to molecules and heat transfer by interfacial scattering of nonthermalized electrons.<sup>36</sup>

## CONCLUSIONS

In summary, we fabricated a series of heterostructure films with tunable sequences of monolayer Ti<sub>3</sub>C<sub>2</sub>T<sub>x</sub> and MoS<sub>2</sub> films through an interfacial self-assembly approach. These macro-scale heterostructure films enabled us to directly investigate excited-state dynamics at the interface using pump-probe techniques. Importantly, we discovered a secondary excitation of MoS<sub>2</sub> in HS-TM under 1.55 eV excitation. This observation is explained by acoustic phonon recycling, where heat generated in Ti<sub>3</sub>C<sub>2</sub>T<sub>x</sub> transfers to MoS<sub>2</sub> and activates electronic excitation. The trilayer HS-TMT and HS-TTM heterostruc-

ture films demonstrated that interfacial thermal transport engineering can extend the excited-state lifetime of MoS<sub>2</sub>, with the HS-TTM configuration exhibiting a time constant exceeding 800 ps. We also observed an ultrafast charge/energy transfer process from Ti<sub>3</sub>C<sub>2</sub>T<sub>x</sub> to MoS<sub>2</sub> occurring within 150 fs, with the transfer efficiency increasing with higher excitation photon energy. This study advances our comprehension of photogenerated carrier dynamics in the Ti<sub>3</sub>C<sub>2</sub>T<sub>x</sub>-MoS<sub>2</sub> heterostructure and presents promising strategies for controlling excited-state lifetimes in MoS<sub>2</sub>, which is expected to impact the advancement of their photochemical and optoelectronic applications.
