Abstract

The accurate estimation of aeolian saltation events is a fundamental requirement in the modelling of wind erosion, dust emission, dune movement and aeolian hazard prediction. A large number of semi-empirical sand transport rate models exist, with many relying on a single value for a shear velocity threshold above which saltation is initiated. However, measuring and modelling the sand transport rate suffers from the effects of a number of epistemic and aleatory uncertainties which make the identification of a single threshold value for shear velocity problematic. This paper focuses on the uncertainty propagation evident in calculations that use a threshold shear velocity to estimate sand transport rate. Probability density functions of threshold shear velocity are provided from the authors' previous studies. Grain diameter and shear velocity are considered as deterministically varying parameters. Several sand transport rate statistical metrics are estimated via the Monte Carlo approach adopting four different sand transport models. The sand transport rate estimation in probabilistic terms allows us to assess the amplification/reduction in the uncertainty and to provide a deeper insight into established transport rate models. We find that if the wind speed is close to the erosion threshold, every tested model amplifies the variability of the resulting estimated sand transport rate, especially in the case of coarse sand. If the wind speed is large, the adopted models present substantial differences in uncertainty. An interpretation of these differences is given by conditioning the sand transport rate models to the type of erosion threshold adopted, the fluid or impact threshold.

Keywords: windblown sand saltation, sand transport rate, threshold shear velocity, uncertainty quantification

1. Introduction

The study of aeolian sand transport belongs to several research fields, from fundamental earth sciences to applied sciences such as civil and environmental engineering. From the scientific perspective, explaining and analysing wind-blown sand represents a challenging task due to the complex interactions between saltating particles, bed load and the wind field. Nevertheless, such analysis is an essential requirement in investigations of desert dust emissions (e.g. [Haustein et al., 2015](#)), dune dynamics (e.g. [Wiggs and Weaver, 2012](#)), agricultural wind erosion (e.g. [Zobeck et al., 2003](#)), land degradation (e.g. [Mayaud et al., 2016](#)), and planetary geomorphology (e.g. [Kok et al., 2012](#)). From the engineering perspective, windblown sand can have deleterious impacts on built structures and human activities (e.g. [Zhang et al., 2010](#); [Xie et al., 2015](#)). For these reasons, the accurate prediction of sand transport events is a significant goal.

Saltation is the dominant mechanism of windblown sand transport. The total saltating load can be quantified by estimating the sand transport rate, i.e. by vertically integrating the horizontal flux of saltating particles. Since this physical quantity represents a straightforward measure to estimate wind erosion, sand transport, and deposition, a number of semi-empirical models to predict sand transport rate (*Q*-models) have been formulated (e.g. [Kawamura,](#)

15 1951; Owen, 1964; Lettau and Lettau, 1978; Kok et al., 2012).

16 Dong et al. (2003) classified sand transport models into four categories defined by their basic form. *Bagnold type*
17 equations (e.g. Bagnold, 1941; Zingg, 1953) relate sand transport rate to the cube of shear velocity u_*^3 but do not
18 explicitly consider the excess of shear velocity compared to a threshold value u_{*t} . This results in unrealistic sand
19 transport rates when u_* is less than u_{*t} . *Modified Bagnold type* equations (e.g. Kawamura, 1951; Owen, 1964; Lettau
20 and Lettau, 1978; Kok et al., 2012) relate sand transport rate to the cube of an effective shear velocity that is defined as
21 a function of both the shear velocity and the threshold value. *O'Brien-Rindlaub type* and *modified O'Brien-Rindlaub*
22 *type* equations (e.g. O'Brien and Rindlaub, 1936; Dong et al., 2003) relate transport rate to wind speed instead of
23 shear velocity. These first three categories usually take into account the particle size directly through the sand grain
24 diameter, d . The remaining models may be categorized as *complex*. These include physical models that account for
25 additional phenomena in the saltation process such as inertial effects (Mayaud et al., 2017) or hysteresis (Kok, 2010).
26 These models include multiple empirical fitting parameters usually related to quantities other than simply sand grain
27 diameter.

28 Because of their ease of use and their sound physical basis, *modified Bagnold type* models are widespread in
29 the literature and popularly employed in practice, see for example the field studies by Fryberger and Dean (1979),
30 Al-Awadhi and Al-Awadhi (2009), Barchyn and Hugenholtz (2011), Sherman and Li (2012), Sherman et al. (2013),
31 Yang et al. (2014) and Liu et al. (2015). However, *modified Bagnold type* models lead to significant variability in their
32 prediction, despite belonging to the same conceptual form (e.g. Sarre, 1987; Sherman et al., 1998, 2013; Sherman and
33 Li, 2012). These discrepancies follow from differences in the structure of models and can be related to the way the
34 effective shear velocity and the grain diameter are treated in the model. For example, whilst some models explicitly
35 account for changes in d (e.g. Lettau and Lettau, 1978), others do not (e.g. Kawamura, 1951), and still others account
36 for the effect of d by introducing other related variables, such as the particle terminal velocity in the model of Owen
37 (1964).

38 These differences can be regarded as the result of the inherent *uncertainty* in the saltation phenomenon. To our
39 knowledge, a comprehensive description of uncertainties concerning the prediction of aeolian sand transport rate is
40 not available in the literature. A useful approach is to consider a general classification of uncertainty in sand transport
41 rate predictions that distinguishes between *aleatory* and *epistemic* uncertainty (Zio and Pedroni, 2013), both of which
42 are relevant to the sand transport case.

43 *Aleatory uncertainty* refers to the inherent randomness in many physical phenomena (e.g. Sørensen, 1993). It
44 arises not only in nature but also in the laboratory environment, where the properties of aeolian processes can be
45 nominally controlled in both space and time.

46 *Epistemic uncertainty* is associated with the lack of knowledge about the properties and conditions of the phenom-
47 ena to be modeled, i.e. *model*, *measurement* and *parameter* uncertainties (see Shao, 2008; Barchyn et al., 2014). We
48 believe that the uncertainty concerning the mode of u_{*t} to be used in sand transport equations can be considered as an
49 *epistemic model* uncertainty too because it is related to the lack of knowledge about the Q -model. Indeed, the mode
50 of u_{*t} to be adopted is not unequivocally established in the literature. Two threshold velocities have been recognized:
51 the fluid (or static) threshold, i.e. the minimum wind speed for initiation of sediment transport without antecedent
52 transport; and the impact (or dynamic) threshold, i.e. the minimum wind speed for sustaining sediment transport
53 with antecedent transport. There is no unanimity in the literature as to which threshold is the most appropriate for
54 modelling sand transport rate: some authors prefer the impact threshold, others suggest the fluid threshold, and still
55 others recommend a combination of the two. Pye and Tsoar (2009) and Kok et al. (2012) recommend the impact
56 threshold defined as a linear function of the fluid threshold (85% and 80% of the fluid threshold, respectively). Simi-
57 larly, Andreotti (2004) and Pahtz et al. (2012) also prefer the impact threshold and provide models for its estimation.
58 Conversely, Shao (2008) refers to the fluid threshold only, whilst Sherman et al. (2013) adopt the fluid threshold for
59 small Q and, for increasing Q , an exponential decreasing u_{*t} to a minimum equal to the impact threshold (85%
60 of the fluid threshold). Kok (2010) provides a more sophisticated model for sand transport which considers a hysteretic
61 threshold between the impact and fluid threshold that depends on the history of the system.

62 The uncertainties reviewed up to this point are innate in Q -models. We expect that the *uncertainty propagation*
63 to Q from other models also occurs, also due to the uncertainty in u_{*t} . A few authors have recently raised this issue.
64 Shao (2008) attributes the Q -model randomness not only to their empirical parameters but also to variability in the
65 threshold shear velocity. Moreover, since a method to determine a single quantitative definition of u_{*t} is not agreed
66 upon (see Stout, 2004), Shao (2008) notes that any estimate of u_{*t} must involve a degree of subjectivity. In particular,

he conjectured that such uncertainties in defining u_{*t} could outweigh the differences inherent in the functional forms of the sand transport rate models. The quantification of uncertainty in u_{*t} has recently been assessed by Raffaele et al. (2016), and Edwards and Namikas (2015) and Webb et al. (2016) note that such uncertainty in threshold estimates can be expected to propagate to sand transport rate predictions.

Given these points, two main questions are pertinent: i. How does the degree of uncertainty in sand transport rate (Q) vary with respect to the uncertainty in estimates for the threshold shear velocity (u_{*t})? ii. How do different sand transport rate models behave when threshold shear velocity is considered as a statistically random variable?

The present study aims to contribute to a solution to these issues. Four key, semi-empirical models of sand transport rate are adopted to evaluate the impact of uncertainty propagation. Threshold shear velocity is assumed as the only random variable affecting sand transport rate and, as a result, instead of having a single deterministic value of sand transport rate for given values of u_* and d , a range of different values describing a probability distribution are obtained.

2. Methods

Here we describe the method for evaluating uncertainty propagation from the parametric uncertainty of the threshold shear velocity to the model prediction of sand transport rate. First, the general approach is described and justified. Secondly, the adopted sand transport rate models and threshold shear velocity probability density functions are given. In this and following sections, the threshold shear velocity conditional probability density function $f(u_{*t} | d)$ is expressed as $f_{u_{*t}}$ for the sake of conciseness.

Uncertainty propagation from threshold shear velocity to predictions of sand transport rate is investigated by comparing dimensionless statistical metrics of both Q and u_{*t} . Both numerical and analytical solutions could be applied to evaluate uncertainty propagation (Smith, 2014). Analytically, for a given grain diameter and shear velocity, the cumulative distribution functions F_Q for sand transport rate can be obtained from the following procedure:

$$F_Q(s) = P[Q \leq s] = P[Q(u_{*t}) \leq s] = P[u_{*t} \leq Q^{-1}(s)] = F_{u_{*t}}[Q^{-1}(s)], \forall d, u_* \quad (1)$$

So, deriving each term, one can find the probability density functions f_Q :

$$f_Q(s) = f_{u_{*t}}[Q^{-1}(s)] \cdot [Q^{-1}(s)]', \forall d, u_* \quad (2)$$

It is worth noting from Equation 2 that the inversion of most of the sand transport rate models can only be performed numerically. Hence, we prefer a numerical approach because a fully analytical solution is not achievable. A classical Monte Carlo (MC) sampling based method (Caflich, 1998) was preferred to other numerical approaches because of its very low computational cost. Furthermore, other numerical approaches (such as functional expansion-based methods like Karhunen-Loeve or polynomial chaos expansions) offer results that are too sophisticated for the relatively simple task covered by the present study. The MC method relies on repeated random sampling in order to obtain numerical probabilistic results. Hence, a set of numerical realizations of the random prediction $Q(u_*, u_{*t})$ was evaluated by varying $u_* \in [0.1, 2] m/s$ and by sampling the random parameter u_{*t} according to $f_{u_{*t}}$. In applying the MC method, it is important to check the convergence of the numerical realizations. Indeed, the rate of convergence of MC is always $1/n^{0.5}$, where n is the number of numerical realizations. It follows that the cardinality # of Q and u_{*t} affects the obtained results and must be chosen in order to reach the convergence of the first statistical moments of Q . Convergence can be checked by means of the weighted absolute error φ_{abs} as well as the weighted residual φ_{res} of the generic parameter φ . They are respectively defined for growing cardinality n as $\varphi_{abs} = |\varphi_{\#} - \varphi_n| / \varphi_{\#}$ and $\varphi_{res,n} = |\varphi_n - \varphi_{n-1}| / \varphi_n$.

In the framework of the MC method, sand transport rate is obtained by referring to some well-known modified Bagnold sand transport models reported in the literature. Semi-empirical modified Bagnold-type sand transport models proposed by Kawamura (1951), Owen (1964), Lettau and Lettau (1978) and Kok et al. (2012) were evaluated to assess the effects of uncertainty on transport predictions. These models are reported in Table 1, where ρ_a is the air density, g is the gravitational acceleration, d is the sand grain diameter, d_r is a reference sand grain diameter ($d_r = 0.25mm$) and K, O, L, C are semi-empirical parameters. For the model of Owen (1964), v_t is the particle's terminal velocity. Chen and Fryrear (2001) parametrized this as a function of the sand grain diameter getting

$v_t = -0.775352 + 4.52645d^{0.5}$, where v_t is expressed in m/s and d in mm .

Table 1: Summary of the adopted sand transport rate models

Reference	Equation	Semi-empirical parameter
Kawamura (1951)	$Q = K \frac{\rho_a}{g} u_*^3 \left(1 - \frac{u_{*t}^2}{u_*^2}\right) \left(1 + \frac{u_{*t}}{u_*}\right)$	$K = 2.78$
Owen (1964)	$Q = O \frac{\rho_a}{g} u_*^3 \left(1 - \frac{u_{*t}^2}{u_*^2}\right)$	$O = 0.25 + \frac{v_t}{3u_*}$
Lettau and Lettau (1978)	$Q = L \sqrt{\frac{d}{d_r}} \frac{\rho_a}{g} u_*^3 \left(1 - \frac{u_{*t}}{u_*}\right)$	$L = 6.7$
Kok et al. (2012)	$Q = C \frac{\rho_a}{g} u_{*t} u_*^2 \left(1 - \frac{u_{*t}^2}{u_*^2}\right)$	$C = 5$

111
112 It is worth stressing that the models proposed by Kawamura (1951) and Kok et al. (2012) do not explicitly take into
113 account the grain diameter only because their semi-empirical parameter refers to $d \approx 0.25mm$. In this study their
114 semi-empirical parameter is considered constant as an approximation. In fact, Kawamura (1951) does not define the
115 relation between K and d , while Kok et al. (2012) provide a relation that cannot be easily computed. However, this
116 assumption doesn't reflect on the uncertainty propagation to Q when expressed in dimensionless statistics such as
117 coefficient of variation and skewness.

118 In this study, the fluid (or static) threshold shear velocity is adopted for several reasons. First, since it represents
119 the starting point for erosion it is considered highly relevant for modelling purposes and application of model results.
120 Secondly, unlike the impact threshold, appropriate probability density functions for the fluid threshold shear velocity
121 are available from the literature (e.g. Duan et al., 2013; Raffaele et al., 2016). Thirdly, the fluid threshold is likely
122 to be more variable than the impact threshold because it is more dependent upon variability in surface properties.
123 Therefore, the analysis carried out in this paper will provide estimates of the maximum likely uncertainty propaga-
124 tion. Fourthly, when assuming the impact threshold as a linear function of the fluid threshold (i.e. 80% – 85% of the
125 fluid threshold), the adoption of the fluid rather than the impact threshold doesn't affect the uncertainty propagation
126 to Q when expressed in dimensionless statistics.

127 In order to account for the uncertainty in u_{*t} , conditional probability density functions of threshold shear velocity,
128 $f_{u_{*t}}$ were taken from Raffaele et al. (2016). Given that u_{*t} varies as a function of d , one $f_{u_{*t}}$ exists for each value of
129 d . We investigated a range of $d \in [0.063, 1.2] mm$ (i.e. from fine to coarse sand) by means of fifty linearly spaced
130 non-parametric conditional probability density functions $f_{u_{*t}}$. Fig. 1 summarizes the statistics of the threshold shear
131 velocity against d using suitable percentiles and statistical metrics. In Fig. 1(a), the trends of mean values $\mu(u_{*t})$ and
132 the 1st, 5th, 25th, 75th, 95th and 99th percentiles $p(u_{*t})$ are plotted against the diameter d . In Fig. 1(b,c,d), the trends of
133 the coefficient of variation $c.o.v.$, skewness sk and p_{95}/p_{50} ratio are plotted, respectively.

134 3. Results

135 The section is organized as follows. Sub-section 3.1 provides preliminary results of the MC method. In Sub-
136 section 3.2 the trend of the obtained statistical metrics is explored in order to clarify the complex graphs resulting
137 from the three-dimensional surfaces of Q statistics.

138 3.1. Preliminary findings

139 First, we discuss the convergence of the first three Q statistical moments for an increasing cardinality n of
140 $Q(u_*, u_{*t})$.

141 The weighted absolute error φ_{abs} as well as the weighted residual φ_{res} of the generic parameter φ were averaged over
142 100 random permutations of the order of $Q(u_*, u_{*t})$ for an assigned value of $u_*/\mu(u_{*t})$.

143 The rate of convergence is the same for each grain diameter, shear velocity and Q -model tested. However, the residuals
144 differ with different Q -models and parameters. For example, in Fig. 2 the convergence of absolute and residual error
145 is given with reference to the Kawamura (1951) model for $u_*/\mu(u_{*t}) = 1.5$ and $d = 0.25 mm$. Fig. 2(a) confirms that
146 the rate of convergence of the absolute error clearly follows the slope $1/n^{0.5}$, in agreement with MC theory (Cafisch,

Figure 1: Threshold shear velocity statistics against d : mean values $\mu(u_{*t})$, $p_1(u_{*t})$, $p_5(u_{*t})$, $p_{25}(u_{*t})$, $p_{75}(u_{*t})$, $p_{95}(u_{*t})$, $p_{99}(u_{*t})$ percentiles (a). Coefficient of variation (b), skewness (c) and 95th percentile - 50th percentile ratio (d) of u_{*t} . Results derived from Raffaele et al. (2016)

Figure 2: Assessment of the MC convergence: weighted absolute error (a) and weighted residual error (b) of the mean value μ , standard deviation σ and skewness sk of sand transport rate estimated by means of the Kawamura (1951) model for $d = 0.25$ mm and $u_* / \mu(u_{*t}) = 1.5$

147 1998). Fig. 2(b) plots the weighted residual to evaluate the total number of realizations # required to reach a desired
 148 accuracy. For the set-up above, even a modest cardinality $n = 5e+2$ allows $\mu_{res,n} \approx \sigma_{res,n} \approx 10^{-3}$ for the mean value
 149 and standard deviation of Q . This is a low residual error if compared with common engineering applications. As
 150 regards sk , $n = 2e+3$ allows a transport rate of about $sk_{res,n} \approx 10^{-3}$. Having in mind the low computational cost of a
 151 single realization and for the sake of precision, a cardinality # = $1e+6$ is adopted in this study.

152 Overall, a probability density function of Q can be determined for each sand transport rate model and for each
 153 value of d and u_* . By way of example, two estimates of f_Q result from varying the Q -models, u_* and d are shown in
 154 Fig. 3(a),(b) and (c), respectively. The adopted $f_{u_{*t}}$ (dotted line) is also shown for each f_Q . The probability density
 155 functions are plotted over the normalized axis $\phi/p_{50}(\phi)$ of the generic variable ϕ . From Fig. 3, it is clear that different
 156 models, as well as different values of u_* and d , induce a significant variation in both variance and skewness of Q .
 157 As a result, the range of predicted values of Q also changes considerably. An increasing or decreasing variance with
 158 respect to the mean value of Q represents an amplification or reduction in the uncertainty, respectively. The skewness
 159 quantifies the degree of non-Gaussianity in that uncertainty.

Figure 3: Comparison between normalized $f_{u_{*t}}$ and f_Q evaluated by varying Q -models (a), u_* (b) and d (c). The changes of both variance and skewness from $f_{u_{*t}}$ to f_Q are due to the uncertainty propagation.

3.2. Sensitivity analysis

For a given Q -model, a probability density function of Q corresponds to any point in the parameter plane $d - u_*$. In this study, this plane is sampled by 50 linearly spaced values of $d \in [0.063, 1.2] \text{ mm}$ and 50 linearly spaced values of $u_* \in [0.1, 2] \text{ m/s}$. This results in as many as 2500 numerical estimates of f_Q for each Q -model, and in 10 billion realizations of Q in total. Given the considerable number of estimated densities f_Q , the uncertainty in sand transport rate is represented by means of its statistical moments, for the sake of brevity and clarity. The mean value μ , the 95th percentile p_{95} , the standard deviation σ and the skewness sk of Q [$\text{kg m}^{-1} \text{s}^{-1}$] for each Q -model are plotted using contour plots in the parameter plane in Fig. 4.

Qualitatively, the results do not appear to differ significantly in average terms. The general trend of $\mu(Q)$ is the same for each sand transport model and also similar to $p_{95}(Q)$. $\mu(Q)$ monotonically increases with increasing u_* for a given d . Conversely, the trend over d for a given u_* is no more globally monotonic except for results from the Kawamura (1951) model. Here $\mu(Q)$ decreases with increasing d for small u_* even if the trend may be locally non-monotonic, while $\mu(Q)$ increases with increasing d for large u_* . Strong discrepancies between the models arise for higher order statistics $\sigma(Q)$ and $sk(Q)$, both qualitatively and quantitatively. However, some similarities in model behaviours can be recognized. First, results from Kawamura (1951) and Kok et al. (2012) are qualitatively similar (Fig. 4c,d and Fig. 4o,p, respectively). Indeed, both $\sigma(Q)$ and $sk(Q)$ show local maxima and minima. Secondly, high moments from Owen (1964) and Lettau and Lettau (1978) (Fig. 4g,h and Fig. 4k,l, respectively) reveal common trends. In particular, it is worth noting that $sk(Q)$ remains constant for increasing values of u_* above a common threshold of u_* for each grain size. In sum, while the model proposed by Owen (1964) behaves qualitatively like the one of Lettau and Lettau (1978), the model proposed by Kawamura (1951) behaves qualitatively like the one of Kok et al. (2012). Whilst some similarities can be identified in the qualitative general trend, the quantitative discrepancies remain significant.

In order to systematically discuss uncertainty propagation from u_{*t} to Q , Q statistics are compared to those of u_{*t} . We condense μ and σ into the coefficient of variation *c.o.v.*, and normalize p_{95} with respect to p_{50} in order to deal with dimensionless statistical metrics. In this way, metrics referring to u_{*t} can be directly compared with those of Q . For the sake of graphical clarity, the comparison is made by reducing the 3D plots in Fig. 4 to 2D plots, where the generic statistical metric φ is plotted versus one parameter for given values of the other.

In Fig. 5, $\varphi(Q)$ are plotted over d for each Q -model and for some sampled values of u_* (black continuous lines). The corresponding statistical metrics of u_{*t} versus d are plotted for comparison (dash dot lines). It is worth recalling that $\varphi(u_{*t})$ does not depend on u_* or the Q -model. Even if Q has a first order dependency on u_* , a stronger determinant is the effective shear velocity (Eq. 3), which takes into account the threshold value u_{*t} . Hence, in Fig. 5 the statistical metrics of Q are also plotted for given values of the averaged effective ratio $u_*/\mu(u_{*t})$ (dashed lines).

The variability of the sand transport rate over d with respect to its mean value, i.e. *c.o.v.*(Q), is controlled by u_*

Figure 4: Contour plots of the first three statistical moments and 95th percentile of Q . Mean value μ , 95th percentile p_{95} , standard deviation σ and skewness sk according to different Q -models

193 (Fig. 5a,d). For slow winds (small u_*), the variability of Q is shown to increase with grain size for a given shear
 194 velocity for all the examined Q -models. For fast winds (large u_*), the results vary substantially depending on the
 195 Q -model. The influence of grain diameter on the variability of Q ($c.o.v.(Q)$) decreases considerably for the Owen
 196 (1964) and Lettau and Lettau (1978) models, while d strongly affects the variability of Q in the Kawamura (1951) and
 197 Kok et al. (2012) models. The $c.o.v.(Q)$ dependence on d is much clearer for fixed $u_*/\mu(u_{*t})$ ratios. Three fundamental
 198 states of the threshold shear velocity can be identified. First, when $u_* > \mu(u_{*t})$ the variability of Q decreases with
 199 increasing particle size, i.e. the low variability applies for coarse sands and large effective shear velocity. Secondly,

Figure 5: Uncertainty propagation from u_{*t} to Q . Q and u_{*t} statistical metrics versus d according to each Q -model

200 when $u_* \approx \mu(u_{*t})$ the variability of Q is not particularly affected by d . Thirdly, when $u_* < \mu(u_{*t})$ the variability
 201 increases with increasing grain diameter d . For a given value of d , the typical relationship is lower variability in Q
 202 at higher values of u_* , except in the case of the [Kok et al. \(2012\)](#) model (Fig. 5d).

203 The trend of $p_{95}/p_{50}(Q)$ versus d and u_* qualitatively follows the trend of $c.o.v.(Q)$ (Fig. 5e-h). Indeed, $p_{95}/p_{50}(Q)$
 204 describes the variability of Q as a function of the tail event $p_{95}(Q)$, i.e. a large sand transport rate with a low
 205 chance of occurrence. Curves are simply stretched in the ordinate direction because $p_{95}/p_{50}(Q)$ address a char-
 206 acteristic variability rather than the standard variation as measured by $c.o.v.$. Analogously to $c.o.v.$, all the models
 207 approach $p_{95}/p_{50}(Q) = 1$ with increasing $u_*/\mu(u_{*t})$, except for the [Kok et al. \(2012\)](#) model where $p_{95}/p_{50}(Q)$ tends to
 208 $p_{95}/p_{50}(u_{*t})$.

209 Turning to the skewness (Fig. 5i-l), the behaviour of the models is qualitatively the same up to $u_* \approx 0.5$ m/s: $sk(Q)$
 210 increases over d , changing sign for $0.3 \leq u_* \leq 0.5$. Conversely, the trend of $sk(Q)$ over d for about $u_* > 0.5$ m/s
 211 varies significantly between the models and this is difficult to interpret. It is worth pointing out that $sk(Q)$ versus d
 212 for the [Owen \(1964\)](#) and [Lettau and Lettau \(1978\)](#) models does not vary for $u_* > 0.5$ m/s. Conversely, $sk(Q)$ for the
 213 [Kawamura \(1951\)](#) and [Kok et al. \(2012\)](#) models changes its trend leading to local minima.

214 To better understand the behaviour of the models with varying u_* , statistical metrics are evaluated over $u_*/\mu(u_{*t})$
 215 ratios for three fixed values of the sand grain diameter. In Fig. 6, $c.o.v.$, p_{95}/p_{50} and sk for Q are plotted over

216 $u_* / \mu(u_{*f}) \in [0.5, 50]$ at $d = \{0.1, 0.25, 0.5\}$ mm. Values of u_* equal to fifty times the mean threshold shear velocity
 217 are out of scope for real world saltation phenomena. In fact, $u_* \approx 1 \div 2$ m/s for extreme winds and this equates to
 218 $u_* / \mu(u_{*f}) \approx 2 \div 10$ in Fig. 6. However, large u_* values are considered herein to assess the asymptotic behaviour of the
 statistical metrics. The values of the corresponding statistical metrics for u_{*f} are also reported for comparison.

Figure 6: Uncertainty propagation from u_{*f} to Q . Q statistical metrics versus $u_* / \mu(u_{*f})$ ratio for each Q -model

219 Generally, all the Q -models show approximately the same trend for all statistical metrics up to $u_* / \mu(u_{*f}) \approx 1$ (i.e.
 220 small or null Q). Conversely, each model shows a different behaviour at larger ratios at higher wind speeds. Hence,
 221 the uncertainty will propagate differently for $u_* / \mu(u_{*f}) > 1$. $c.o.v.(Q)$ and $p_{95}/p_{50}(Q)$ (Fig. 6a-f) provide a reasonable
 222 measure of the variability of Q , and some information on the uncertainty propagation from u_{*f} to Q , i.e. if variability
 223 is damped or amplified. Focusing on $c.o.v.(Q)$, the uncertainty in u_{*f} is amplified where $u_* / \mu(u_{*f}) < 1.5$. Conversely,
 224

225 the uncertainty is damped where $u_*/\mu(u_{*t}) > 1.5$, except in the case of the [Kok et al. \(2012\)](#) model. In the case of
 226 $u_*/\mu(u_{*t}) > 1.5$, the variability resulting from the [Owen \(1964\)](#) and [Lettau and Lettau \(1978\)](#) models decreases and
 227 tends monotonically to zero, while the variability resulting from the [Kawamura \(1951\)](#) and [Kok et al. \(2012\)](#) models
 228 exhibit local minima before tending to the curve of [Lettau and Lettau \(1978\)](#) and $c.o.v.(u_{*t})$, respectively. The model
 229 that shows the fastest convergence rate to zero is the one proposed by [Owen \(1964\)](#). The trend of $p_{95}/p_{50}(Q)$ high-
 230 lights once again that the variability in Q decreases for increasing values of u_* , except for data derived from the model
 231 of [Kok et al. \(2012\)](#).

232 The skewness values (Fig. 6g-i) better highlight the different behaviour of each model against $u_*/\mu(u_{*t})$. In gen-
 233 eral, the sand transport rate predictions are non-Gaussian. For small $u_*/\mu(u_{*t})$, they are all highly positively skewed.
 234 Indeed, f_Q will show an extremely large frequency of null transport (i.e. a peak for $Q = 0$) and very low frequencies
 235 of non-null transport (i.e. right-tailed distribution). For intermediate $u_*/\mu(u_{*t})$, the results from the [Kawamura \(1951\)](#)
 236 and [Kok et al. \(2012\)](#) models are highly negatively skewed, while the skewness from the [Lettau and Lettau \(1978\)](#)
 237 and [Owen \(1964\)](#) models is related to $sk(u_{*t})$. For large $u_*/\mu(u_{*t})$, the degree of non-Gaussianity decreases to values
 238 related to $sk(u_{*t})$.

239 The above results are determined by MC-based numerical experiments. The non-trivial trends observed suggest
 240 there is value in interpreting them in analytical terms by basic a-posteriori uncertainty propagation analysis. In order
 241 to do so, we generalized the adopted modified Bagnold type models to the same basic form:

$$Q = \Phi \frac{\rho_a}{g} u_{*,eff}^3(u_*, u_{*t}) \quad (3)$$

242 where Φ is the dimensionless semi-empirical parameter and $u_{*,eff}^3$ is the effective shear velocity determined as a
 243 function of u_* and u_{*t} . The expressions of $u_{*,eff}^3$ is given in the second column of Table 2, for each Q -model.

244 In deterministic terms, $u_{*,eff}^3$ is a third order polynomial of the variables u_* and u_{*t} . Although, the analytical study of
 245 the function $u_{*,eff}^3$ is feasible, it is out of scope of the present study. In probabilistic terms, $u_{*,eff}^3$ is a transformation of
 246 the random variable u_{*t} and a function of the deterministic variable u_* . The analytical study of the statistical metrics
 247 of Q is unfeasible, since uncertainty propagation depends on the combination of u_* and u_{*t} in a non-trivial way. Some
 248 light can be shed by the analytical evaluation of the limits of the statistical metrics of Q for $u_* \rightarrow +\infty$. Given Equation
 249 3, the limit of Q metrics is equivalent to the one of $u_{*,eff}^3(u_*, u_{*t})$. The limits of $c.o.v.(Q)$, $sk(Q)$ and $p_{95}/p_{50}(Q)$ are
 250 obtained having in mind the basic properties of the same statistical metrics. For example, by referring to the $c.o.v.(Q)$
 251 resulting from the [Kok et al. \(2012\)](#) model we have:

$$\lim_{u_* \rightarrow +\infty} c.o.v.(Q) = \lim_{u_* \rightarrow +\infty} \frac{\sigma(Q)}{\mu(Q)} = \lim_{u_* \rightarrow +\infty} \frac{\sigma(u_{*,eff}^3)}{\mu(u_{*,eff}^3)} = \lim_{u_* \rightarrow +\infty} \frac{u_*^2 \sigma(u_{*t})}{u_*^2 \mu(u_{*t})} = \frac{\sigma(u_{*t})}{\mu(u_{*t})} = c.o.v.(u_{*t}) \quad (4)$$

252 Conversely, by referring to the $c.o.v.(Q)$ resulting from all the other models:

$$\lim_{u_* \rightarrow +\infty} c.o.v.(Q) = \lim_{u_* \rightarrow +\infty} \frac{\sigma(Q)}{\mu(Q)} = \lim_{u_* \rightarrow +\infty} \frac{\sigma(u_*^3)}{\mu(u_*^3)} = \lim_{u_* \rightarrow +\infty} \frac{\sigma(u_*^3)}{\mu(u_*^3)} = 0 \quad (5)$$

253 Table 2 reports the full list of the analytical limits for each Q -model and statistical metric. In particular, they confirm
 254 the right-sided asymptotic tendencies of Fig. 6.

255 Previously, we explored the asymptotic behaviour of the statistical metrics of Q . However, the limits for $u_* \rightarrow +\infty$
 256 are not relevant in the practice. Hence, we reduced the range of the shear velocity under investigation so to assess
 257 realistic values of the coefficient of variation. In doing this we set the roughness length $z_0 = 0.003 \text{ m}$ and the interval
 258 $u_* \in [0.1, 1] \text{ m/s}$. Such an interval corresponds to approximate wind speed values between 2 (light breeze) and 8 (gale)
 259 on the Beaufort scale, i.e. a scale that relates wind speed to observed weather conditions ([Hasse, 2015](#)). Furthermore,
 260 we adopted an additional condition on the mean value of Q in order to discard very large $c.o.v.$ which correspond to
 261 very low sand transport rates. Hence, values of $\mu(Q) \geq 10^{-3} \text{ kg m}^{-1} \text{ s}^{-1}$ are used in the analysis. The resulting values
 262 of the ratio $c.o.v.(Q)/c.o.v.(u_{*t})$ are reported in Fig. 7 for each model, and for three values of the sand grain diameter,
 263 namely $d \in \{0.1, 0.25, 0.50\} \text{ mm}$.

Table 2: Limits of dimensionless statistical metrics of Q for $u_* \rightarrow +\infty$

Reference	$u_{*,eff}^3(u_*, u_{*t})$	$\lim_{u_* \rightarrow +\infty} c.o.v.(Q)$	$\lim_{u_* \rightarrow +\infty} p_{95}/p_{50}(Q)$	$\lim_{u_* \rightarrow +\infty} sk(Q)$
Kawamura (1951)	$u_*^3 \left(1 - \frac{u_{*t}^2}{u_*^2}\right) \left(1 + \frac{u_{*t}}{u_*}\right)$	0	0	$sk(u_{*t})$
Owen (1964)	$u_*^3 \left(1 - \frac{u_{*t}^2}{u_*^2}\right)$	0	0	$-sk(u_{*t}^2)$
Lettau and Lettau (1978)	$u_*^3 \left(1 - \frac{u_{*t}}{u_*}\right)$	0	0	$-sk(u_{*t})$
Kok et al. (2012)	$u_*^2 u_{*t} \left(1 - \frac{u_{*t}^2}{u_*^2}\right)$	$c.o.v.(u_{*t})$	$p_{95}/p_{50}(u_{*t})$	$sk(u_{*t})$

Figure 7: Uncertainty propagation from u_{*t} to Q for realistic values of u_* . $c.o.v.(Q)/c.o.v.(u_{*t})$ versus $u_*/\mu(u_{*t})$ for each Q -model and $u_* \in [0.1, 1] m/s$

264 Fig. 7 quantifies the actual magnitude of the uncertainty propagation. In particular, $c.o.v.(Q)/c.o.v.(u_{*t}) > 1$ reflects
 265 uncertainty amplification, while $c.o.v.(Q)/c.o.v.(u_{*t}) < 1$ reflects uncertainty damping. Generally, $c.o.v.(Q)/c.o.v.(u_{*t})$
 266 covers a range from 1 to 2 orders of magnitude. The variability in Q changes significantly in the adopted range of
 267 wind speed, ranging from small values below unity for gales (damped uncertainty from u_{*t} to Q) to very high values
 268 above unity and up to 20 for breezes (amplified uncertainty), notably for coarser sands. Indeed, $c.o.v.(Q)/c.o.v.(u_{*t})$
 269 increases with increasing d for small values of $u_*/\mu(u_{*t})$. Conversely, $c.o.v.(Q)/c.o.v.(u_{*t})$ remains almost constant
 270 with increasing d for large values of $u_*/\mu(u_{*t})$. Hence, the variation in particle size mostly affects the uncertainty
 271 propagation when u_* is close to $\mu(u_{*t})$.

272 4. Discussion

273 Our results indicate that the uncertainty in threshold shear velocity u_{*t} propagates into predictions of sand transport
 274 rate Q . The numerical uncertainty propagation investigated in this study can be viewed as a reflection of both *physical*
 275 and *statistical* processes. From a physical point of view, the variability of u_{*t} affects the mechanics of the sand
 276 saltation. From a statistical point of view, the modelling, measurement, and parametric uncertainty in u_{*t} propagates
 277 to Q . However, the characteristics of this propagation vary depending upon the Q -model, the sand grain diameter d ,
 278 and the wind shear velocity u_* .

279 The discrepancies in uncertainty propagation among Q -models can be ascribed to the general form of $u_{*,eff}^3$. For
 280 the sake of clarity, the effective shear velocity was split between $u_{*,eff}^3 = \mathcal{U}_* \Psi_*$, where \mathcal{U}_* representing *sustained*
 281 *saltation* and Ψ_* representing *triggering of saltation*. In particular, \mathcal{U}_* express the scaling of the particle speed, while

282 Ψ_* express the effective shear velocity translation as a function of u_{*t} . The resulting values of \mathcal{U}_* and Ψ_* for each
 283 Q -model are reported in Table 3.

Table 3: General form of the effective shear velocity $u_{*eff}^3 = \mathcal{U}_* \Psi_*$. Saltation sustaining \mathcal{U}_* and saltation triggering Ψ_* according to each sand
 transport rate model

Reference	\mathcal{U}_*	Ψ_*
Kawamura (1951)	$u_* + u_{*t}$	$u_*^2 - u_{*t}^2$
Owen (1964)	u_*	$u_*^2 - u_{*t}^2$
Lettau and Lettau (1978)	u_*^2	$u_* - u_{*t}$
Kok et al. (2012)	u_{*t}	$u_*^2 - u_{*t}^2$

283 The physical interpretation of our results is clear from Table 3. The [Kok et al. \(2012\)](#) model propagates the same
 284 amount of uncertainty of u_{*t} to Q for strong winds. In formulas, for the generic dimensionless statistical metric φ , it
 285 holds that $\lim_{u_* \rightarrow +\infty} \varphi(Q) = \varphi(u_{*t})$. Conversely, the other models behave differently: the uncertainty is damped from
 286 u_{*t} to Q for strong winds and the variation tends to zero. An interpretation of these marked differences in behaviour
 287 of the models can be obtained with reference to the saltation sustaining \mathcal{U}_* and the saltation triggering Ψ_* .
 288 \mathcal{U}_* drives the uncertainty propagation for strong winds since $\lim_{u_* \rightarrow +\infty} \varphi(\Psi_*) = 0$. [Kok et al. \(2012\)](#) explicitly adopt
 289 the impact threshold for \mathcal{U}_* . Under this assumption the asymptotic trend of Q statistical metrics looks physically
 290 sound since saltation is carried out by grain impacts and the particle terminal velocity does not depend on u_* (see [Kok](#)
 291 [et al., 2012](#), and related references). [Owen \(1964\)](#) and [Lettau and Lettau \(1978\)](#) adopt u_* and u_*^2 , respectively. Hence,
 292 saltation is sustained purely by wind entrainment. [Kawamura \(1951\)](#) adopts the sum of u_* and u_{*t} . However, the
 293 statistical metrics of the [Kawamura \(1951\)](#) model tend to the ones of [Owen \(1964\)](#) and [Lettau and Lettau \(1978\)](#) for
 294 strong winds. In this sense, the models of [Kawamura \(1951\)](#), [Owen \(1964\)](#) and [Lettau and Lettau \(1978\)](#) are consistent
 295 with the adoption of the fluid threshold. Under this assumption saltation is initiated purely by wind entrainment and
 296 uncertainty in the fluid threshold has a greater impact at wind speeds close to the threshold. This issue represents a
 297 source of epistemic model uncertainty since uncertainty in threshold choice is not a resolved debate in the scientific
 298 literature. We hope that the present study contributes to the discussion on this open issue and stimulates debate. It
 299 is worth pointing out that the effective shear velocity in [Kawamura \(1951\)](#) is the summation of the u_{*eff}^3 from [Owen](#)
 300 [\(1964\)](#) and [Kok et al. \(2012\)](#). Indeed, the statistical metrics of Q resulting from the [Kawamura \(1951\)](#) model are
 301 hybrid (see Fig. 6).
 302

303 As regards Ψ_* , it is the same for all the Q -models except for [Lettau and Lettau \(1978\)](#). Indeed, for the [Kawamura](#)
 304 [\(1951\)](#), [Owen \(1964\)](#) and [Kok et al. \(2012\)](#) models Ψ_* reflects the general physical scaling $Q \propto \tau_{eff} = \rho_a(u_*^2 - u_{*t}^2)$,
 305 where τ_{eff} is the effective shear stress. Conversely, the [Lettau and Lettau \(1978\)](#) model shows a linear translation. We
 306 believe that the reasons for this discrepancy could be ascribed to the empirical fitting of the Q -model.
 307

In light of our results, three main observations can be made:

- 308 1. Differences in the propagation of uncertainty between different sand transport models are significant and can
 309 reach an order of magnitude. [Sarre \(1987\)](#), [Sherman et al. \(1998, 2013\)](#) and [Sherman and Li \(2012\)](#) have
 310 highlighted the discrepancies between models in deterministic terms. The adoption of one model over another
 311 gives rise to differences not only in the mean values, but also much larger differences in terms of variance,
 312 skewness and extreme percentiles (see Fig. 4). These kinds of discrepancies between model predictions become
 313 more noticeable in the range $u_*/\mu(u_{*t}) \in [2, 5]$ (see Fig. 6). This range is of practical interest for real world
 314 windblown sand events;
- 315 2. Differences in uncertainty propagation caused by varying u_* show that for slow wind speeds the uncertainty
 316 in Q is amplified with respect to the uncertainty in u_{*t} . Slow wind speeds occur frequently in nature due to
 317 the Weibull probability density function of wind speed. Hence, amplification in Q uncertainty is a potentially
 318 large practical issue if not accounted for correctly. In contrast, in strong winds the uncertainty of u_{*t} does not
 319 significantly affect Q , except in the model results of [Kok et al. \(2012\)](#) (see Fig. 6a-c). The physical interpretation
 320 of the local and global minima of the statistical metrics occurring for intermediate values of $u_*/\mu(u_{*t}) \in [2, 3]$
 321 in [Kawamura \(1951\)](#) and [Kok et al. \(2012\)](#) is not straightforward (Fig. 6). Analytically, they result from the

322 presence of u_{*t} in the saltation sustaining term \mathcal{U}_* . In the practice, the global minima of the skewness imply an
323 underestimation of Q for related wind speeds by employing the [Kawamura \(1951\)](#) and [Kok et al. \(2012\)](#) models
324 with respect to the [Owen \(1964\)](#) and [Lettau and Lettau \(1978\)](#) models;

- 325 3. Differences in uncertainty propagation caused by varying the sand grain diameter, d , highlight that, for slow
326 winds the variability in Q increases for coarse sands whilst, for strong winds, the variability in Q is less affected
327 by d , except in the model results of [Kok et al. \(2012\)](#) (see Fig. 5a-d). For realistic values of u_* , errors in the
328 estimation of d propagate to Q prediction primarily for slow winds (Fig. 7). However, it is worth pointing out
329 that the effect of d on the nominal sand transport rate remains an open issue ([Dong et al., 2003](#); [Valence, 2015](#)).

330 In light of the above observations, the choice of a Q -model should be performed not only to achieve the best prediction
331 of the mean sand transport rate, but also in consideration of the uncertainty propagation in practical estimation of
332 probabilistic sand transport rate. However, care must be taken since the choice of the model considerably affects the
333 uncertainty of Q predictions. Further experimental investigations on sand transport rate uncertainty could shed some
334 light on these issues.

335 5. Conclusions

336 The present study critically investigated the uncertainty propagation from threshold shear velocity to sand trans-
337 port rate. In particular, threshold shear velocity was considered as the only source of randomness in sand transport
338 rate models, while the other parameters were assumed to be deterministic. Statistical moments and metrics of Q were
339 assessed via the Monte Carlo method by varying the adopted sand transport model and the values of u_* and d .

340 Our results have allowed us to assess the amplification or reduction in the uncertainty of sand transport rate with
341 respect to the uncertainty in threshold shear velocity. The strong differences in uncertainty propagation between exam-
342 ined sand transport rate models led us to ascribe them to the general form of the effective shear velocity. In particular,
343 in the case of slow speed winds close to the erosion threshold, every model we have tested tends to amplify the vari-
344 ability of Q , in some cases up to 20 times the variability of u_{*t} . In addition, the variability of Q is seen to increase for
345 coarse sand. These results allow further insight into the behaviour of the sand transport rate models. In the case of
346 strong winds, Q -models present two substantial differences. The models of [Kawamura \(1951\)](#); [Owen \(1964\)](#); [Lettau
347 and Lettau \(1978\)](#) dampen the uncertainty in u_{*t} and the effect of d on Q uncertainty, while the model of [Kok et al.
348 \(2012\)](#) propagates the exact amount of uncertainty in u_{*t} to Q . The adoption of a particular sand transport model
349 therefore has implications not only on the mean value of Q but also on Q uncertainty.

350 In light of these results, we highlight three research opportunities:

351 First, considering the large discrepancies in statistical terms between different models belonging to the same basic
352 form of *modified Bagnold type* models, it would be worth assessing by means of experimental measurements how the
353 uncertainty physically propagates from u_{*t} to Q .

354 Second, the development of a generalized probabilistic model for sand transport rate would be worth further investi-
355 gation.

356 Third, since our results refer to the uncertainty evident in the instantaneous sand transport rate, it might be worth
357 investigating how the uncertainty propagates when evaluating the drift potential (DP), i.e. the cumulative value of the
358 sand transport rate over time ([Fryberger and Dean, 1979](#)). We conjecture that the uncertainty in DP will be damped.
359 Indeed, the sum of independent and identically distributed random variables is expected from theory to reduce the
360 resultant coefficient of variation. However, the entity of the uncertainty in DP should be quantified and, if significant,
361 considered in practice.

362 Acknowledgments

363 The study has been developed in the framework of the Windblown Sand Modeling and Mitigation joint research,
364 development and consulting group established between Politecnico di Torino and Optiflow Company. The research
365 activity of Luca Bruno and Giles F.S. Wiggs has been developed within the MSCA-ITN-2016-EID SMaRT research
366 project. This project has received funding from the European Union's Horizon 2020 research and innovation pro-
367 gramme under grant agreement No 721798. The authors wish to thank Luigi Preziosi and Davide Fransos, members
368 of the WSMM group, and Franco Pellerey, Politecnico di Torino, for the helpful discussions about the topics of the
369 paper.
