24

25 The Refined Zigzag Theory (RZT) is assessed for the buckling and nonlinear static response  
26 analysis of multilayered composite and sandwich beams. A nonlinear formulation of the RZT is  
27 developed taking into account geometric imperfections and nonlinearities using the Von Kármán  
28 nonlinear strain-displacement relations. FE analyses are conducted employing  $C^0$ -beam elements  
29 based on the RZT and the Timoshenko Beam Theory (TBT) to model three sandwich beams with  
30 different core materials and slenderness ratios, in both simply supported and cantilever  
31 configurations. The reference solutions are obtained by high-fidelity FE commercial codes,  
32 Abaqus<sup>®</sup> and Nastran<sup>®</sup>. The first two buckling loads are evaluated for the beams without initial  
33 imperfections. Several shapes are then assumed as geometric imperfections to calculate the beams  
34 nonlinear response to axial-compressive loads. The comparisons show the very high accuracy of the  
35 RZT (comparable to high-fidelity FE commercial codes) for both the buckling and nonlinear static

## 8 9 **1. Introduction**

10  
11 In the last sixty years, the usage of multilayered composite and sandwich materials has significantly  
12  
13 increased in civil, mechanical and aerospace engineering applications. The percentage of  
14  
15 composites and sandwiches employed in airplane structures has risen from 2% to more than 50% in  
16  
17 modern aircrafts [1]. The main advantages of such materials are the good resistance to corrosion,  
18  
19 the high stiffness-to-weight and strength-to-weight ratios and the “tailoring” freedom related to the  
20  
21 possibility to obtain optimal structural responses by adopting selected stacking sequences. These  
22  
23 properties make multilayered composite structures very attractive, especially for primary structural  
24  
25 components of aircrafts. In working conditions, a large proportion of an aircraft’s structure is  
26  
27 subjected to axial and bending loads and the buckling is one of the most typical failure modes. The  
28  
29 buckling is a nonlinear phenomenon associated with large transverse displacements when a small  
30  
31 load increment (with respect to a critical level) is added to the axial compressive or shear load  
32  
33 applied to a beam- or plate-like structure. An accurate understanding of this phenomenon in metal  
34  
35 structures allows the usage of such structures also in the post-buckling regime, leading to a  
36  
37 considerable reduction of the thicknesses required to carry the applied loads. On the other hand,  
38  
39 composites and sandwiches are still used only in the pre-buckling regime because their behavior  
40  
41 still cannot be predicted with high accuracy in critical situations. As a consequence, one of the  
42  
43 major challenges for the aerospace industries is the possibility to employ composites in post-  
44  
45 buckling regime to further reduce the structural weight [1].  
46  
47  
48  
49  
50

51  
52 Various approaches have been adopted for predicting critical buckling loads in structural members  
53  
54 usually subjected to compressive loads. In some of these approaches, geometric imperfections are  
55  
56 also considered. Geometric imperfections taken into account are usually related to initial deviations  
57  
58 from a straight beam axis configuration (pre-deflections). In other words, perfect beams are those  
59  
60

1  
2  
3 with an initially straight axis configuration. In [2], Brush and Almroth collected the most common  
4  
5 methods and investigated the stability of structures considering geometric nonlinearities in the  
6  
7 elementary bending analysis. A first attempt to analyze the behavior of composite and sandwich  
8  
9 beams was conducted applying the Classical Lamination Theory (CLT) and the classical theory for  
10  
11 beams (Bernoulli-Euler beam theory). As an example, Barbero and Raftoyiannis [3] evaluated the  
12  
13 critical buckling loads and the failure modes of pultruded composite columns with thin-walled cross  
14  
15 sections, employing the CLT for the stiffness characteristics and then the Euler's critical load  
16  
17 formula. Columns of various lengths were considered to investigate the transition of the first failure  
18  
19 mode from global to local buckling when the beam length decreases. The classical theory was also  
20  
21 adopted to investigate the nonlinear behavior of composite beams with geometric imperfections  
22  
23 both in pre- and post-buckling regimes. In [4], the effect of piezoelectric layers attached to the beam  
24  
25 was included in the nonlinear formulation of Bernoulli-Euler beam theory for initially imperfect  
26  
27 composite beams under compression. The analysis showed that the nonlinear response of slender  
28  
29 composite beams in the pre-buckling regime can be significantly modified by the piezoelectric  
30  
31 actuation, obtaining a load-displacement equilibrium path that is close to the ideal solution for  
32  
33 perfect beams. Emam and Nayfeh [5] found a closed form solution for the equilibrium  
34  
35 configurations of composite beams loaded beyond the critical buckling load and studied both the  
36  
37 stability in post-buckling regime and the dynamic behavior in the buckled state considering various  
38  
39 boundary conditions. The mathematical model was based on the Bernoulli-Euler beam theory.  
40  
41  
42  
43  
44

45 However, many authors demonstrated the inaccuracy of this theory for the analyses of multilayered  
46  
47 composite and sandwich structures. Khedir and Reddy in [6] showed that the Bernoulli-Euler beam  
48  
49 theory highly overestimates the buckling loads of cross-ply laminated beams. They compared the  
50  
51 exact analytical solutions of the governing equations for the buckling analysis based on four  
52  
53 different theories: the Bernoulli-Euler beam theory, the Timoshenko beam theory (or First-order  
54  
55 Shear Deformation Theory, FSDT), the Second-Order Shear Deformation Theory (SSDT) and the  
56  
57 Reddy-Third order Shear Deformation Theory (TSDT). The critical loads evaluated with the shear-  
58  
59  
60

1  
2  
3 deformation theories were rather similar to one another but much lower than Bernoulli-Euler  
4 values. A nonlinear formulation of the Reddy TSDT was developed in [7] to study the pre- and  
5 post-buckling of imperfect laminated beams. The governing equations were solved numerically for  
6 different types of boundary conditions to evaluate the equilibrium path of longitudinal and  
7 transverse displacements when the axial-compressive load increases from zero beyond the buckling  
8 load. Various imperfection functions and lay-ups were considered for investigating their effect on  
9 the structural behavior in post-buckling regime. In [8-10], shear deformation theories of various  
10 orders were employed to study the stability of composite laminates and functionally-graded  
11 material (FGM) plates under thermal loads. Accurate predictions of the critical temperature were  
12 obtained even using theories based on four kinematic variables. Higher-order and trigonometric  
13 shear deformation theories based on a number of unknowns lower than conventional theories were  
14 developed also for the static and free vibration analysis of FGM plates [11-19]. The maximum  
15 deflection and the natural frequencies were accurately calculated by theories based on four variables  
16 and involving the temperature [11-14] and moisture [15,16] effects, and by five-variable theories  
17 able to model also the thickness stretching [17-19].

36 The importance of the shear deformation in the buckling and post-buckling analysis, especially for  
37 composite and sandwich structures, was observed also by Sheinman. In [20], he developed a  
38 nonlinear formulation based on a TSDT to investigate the post-buckling behavior of laminated  
39 beams, showing that not only the shear deformation must be considered in composite beam analyses  
40 but also that a higher-order theory is necessary when the beam length-to-thickness ratio is low.  
41 However, Tessler et al. observed that the FSDT and the HSDTs (Higher-order Shear Deformation  
42 Theories), which belong to a class of theories called *Equivalent-Single Layer* (ESL), can lead to  
43 erroneous predictions of the in-plane and transverse-shear stresses in case of either thick beams (or  
44 plates) or highly heterogeneous material lay-ups [21-26]. The major drawback of these theories is  
45 the through-the thickness discontinuity of the transverse stresses as a consequence of a  $C^1$ -  
46 continuous displacement field assumption. *Layer-Wise* (LW) theories overcome these problems

3 assuming an independent displacement field for each layer and enforcing the stress continuity at  
4 layer interfaces. They are able to accurately reproduce the zigzag pattern along the thickness of the  
5 in-plane displacements, but their computational cost is affordable only in case of few material  
6 layers [27, 28]. A compromise between the ESL and the LW theories in terms of accuracy and  
7 computational effort is represented by the *zigzag theories*, where the displacement field is  
8 developed in such a way that the transverse shear stresses continuity is ensured and the numbers of  
9 kinematic variables is independent of the number of layers [29, 30]. Among this class of theories,  
10 the Refined Zigzag Theory (RZT) [21-26], has proven to be one of the most amenable to  
11 engineering practice because of its superior capacity to predict static, dynamic and buckling  
12 behavior of composite and sandwich structures, including very thick laminates with highly  
13 heterogeneous material properties, with very low computational cost. In [25], RZT was compared to  
14 TSDT and a HSDT for the static, free-vibration and buckling analysis of sandwich plates, showing  
15 better performances. The promising characteristics of the RZT has led to an interest in extending  
16 the theory to the nonlinear analysis of composite and sandwich beams under axial-compressive  
17 loads.

35  
36 Aim of the present effort is to assess the Refined Zigzag Theory for the buckling and nonlinear  
37 response analysis of composite and sandwich beams also in presence of geometric imperfections.

38  
39  
40 At first, a nonlinear formulation of RZT for beams has been developed using Von Kàrmàn strain-  
41 displacement relations. The nonlinear response of geometrically imperfect composite and sandwich  
42 beams in the pre-buckling regime can be modelled. A finite element approximation based on RZT  
43  $C^0$ -beam elements [24] has been introduced to solve the nonlinear equilibrium equations for any  
44 kind of boundary conditions. The RZT capability to solve this kind of problems has been assessed  
45 by comparison with high fidelity, two-dimensional Abaqus<sup>®</sup> and MSC/Nastran<sup>®</sup> FE models, for  
46 simply-supported and cantilevered sandwich beams.

## 57 58 59 2. Nonlinear formulation of the Refined Zigzag Theory for geometrically imperfect beams 60

In this section, a nonlinear formulation of the Refined Zigzag Theory for geometrically imperfect beams is developed.

### 2.1 Displacements, strains, and stresses

Consider a beam of length  $L$  and cross-sectional area  $A = 2h \times b$ , where  $2h$  is the total thickness and  $b$  the cross-sectional width. The beam is composed of  $N$  orthotropic material layers perfectly bonded to each other (Figure 1); each layer is denoted by the superscript  $(k)$ .

[insert Figure 1.]

The longitudinal axis of the beam is denoted by  $x$ , with  $x \in [x_a, x_b]$  ( $L = x_b - x_a$ ), whereas the thickness coordinate is  $z$ , with  $z \in [-h, h]$ . The thickness of the  $k$ th layer is  $2h^{(k)}$  and its thickness coordinate ranges from  $z_{(k-1)}$  to  $z_{(k)}$  (Figure 2a). It is assumed that the beam can be deformed only in the  $(x, z)$  plane. Distributed loads (units of force/length) are applied at the bottom ( $z = -h$ ) and top ( $z = +h$ ) beam surfaces; namely, the axial,  $p^b(x)$  and  $p^t(x)$ , and transverse,  $q^b(x)$  and  $q^t(x)$ , loads. The end cross-sections are subjected to the action of prescribed axial ( $T_{xa}, T_{xb}$ ) and transverse shear ( $T_{za}, T_{zb}$ ) tractions (Figure 1).

The orthogonal components of the displacement vector of the Refined Zigzag Theory can be written in the following matrix form [24]

$$\begin{Bmatrix} u_x^{(k)}(x, z) \\ u_z(x, z) \end{Bmatrix} = \begin{bmatrix} 1 & 0 & z & \phi^{(k)}(z) \\ 0 & 1 & 0 & 0 \end{bmatrix} \begin{Bmatrix} u(x) \\ w(x) \\ g(x) \\ \psi(x) \end{Bmatrix} \equiv \mathbf{Z}_u(z) \mathbf{u}(x) \quad (1)$$

where  $u_x^{(k)}$  and  $u_z$  are the displacements in the directions of the  $x$  and  $z$ -axis, respectively, and  $\mathbf{u}$

is a vector containing the four kinematic variables of the theory: the uniform axial displacement,  $u(x)$ , the deflection,  $w(x)$ , the average cross-sectional (bending) rotation,  $\vartheta(x)$ , and the zigzag rotation,  $\psi(x)$ . Note that  $u_z = w(x)$  is through-the-thickness uniform hence the superscript  $(k)$  does not appear in the notation for this quantity. Moreover,  $\psi(x)$  is the RZT additional kinematic variable with respect to the Timoshenko beam theory and measures the magnitude of the zigzag contribution to the axial displacement,  $\phi^{(k)}(z)\psi(x)$ , i.e., the cross-sectional piecewise continuous distortion typical of multilayered structures.

The zigzag function,  $\phi^{(k)} = \phi^{(k)}(z)$ , has units of length, is a piecewise linear,  $C^0$ -continuous function of the thickness coordinate and is completely defined once its  $(N + 1)$  interfacial values  $\phi_{(i)}$  ( $i = 0, 1, \dots, N$ ) are known (see Figure 2b).

[insert Figure 2.]

$\phi^{(k)}$  is set to vanish on the top and bottom laminate surface, i.e.,  $\phi_{(0)} \equiv \phi^{(1)}(z_{(0)}) = 0$  and  $\phi_{(N)} \equiv \phi^{(N)}(z_{(N)}) = 0$ . The internal values,  $\phi_{(j)} \equiv \phi^{(j)}(z_{(j)}) = \phi^{(j+1)}(z_{(j)})$  ( $j = 1, 2, \dots, N - 1$ ) can be obtained as follows

$$\phi_{(j)} = \phi_{(j-1)} + 2h^{(j)}\beta^{(j)} \quad (j = 1, 2, \dots, N - 1) \quad (2)$$

where  $\beta^{(k)}$  is the zigzag function slope in each layer.  $\beta^{(k)}$  can be obtained by using the following expression

$$\beta^{(k)} \equiv \phi_{,z}^{(k)} = \frac{G}{G_{xz}^{(k)}} - 1 \quad (k = 1, 2, \dots, N) \quad (3)$$

where  $G_{xz}^{(k)}$  is the  $k$ th layer transverse shear modulus and  $G$  denotes a weighted-average transverse shear modulus of the laminate

$$G \equiv \left( \frac{1}{2h} \int_{-h}^{+h} \frac{dz}{G_{xz}^{(k)}} \right)^{-1} = \left( \frac{1}{h} \sum_{k=1}^N \frac{h^{(k)}}{G_{xz}^{(k)}} \right)^{-1} \quad (4)$$

The complete derivation of Eqs. (2)-(4) can be found in [21].

Geometric imperfections and nonlinearity are included in the model by considering the Von Kármán nonlinear strain-displacement relations

$$\begin{aligned} \varepsilon_x &= u_{,x,x} + \frac{1}{2} u_{z,x}^2 + u_{z,x} w_{,x}^* \\ \gamma_{xz} &= u_{x,z} + u_{z,x} \end{aligned} \quad (5)$$

where the function  $w^*$  describes initial imperfections, i.e. initial stress-free transverse deviations from a straight axis configuration (see Figure 1). Considering that only planar deformations in the  $(x, z)$  plane are investigated, geometric imperfections are assumed to occur in the same plane.

Substituting the displacement components (Eq. (1)) into Eq. (5), the following nonlinear strains for the Refined Zigzag Theory are obtained

$$\begin{aligned}
 \mathcal{E}_x^{(k)}(x, z) &= u_{,x}(x) + z\theta_{,x}(x) + \phi^{(k)}(z)\psi_{,x}(x) + \frac{1}{2}w_{,x}^2(x) + w_{,x}(x)w_{,x}^*(x) \\
 &= \mathbf{Z}_\varepsilon^{(k)}(z)\boldsymbol{\omega}(x) + \frac{1}{2}\boldsymbol{\omega}(x)^T \mathbf{H}\boldsymbol{\omega}(x) + \boldsymbol{\omega}^*(x)^T \boldsymbol{\omega}(x)
 \end{aligned} \tag{6}$$

$$\begin{aligned}
 \gamma_{xz}^{(k)}(x, z) &= w_{,x}(x) + \theta(x) + \beta^{(k)}\psi(x) \\
 &= \mathbf{Z}_\gamma^{(k)}(z)\boldsymbol{\omega}(x)
 \end{aligned}$$

where

$$\begin{aligned}
 \boldsymbol{\omega} &\equiv [u_{,x} \quad w_{,x} \quad \vartheta \quad \psi \quad \vartheta_{,x} \quad \psi_{,x}]^T \\
 \boldsymbol{\omega}^* &\equiv [0 \quad w_{,x}^* \quad 0 \quad 0 \quad 0 \quad 0]^T
 \end{aligned} \tag{7}$$

The zero-one matrix  $\mathbf{H}$  and the matrices  $\mathbf{Z}_\varepsilon^{(k)}$  and  $\mathbf{Z}_\gamma^{(k)}$  (function of the thickness coordinate) are defined in Appendix A.

The material of each layer is linearly elastic and orthotropic, with the orthotropy directions corresponding to the axes of the coordinate system,  $(x, y, z)$ . A plane-stress behavior is assumed in the  $(x, z)$  plane. Moreover, the transverse normal stress,  $\sigma_z^{(k)}$ , is negligible with respect to the axial and transverse shear stresses. Consequently, the constitutive equations for the  $k$ th layer are

$$\begin{aligned}
 \sigma_x^{(k)} &= E_x^{(k)} \varepsilon_x^{(k)} \\
 \tau_{xz}^{(k)} &= G_{xz}^{(k)} \gamma_{xz}^{(k)}
 \end{aligned} \tag{8}$$

where  $E_x^{(k)}$  and  $G_{xz}^{(k)}$  are, respectively, the Young modulus along the  $x$ -direction and the transverse-shear modulus in the  $(x, z)$  plane.

## 2.2 Principle of Virtual Works

The Principle of Virtual Works (PVW) is employed to derive the Euler–Lagrange equilibrium equations and the set of consistent boundary conditions. The PVW is written in the form

$$\delta U - \delta L_e = 0 \quad (9)$$

where  $U$  is the strain energy and  $L_e$  is the work done by external forces. Introducing the vectors of strain and stress components as  $\boldsymbol{\varepsilon} \equiv [\varepsilon_x^{(k)} \quad \gamma_{xz}^{(k)}]^T$  and  $\boldsymbol{\sigma} \equiv [\sigma_x^{(k)} \quad \tau_{xz}^{(k)}]^T$ , the virtual variation of  $U$  is

$$\delta U = \int_V \boldsymbol{\delta \varepsilon}^T \boldsymbol{\sigma} dv = \int_{x_a}^{x_b} \int_A [\delta \varepsilon_x^{(k)} \sigma_x^{(k)} + \delta \gamma_{xz}^{(k)} \tau_{xz}^{(k)}] dA dx \quad (10)$$

For the loading conditions represented in Figure 1

$$\begin{aligned} \delta L_e = & \int_{x_a}^{x_b} \left[ \delta u_x^{(1)}(-h) p^b + \delta u_x^{(N)}(+h) p^t + \delta u_z^{(1)}(-h) q^b + \delta u_z^{(N)}(+h) q^t \right] dx \\ & - \int_A \left[ \delta u_x^{(k)}(x_a, z) T_{xa} + \delta u_z(x_a, z) T_{za} \right] dA + \int_A \left[ \delta u_x^{(k)}(x_b, z) T_{xb} + \delta u_z(x_b, z) T_{zb} \right] dA \end{aligned} \quad (11)$$

Eqs. (6) and (8) are now substituted into Eq. (10). The latter, together with Eq. (11), is then substituted into Eq. (9). Integrating over the beam's cross-section yields a one-dimensional form of the PVW based on the nonlinear formulation of RZT

$$\begin{aligned} & \int_{x_a}^{x_b} \left[ N_x \delta(u_{,x} + \frac{1}{2} w_{,x}^2 + w_{,x} w_{,x}^*) + M_x \delta \theta_{,x} + V_x \delta(w_{,x} + \theta) + M_\phi \delta \psi_{,x} + V_\phi \delta \psi - p \delta u - q \delta w - m \delta \theta \right] dx \\ & + \left[ \bar{N}_{xa} \delta u(x_a) + \bar{M}_{xa} \delta \theta(x_a) + \bar{V}_{xa} \delta w(x_a) + \bar{M}_{\phi a} \delta \psi(x_a) \right] \\ & - \left[ \bar{N}_{xb} \delta u(x_b) + \bar{M}_{xb} \delta \theta(x_b) + \bar{V}_{xb} \delta w(x_b) + \bar{M}_{\phi b} \delta \psi(x_b) \right] = 0 \end{aligned} \quad (12)$$

where

$$\left[ N_x, M_x, M_\phi, V_x, V_\phi \right] \equiv \int_A \left[ \sigma_x^{(k)}, z\sigma_x^{(k)}, \phi^{(k)}\sigma_x^{(k)}, \tau_{xz}^{(k)}, \beta^{(k)}\tau_{xz}^{(k)} \right] dA \quad (13.1)$$

$$\left[ \bar{N}_{x\alpha}, \bar{M}_{x\alpha}, \bar{M}_{\phi\alpha}, \bar{V}_{x\alpha} \right] \equiv \int_A \left[ T_{x\alpha}, zT_{x\alpha}, \phi^{(k)}T_{x\alpha}, T_{z\alpha} \right] dA, \quad (\alpha = a, b) \quad (13.2)$$

are the internal and applied stress resultant forces and moments, respectively, and

$$\left[ p, q, m \right] \equiv \left[ (p^b + p^t), (q^b + q^t), (h(p^t - p^b)) \right] \quad (14)$$

are the resultant distributed loads.

Starting from definition (13.1) and making use of Eqs. (6) and (8), the nonlinear constitutive equations for the RZT imperfect beam are obtained and summarized in the following matrix form

$$\mathbf{R} = \Delta \boldsymbol{\omega} + \bar{\Delta} \left( \frac{1}{2} \boldsymbol{\omega}^T \mathbf{H} \boldsymbol{\omega} + \boldsymbol{\omega}^{*T} \boldsymbol{\omega} \right) \quad (15)$$

where  $\mathbf{R} \equiv [N_x \quad V_x \quad V_\phi \quad M_x \quad M_\phi]^T$ ,  $\Delta$  is the matrix containing the stiffness coefficients and  $\bar{\Delta}$

is the first column of the matrix  $\Delta$ . Refer to Appendix A for the definition of  $\Delta$ .

Integration by parts of Eq. (12) yields the nonlinear equilibrium equations in terms of resultant forces and moments

$$\begin{aligned}
 &N_{x,x} + p = 0 \\
 &V_{x,x} + \left[ N_x (w_{,x} + w_{,x}^*) \right]_{,x} + q = 0 \\
 &M_{x,x} - V_x + m = 0 \\
 &M_{\phi,x} - V_{\phi} = 0
 \end{aligned} \tag{16}$$

and a set of consistent boundary conditions (geometric and kinetic, respectively)

$$\begin{aligned}
 &\text{either } u(x_{\alpha}) = \bar{u}_{\alpha} \text{ or } N_x(x_{\alpha}) = \bar{N}_{x\alpha} \\
 &\text{either } w(x_{\alpha}) = \bar{w}_{\alpha} \text{ or } V_x(x_{\alpha}) = \bar{V}_{x\alpha} \\
 &\text{either } \mathcal{G}(x_{\alpha}) = \bar{\mathcal{G}}_{\alpha} \text{ or } M_x(x_{\alpha}) = \bar{M}_{x\alpha} \\
 &\text{either } \psi(x_{\alpha}) = \bar{\psi}_{\alpha} \text{ or } V_{\phi}(x_{\alpha}) = \bar{M}_{\phi\alpha}
 \end{aligned} \tag{17}$$

where the quantities denoted by an overbar are the kinematic variables and the stress resultants prescribed at the beam ends,  $x_{\alpha} \equiv (x_a, x_b)$ . Substituting Eqs. (15) into Eqs. (16), the equilibrium equations can be expressed in terms of displacement components

$$\begin{aligned}
 &A_{11} \left[ u_{,xx} + \left( \frac{1}{2} w_{,x}^2 + w_{,x} w_{,x}^* \right)_{,x} \right] + B_{12} \theta_{,xx} + B_{13} \psi_{,xx} + p = 0 \\
 &\bar{G}A (w_{,xx} + \theta_{,x}) + (G - \bar{G}) A \psi_{,x} + \left\{ A_{11} \left[ u_{,x} + \left( \frac{1}{2} w_{,x}^2 + w_{,x} w_{,x}^* \right) \right] + B_{12} \theta_{,x} + B_{13} \psi_{,x} \right\} (w_{,x} + w_{,x}^*)_{,x} + q = 0 \\
 &B_{12} \left[ u_{,xx} + \left( \frac{1}{2} w_{,x}^2 + w_{,x} w_{,x}^* \right)_{,x} \right] + D_{11} \theta_{,xx} + D_{12} \psi_{,xx} - \bar{G}A (w_{,x} + \theta) - (G - \bar{G}) A \psi + m = 0 \\
 &B_{13} \left[ u_{,xx} + \left( \frac{1}{2} w_{,x}^2 + w_{,x} w_{,x}^* \right)_{,x} \right] + D_{12} \theta_{,xx} + D_{22} \psi_{,xx} - (G - \bar{G}) A (w_{,x} + \theta) - (\bar{G} - G) A \psi = 0
 \end{aligned} \tag{18}$$

where the stiffness coefficients are defined in Appendix A.

An approximate solution of Eqs. (18) is now obtained for general boundary and loading conditions by means of the finite element method.

### 3. Finite element formulation

Before introducing the finite element approximation into the PVW statement, the strain energy virtual variation  $\delta U$ , Eq. (10), is expressed as a function of  $\boldsymbol{\omega}$  and  $\boldsymbol{\omega}^*$  by using Eqs. (6)-(8). After some straightforward operations and neglecting higher order terms, the following expression is obtained

$$\begin{aligned} \delta U = & \int_{x_a}^{x_b} \int_A \left[ \delta \boldsymbol{\omega}^T \mathbf{Z}_e^{(k)T} E_x^{(k)} \mathbf{Z}_e^{(k)} \boldsymbol{\omega} \right] dA dx + \frac{1}{2} \int_{x_a}^{x_b} \int_A \left[ \delta \boldsymbol{\omega}^T \mathbf{Z}_e^{(k)T} E_x^{(k)} \boldsymbol{\omega}^T \mathbf{H} \boldsymbol{\omega} \right] dA dx \\ & + \int_{x_a}^{x_b} \int_A \left[ \delta \boldsymbol{\omega}^T \mathbf{Z}_e^{(k)T} E_x^{(k)} \boldsymbol{\omega}^* \boldsymbol{\omega} \right] dA dx + \int_{x_a}^{x_b} \int_A \left[ \delta \boldsymbol{\omega}^T \mathbf{H} \boldsymbol{\omega} E_x^{(k)} \mathbf{Z}_e^{(k)} \boldsymbol{\omega} \right] dA dx \\ & + \int_{x_a}^{x_b} \int_A \left[ \delta \boldsymbol{\omega}^T \boldsymbol{\omega}^* E_x^{(k)} \mathbf{Z}_e^{(k)} \boldsymbol{\omega} \right] dA dx + \int_{x_a}^{x_b} \int_A \left[ \delta \boldsymbol{\omega}^T \mathbf{Z}_\gamma^{(k)T} G_{xz}^{(k)} \mathbf{Z}_\gamma^{(k)} \boldsymbol{\omega} \right] dA dx \end{aligned} \quad (19)$$

Since  $\boldsymbol{\omega}$ ,  $\boldsymbol{\omega}^*$  and  $\mathbf{H}$  do not depend on the cross-sectional coordinate axes, the following expression for  $\delta U$  can be obtained from Eq. (19)

$$\begin{aligned} \delta U = & \int_{x_a}^{x_b} \delta \boldsymbol{\omega}^T \int_A \left[ \mathbf{Z}_e^{(k)T} E_x^{(k)} \mathbf{Z}_e^{(k)} \right] dA \boldsymbol{\omega} dx + \frac{1}{2} \int_{x_a}^{x_b} \delta \boldsymbol{\omega}^T \int_A \left[ \mathbf{Z}_e^{(k)T} E_x^{(k)} \right] dA \boldsymbol{\omega}^T \mathbf{H} \boldsymbol{\omega} dx \\ & + \int_{x_a}^{x_b} \delta \boldsymbol{\omega}^T \int_A \left[ \mathbf{Z}_e^{(k)T} E_x^{(k)} \right] dA \boldsymbol{\omega}^* \boldsymbol{\omega} dx + \int_{x_a}^{x_b} \delta \boldsymbol{\omega}^T \mathbf{H} \boldsymbol{\omega} \int_A \left[ E_x^{(k)} \mathbf{Z}_e^{(k)} \right] dA \boldsymbol{\omega} dx \\ & + \int_{x_a}^{x_b} \delta \boldsymbol{\omega}^T \boldsymbol{\omega}^* \int_A \left[ E_x^{(k)} \mathbf{Z}_e^{(k)} \right] dA \boldsymbol{\omega} dx + \int_{x_a}^{x_b} \delta \boldsymbol{\omega}^T \int_A \left[ \mathbf{Z}_\gamma^{(k)T} G_{xz}^{(k)} \mathbf{Z}_\gamma^{(k)} \right] dA \boldsymbol{\omega} dx \end{aligned} \quad (19\text{bis})$$

The kinematic variables are approximated within the beam finite element by using the *anisoparametric* interpolation [24]. In order to avoid shear locking, the deflection  $w(x)$  is approximated using a quadratic polynomial whereas  $u(x)$ ,  $\vartheta(x)$  and  $\psi(x)$  are linearly interpolated. A consistent constraining condition based on the resultant shear force  $V_x$  is used to simplify the element topology [24]: two nodes and four degrees of freedom per node are obtained (Figure 3).

[insert Figure 3.]

The matrix form of the element-wise approximation of the kinematic variables,  $\mathbf{u}$ , is

$$\mathbf{u} = \begin{Bmatrix} u(x) \\ w(x) \\ \mathcal{G}(x) \\ \psi(x) \end{Bmatrix} \cong \mathbf{N}\mathbf{u}^e \quad (20)$$

where  $\mathbf{u}^e \equiv [u_1 \quad w_1 \quad \mathcal{G}_1 \quad \psi_1 \quad u_2 \quad w_2 \quad \mathcal{G}_2 \quad \psi_2]^T$  is the vector of nodal degrees of freedom and  $\mathbf{N}$  is the shape-function matrix (refer to [24] for details on the shape functions definition).

The initial imperfection function  $w^*(x)$  is an input of the problem and is approximated within each element as a parabolic function

$$w^*(x) \cong \mathbf{N}_w^* \mathbf{u}^{*e} \quad (21)$$

where  $\mathbf{N}_w^*$  contains the Lagrange parabolic polynomials and  $\mathbf{u}^{*e} \equiv [w_1^* \quad w_m^* \quad w_2^*]^T$  is the vector containing the values of the initial imperfection at the ends and at the mid-point of the element (Figure 4).

[insert Figure 4.]

The PVW statement is now discretized applying the finite element approximation to derive the element-level equilibrium equation corresponding to the nonlinear formulation of RZT. The vectors  $\boldsymbol{\omega}$  and  $\boldsymbol{\omega}^*$  are related to the corresponding nodal degrees-of-freedom vectors by the relations

$$\boldsymbol{\omega} = \mathbf{B}^e \mathbf{u}^e$$

$$\boldsymbol{\omega}^* = \mathbf{B}^{*e} \mathbf{u}^{*e} \quad (22)$$

where  $\mathbf{B}^e$  and  $\mathbf{B}^{*e}$  contain the derivatives with respect to the  $x$ -coordinate of the shape functions defined in Eq. (20) and Eq. (21), respectively (refer to Appendix B). The finite element approximation of the strain energy variation is obtained substituting Eq. (22) into Eq. (19bis)

$$\begin{aligned} \delta U \cong & \delta \mathbf{u}^{eT} \int_0^{L_e} \mathbf{B}^{eT} \cdot \int_A (\mathbf{Z}_x^{(k)T} E_x^{(k)} \mathbf{Z}_x^{(k)}) dA \cdot \mathbf{B}^e dx \cdot \mathbf{u}^e + \frac{1}{2} \delta \mathbf{u}^{eT} \int_0^{L_e} \mathbf{B}^{eT} \mathbf{Z}_N^{eT} \cdot [\mathbf{u}^{eT} \mathbf{B}^{eT} \mathbf{H} \mathbf{B}^e] dx \cdot \mathbf{u}^e \\ & + \delta \mathbf{u}^{eT} \int_0^{L_e} \mathbf{B}^{eT} \mathbf{Z}_N^{eT} \cdot [\mathbf{u}^{*eT} \mathbf{B}^{*eT} \mathbf{B}^e] dx \cdot \mathbf{u}^e + \delta \mathbf{u}^{eT} \int_0^{L_e} [\mathbf{B}^{eT} \mathbf{H} \mathbf{B}^e \mathbf{u}^e] \cdot \mathbf{Z}_N^e dx \cdot \mathbf{u}^e \\ & + \delta \mathbf{u}^{eT} \int_0^{L_e} [\mathbf{B}^{eT} \mathbf{B}^{*e} \mathbf{u}^{*e}] \cdot \mathbf{Z}_N^e dx \cdot \mathbf{u}^e + \delta \mathbf{u}^{eT} \int_0^{L_e} \mathbf{B}^{eT} \cdot \int_A (\mathbf{Z}_y^{(k)T} G_{xz}^{(k)} \mathbf{Z}_y^{(k)}) dA \cdot \mathbf{B}^e dx \cdot \mathbf{u}^e \end{aligned} \quad (23)$$

where  $\mathbf{Z}_N^e \equiv \int_A [E_x^{(k)} \mathbf{Z}_x^{(k)}] dA$  and  $L_e$  is the finite element length.

Assuming that the internal axial-force resultant,  $N_x$ , can be approximated as the integral over the beam cross-section of the linear component of the axial stress (refer to Eqs. (8) and (5))

$$\begin{aligned} N_x \cong & \int_A E_x^{(k)} u_{x,x} dA \\ & = \int_A E_x^{(k)} \mathbf{Z}_x^{(k)}(z) \boldsymbol{\omega}(x) dA = \int_A E_x^{(k)} \mathbf{Z}_x^{(k)}(z) \mathbf{B}^e(x) \mathbf{u}^e dA \\ & = \int_A E_x^{(k)} \mathbf{Z}_x^{(k)}(z) dA \mathbf{B}^e(x) \mathbf{u}^e = \mathbf{Z}_N^e \mathbf{B}^e(x) \mathbf{u}^e \end{aligned} \quad (23a)$$

Eq. (23) can be rewritten as follows

$$\begin{aligned}
\delta U \cong & \delta \mathbf{u}^{eT} \int_0^{L_e} \mathbf{B}^{eT} \cdot \int_A (\mathbf{Z}_\varepsilon^{(k)T} E_x^{(k)} \mathbf{Z}_\varepsilon^{(k)}) dA \cdot \mathbf{B}^e dx \cdot \mathbf{u}^e + \frac{1}{2} \int_0^{L_e} \delta N_x \cdot [\mathbf{u}^{eT} \mathbf{B}^{eT} \mathbf{H} \mathbf{B}^e] dx \cdot \mathbf{u}^e \\
& + \int_0^{L_e} \delta N_x \cdot [\mathbf{u}^{*eT} \mathbf{B}^{*eT} \mathbf{B}^e] dx \cdot \mathbf{u}^e + \delta \mathbf{u}^{eT} \int_0^{L_e} [\mathbf{B}^{eT} \mathbf{H} \mathbf{B}^e] \cdot N_x dx \cdot \mathbf{u}^e \\
& + \delta \mathbf{u}^{eT} \int_0^{L_e} [\mathbf{B}^{eT} \mathbf{B}^{*e}] \cdot N_x dx \cdot \mathbf{u}^{*e} + \delta \mathbf{u}^{eT} \int_0^{L_e} \mathbf{B}^{eT} \cdot \int_A (\mathbf{Z}_\gamma^{(k)T} G_{xz}^{(k)} \mathbf{Z}_\gamma^{(k)}) dA \cdot \mathbf{B}^e dx \cdot \mathbf{u}^e
\end{aligned} \tag{23bis}$$

Some terms can be collected thus leading to the following expression

$$\begin{aligned}
\delta U \cong & \delta \mathbf{u}^{eT} \int_0^{L_e} \mathbf{B}^{eT} \cdot \int_A (\mathbf{Z}_\varepsilon^{(k)T} E_x^{(k)} \mathbf{Z}_\varepsilon^{(k)}) dA \cdot \mathbf{B}^e dx \cdot \mathbf{u}^e + \frac{3}{2} \delta \mathbf{u}^{eT} \int_0^{L_e} [\mathbf{B}^{eT} \mathbf{H} \mathbf{B}^e \mathbf{u}^e] \cdot \mathbf{Z}_N^e \mathbf{B}^e dx \cdot \mathbf{u}^e \\
& + 2 \delta \mathbf{u}^{eT} \int_0^{L_e} [\mathbf{B}^{eT} \mathbf{B}^{*e} \mathbf{u}^{*e}] \cdot \mathbf{Z}_N^e \mathbf{B}^e dx \cdot \mathbf{u}^e + \delta \mathbf{u}^{eT} \int_0^{L_e} \mathbf{B}^{eT} \cdot \int_A (\mathbf{Z}_\gamma^{(k)T} G_{xz}^{(k)} \mathbf{Z}_\gamma^{(k)}) dA \cdot \mathbf{B}^e dx \cdot \mathbf{u}^e
\end{aligned} \tag{24}$$

The virtual work of external forces in the case of loads distributed along the element span is

$$\delta L_e \cong \delta \mathbf{u}^{eT} \mathbf{f}^e \tag{25}$$

where  $\mathbf{f}^e$  is the element consistent load vector corresponding to distributed loads of Eq. (14) and is defined as

$$\mathbf{f}^e = \int_0^{L_e} \widehat{\mathbf{N}}^T \mathbf{q} dx \tag{26}$$

The matrix  $\widehat{\mathbf{N}}$  is composed by the first three rows of the shape-function matrix  $\mathbf{N}$  of Eq. (20), and

$$\mathbf{q} \equiv [p \quad q \quad m]^T.$$

Substituting Eqs. (24) and (25) into the PVW statement, Eq. (9), the element-level nonlinear equilibrium equation can be obtained

$$\mathbf{K}^e \mathbf{u}^e + \frac{3}{2} \overline{\mathbf{K}}_G^e(\mathbf{u}^e) \cdot \mathbf{u}^e + \overline{\mathbf{K}}_G^{*e}(\mathbf{u}^{*e}) \cdot \mathbf{u}^e = \mathbf{f}^e \quad (27)$$

where the linear stiffness matrix,  $\mathbf{K}^e$ , and the geometric stiffness matrices,  $\overline{\mathbf{K}}_G^e(\mathbf{u}^e)$  and  $\overline{\mathbf{K}}_G^{*e}(\mathbf{u}^{*e})$ , are defined as

$$\mathbf{K}^e \equiv \int_0^{L^e} \mathbf{B}^{eT} \Delta \mathbf{B}^e dx, \quad \overline{\mathbf{K}}_G^e(\mathbf{u}^e) \equiv \int_0^{L^e} \mathbf{B}^{eT} \mathbf{H} \mathbf{B}^e \mathbf{u}^e \mathbf{Z}_N^e \mathbf{B}^e dx, \quad \overline{\mathbf{K}}_G^{*e}(\mathbf{u}^{*e}) \equiv \int_0^{L^e} \mathbf{B}^{eT} \mathbf{B}^{*eT} \mathbf{u}^{*eT} \mathbf{Z}_N^e \mathbf{B}^e dx \quad (28)$$

The matrix  $\overline{\mathbf{K}}_G^e(\mathbf{u}^e)$  is associated to the nonlinearities and it is function of the nodal degrees of freedom, while  $\overline{\mathbf{K}}_G^{*e}(\mathbf{u}^{*e})$  is dependent on the initial geometric imperfections.

If the internal axial-force resultant  $N_x$  is constant along the beam and corresponding to the externally applied compressive force  $N_0$  ( $N_x = -N_0$ ), the quantity  $\delta N_x$  in Eq. (23bis) vanishes and Eq. (27) becomes

$$\left( \mathbf{K}^e - N_0 \mathbf{K}_G^e \right) \mathbf{u}^e = N_0 \mathbf{K}_G^{*e} \mathbf{u}^{*e} + \mathbf{f}^e \quad (29)$$

where  $\mathbf{K}_G^e$  and  $\mathbf{K}_G^{*e}$  are no more dependent on the nodal-degrees of freedom and on the initial imperfections, respectively

$$\mathbf{K}_G^e \equiv \int_0^{L^e} \mathbf{B}^{eT} \mathbf{H} \mathbf{B}^e dx, \quad \mathbf{K}_G^{*e} \equiv \int_0^{L^e} \mathbf{B}^{eT} \mathbf{B}^{*eT} dx \quad (30)$$

Buckling loads can be evaluated for symmetrically laminated beams without initial geometric imperfections by using the Euler's method of the adjacent equilibrium configurations. Considering that the beams remain straight in the pre-buckling state, the linearized stability equations can be obtained from Eq. (29)

$$\left(\mathbf{K}^e - N_0 \mathbf{K}_G^e\right) \hat{\mathbf{u}}^e = \mathbf{0} \quad (31)$$

where  $\hat{\mathbf{u}}^e$  are incremental with respect to the pre-buckling state. Eq. (31) defines an eigenvalue problem providing both buckling loads and the corresponding buckling shapes.

#### 4. Numerical results

The accuracy of the nonlinear model based on RZT for the analysis of multilayered beams has been assessed through a set of numerical test cases. Both critical loads of perfect beams and nonlinear static response of initially imperfect beams have been investigated. The focus of these numerical results is on sandwich beams with different core materials and slenderness ratios. Comparison with Timoshenko Beam Theory (TBT) results are also presented, as well as with high-fidelity FEM results based on commercial codes and used as benchmarks.

##### 4.1 Beams geometry, materials, boundary conditions and applied loads

Three sandwich beams have been considered with symmetric lay-up (Table 1): two facesheets with thickness  $h_f$  and a core with thickness  $h_c$ . The width of the cross-section is  $b$  and the length of the beam is  $L$ .

Table 1. Sandwich beams geometry.

Beam	L (mm)	b (mm)	h <sub>c</sub> (mm)	h <sub>f</sub> (mm)
IG_32_5	320.00	48.53	6.07	5.00
WF_32_5	320.00	48.18	6.10	5.00
IG_96_2	960.00	72.40	19.93	2.00

Beams IG\_32\_5 and WF\_32\_5 share the same nominal geometry (slenderness ratio 20 and face-to-core thickness ratio 0.82) but they have a different face-to-core stiffness ratio. Beam IG\_96\_2 has a higher slenderness ratio (40) and a higher core-to-face thickness ratio (10).

Facesheets are made of a 7075 aluminum alloy (Ergal<sup>®</sup>) whereas cores are made of Rohacell<sup>®</sup> structural foams. Two types of foams have been used, namely WF110 and IG31. Material properties have been evaluated with a dedicated experimental tests campaign for a previous research activity [31], Table 2.

Table 2. Materials mechanical properties.

Material	E (MPa)	G (MPa)
Ergal <sup>®</sup>	69,570	25,766
Rohacell <sup>®</sup> IG31	40.3	12.4
Rohacell <sup>®</sup> WF110	196	65.4

Both cantilevered (CF) and simply-supported (SS) boundary conditions have been considered. A compressive load is applied at the beam end that is free to move axially.

[insert Figure 5.]

#### 4.2 Models

Sandwich beams have been analyzed using beam finite elements based on both RZT and TBT. The beam length has been divided into 40 elements, found to guarantee convergence<sup>2</sup>. Both RZT and TBT elements formulation is based on anisoparametric interpolation (refer to Section 3 and to [24] for further details). Moreover, a shear correction factor has been used within TBT analysis that is based on the transverse-shear strain energy [32].

High-fidelity FE models based on commercial codes have also been used in order to provide reference results with high accuracy. Both Abaqus<sup>®</sup> and MSC/Nastran<sup>®</sup> have been adopted. Plane stress analyses have been performed using S4R and QUAD4 elements, respectively. The detailed description of the mesh for the considered beams is reported in Table 3.

**Table 3.** Mesh details for the FEM analyses performed with commercial codes.

	No. of nodes	No. of elements			
		along the beam length	along $h_f$	along $h_c$	total
(IG/WF)_32_5	5457	320	5	6	5120
IG_96_2	25947	960	2	20	23040

The compressive force is simulated as a distributed load over the cross-section of the beam. The load in each layer (per unit length of the thickness coordinate) is proportional to the corresponding

<sup>2</sup> The criterion adopted to determine the number of finite elements in the TBT and RZT analyses is as follows: a mesh with more than 40 elements provides negligible improvements (<1%) to the evaluation of the 1<sup>st</sup> and 2<sup>nd</sup> buckling loads of any of the considered beams. Similarly, increasing the number of elements for the nonlinear static response analyses does not lead to appreciable differences in the load-displacement response curves.

Young modulus in order to make the cross-section move remaining flat and to avoid local effects (that neither RZT and TBT could model).

4.3 Buckling loads

The first two buckling loads have been evaluated for the different combinations of beam stacking sequences and boundary conditions, Tables 4-6. The RZT solution has been obtained solving the eigenvalue problem associated to Eq. (31). An analogous solution has been obtained with the TBT.

The value of the shear correction factor adopted within TBT analysis is also reported for each case.

Table 4. First two buckling loads of the IG\_32\_5 sandwich beam. Loads are expressed in N.

BCs	RZT	TBT ( $k^2=1.1163 \times 10^{-3}$ )	ABAQUS
CF	9,905	9,159	9,850
	26,856	13,196	26,292
SS	17,681	12,346	17,361
	38,980	13,522	37,745

Table 5. First two buckling loads of the WF\_32\_5 sandwich beam. Loads are expressed in N.

BCs	RZT	TBT ( $k^2=5.7162 \times 10^{-3}$ )	ABAQUS
CF	19,540	19,409	19,498
	64,303	55,153	63,985

SS	45,311	42,828	45,005
	81,329	61,332	80,009

**Table 6.** First two buckling loads of the IG\_96\_2 sandwich beam. Loads are expressed in N.

BCs	RZT	TBT ( $k^2=1.4914 \times 10^{-2}$ )	ABAQUS
CF	5,026	5,025	5,017
	16,076	15,994	15,973
SS	11,946	11,926	11,894
	18,354	18,162	18,172

The Refined Zigzag Theory is highly accurate in predicting the first two buckling loads for the considered beams. The more challenging problem is associated with the IG\_32\_5 beam that is characterized by a slenderness ratio of 20, by thick facesheets and a weak core. Nevertheless, the maximum error on the critical load is below 2% with respect to the Abaqus solution and the maximum error on the second critical load is around 3%. Beam WF\_32\_5 has a stiffer core and beam IG\_96\_2 is more slender, therefore lower errors are experienced.

A similar trend is exhibited by the Timoshenko Beam Theory, however higher discrepancies are shown with respect to the Abaqus reference solution. The critical load is evaluated with a good accuracy for beams WF\_32\_5 and IG\_96\_2, whereas it is heavily underestimated (30% error) for the simply supported IG\_32\_5 beam. Higher errors are found for the second buckling load of both IG\_32\_5 and WF\_32\_5 beams. It is interesting that, for the same beam, the buckling loads of the simply supported boundary conditions are less accurate with respect to the cantilevered configuration.

As already highlighted in other works [25], although an ad hoc shear correction factor is adopted, TBT is not accurate for the analysis of sandwich structures with high face-to-core thickness ratio and face-to-core stiffness ratio. And this applies also to the buckling analysis.

#### 4.4 Nonlinear static response analysis

The nonlinear static response of initially imperfect sandwich beams subjected to a compressive load has been analyzed using different approaches to introduce the imperfection.

At first, a cantilevered IG\_32\_5 beam has been modeled in MSC/Patran<sup>®</sup> as a slightly-curved beam to reproduce the geometric initial imperfection. The geometric imperfection is described by the following expression

$$w^*(x) = \frac{L^2 + \mu^2 - \sqrt{(L^2 + \mu^2)^2 - 4\mu^2 x^2}}{2\mu} \quad (32)$$

In particular, the beam axis is not straight but is a circumference arc and the maximum imperfection is manifested at the beam tip,  $w^*(x=L) = \mu = 1 \text{ mm}$ . The same mesh details reported in Table 3 are valid for the mesh of the imperfect beam. The RZT nonlinear response has been obtained by solving Eq. (29) at different axial load levels,  $N_0$ . An analogous solution is adopted for the TBT. Figure 6 shows the load-tip deflection curve as computed using MSC/Nastran<sup>®</sup> and the TBT and RZT FE solutions.

[insert Figure 6.]

<sup>3</sup> The MSC/NASTRAN<sup>®</sup> nonlinear static response (SOL 106) has been obtained using the modified Newton's method with 10 load increments, a maximum number of 25 iterations for each load increment and a convergence criterion based on both the load equilibrium residual and the work error. For further details, refer to [33].

1  
2  
3 All of the considered beam theories correctly provide a load-deflection curve that asymptotically  
4 approaches the corresponding critical load (see Table 4).  
5

6  
7 RZT confirms its accuracy for the nonlinear analysis of sandwich beams with initial geometric  
8 imperfections. The latter are correctly modeled by using the Von Kármán definition of nonlinear  
9 strains, Eq. (5).  
10

11  
12 An Abaqus<sup>®</sup> command allows the introduction of the geometric imperfections as a linear  
13 combination of selected buckling modes, thus perfect beam models have been realized and different  
14 imperfection cases have been considered for each beam without the need to modify the model. In  
15 particular, all of the considered beams have been analyzed in both the SS and CF configurations and  
16 in presence of initial imperfections corresponding to the first buckling shape, to the second buckling  
17 shape and to a linear combination of the first two shapes (70% of the first plus 30% of the second).  
18 For all the cases, the actual deviation from the straight perfect geometry has been calculated setting  
19 to 1 mm the maximum displacement of the first and second buckling mode. **Figures 7-15** show the  
20 response predictions obtained using Abaqus<sup>®</sup> as well RZT and TBT<sup>4</sup>.

19  
20 As expected, in case of initial geometric imperfections, either as generic function (Figure 6) or as  
21 linear combination of the buckling modes (Figures 9, 12 and 15), the load-deflection curves tend  
22 asymptotically to the first buckling load. However, when the second buckling mode is assumed as  
23 initial imperfection, the load-asymptotic value is the second buckling load of the beam (see Table  
24 4).  
25  
26  
27  
28  
29  
30

31 The deflection of the whole beam is shown in Figures 16-20 for the IG31\_32\_5 in case of initial  
32 imperfection as a linear combination of the buckling modes. In Figures 16 the applied load is zero,  
33 while in Figures 17-20 it corresponds, respectively, to 25%, 45%, 70% and 90% of the critical  
34 buckling load  $N_{cr}$ .

7 The vertical displacements of the nodes on the beam axis of the Abaqus model are used as  
8 reference. A perfect match between RZT and Abaqus can be observed in all cases, also for high  
9 values of  $N_0$ . It is worth noting that the deformed shape tends to the first buckling mode when  $N_0$   
10 approaches the first buckling load, which is the asymptotic value in the corresponding load-  
11 displacement curve, as shown in Figure 9.  
12  
13  
14  
15  
16  
17

18 Figures 7-20 prove the superior capability of the RZT in predicting the nonlinear response of  
19 sandwich beams also in presence of complex initial geometric imperfections. The accuracy of the  
20 RZT load-deflection curves (Figures 7-15) and deformed shapes (Figures 16-20) is confirmed by  
21 the Abaqus results for the considered cases of beam slenderness and face-to-core stiffness and  
22 thickness ratios.

#### 32 4.5 Discussion

33 It is remarkable that this level of accuracy is achieved by RZT at an affordable computational cost:  
34 40 elements, 41 nodes and 164 dofs. This is possible thanks to: (1) the RZT capability to accurately  
35 take into account the transverse shear deformation and to model the cross-section distortion of  
36 laminated beams even in presence of a highly heterogeneous stacking sequence, (2) to the need of  
37 only one additional kinematic variable with respect to the TBT, and (3) to the fact that the  
38 computational cost is independent of the number of physical layers. The number of nodes required  
39 by the FE analyses performed with commercial codes is at least 5,400 (for thick beams with thick  
40 facesheets, refer to Table 3), meaning more than 10,800 dofs (two orders of magnitude more than  
41 for RZT). For more complex stacking sequences (more physical layers), the difference would be  
42 even more pronounced.  
43

57  
58  
59  
60

1  
2  
3 It is therefore demonstrated that RZT can be recommended as a computationally affordable and  
4  
5 accurate model for the analysis of laminated and sandwich beams also in the nonlinear static  
6  
7 response regime.  
8  
9

## 11 Conclusions

12  
13 A nonlinear formulation based on the Refined Zigzag Theory (RZT) has been developed to assess  
14 the theory for the buckling and nonlinear static response analysis of multilayered composite and  
15 sandwich beams with geometric imperfections. Numerical tests have been conducted on three  
16 sandwich beams with different core materials and slenderness ratios in both simply supported and  
17 cantilever configurations.  $C^0$ -beam finite elements based on the RZT and on the Timoshenko Beam  
18 Theory (TBT) have been employed for the analyses, and the initial imperfection within each  
19 element has been approximated by quadratic Lagrange polynomials. The RZT and TBT results have  
20 been compared to the solutions of high-fidelity commercial codes (Abaqus and Nastran) used as  
21 benchmarks.  
22  
23

24 Firstly, perfect beams have been considered to evaluate the first and the second buckling loads. The  
25 RZT error of the critical buckling load with respect to the corresponding Abaqus solution is always  
26 below 2%. Moreover, RZT is much more accurate than TBT for beams with low slenderness ratio  
27 and thicker facesheets, especially in case of higher face-to-core stiffness ratio. Then, geometric  
28 imperfections have been introduced in the models to evaluate the nonlinear response of the beams  
29 under axial compressive loads. To assess the theory for any kind of geometric imperfection, several  
30 shapes have been considered as initial deviation from the straight perfect geometry. As first case,  
31 the IG31\_32\_5 beam in cantilever boundary conditions has been analyzed assuming a  
32 circumference-arc shape as imperfection; the reference 2D model has been realized in Nastran.  
33  
34 Furthermore, all the beams have been analyzed in Abaqus in both the SS and CF configurations and  
35 with initial imperfections corresponding to the first buckling shape, to the second buckling shape  
36 and to a linear combination of the first two shapes (70% of the first plus 30% of the second). The  
37

57  
58  
59  
60

1  
2  
3 results have shown a very good agreement between the RZT and commercial codes solutions for the  
4  
5 evaluation of the nonlinear load-displacement equilibrium path. In all cases, the level of accuracy of  
6  
7 the RZT is remarkable also for applied loads close to the critical buckling values, proving the  
8  
9 superior capability of the RZT in predicting the response of sandwich beams also in presence of  
10  
11 complex geometric nonlinearities.  
12

13  
14 The combination of high accuracy and low computational cost (only one kinematic variable more  
15  
16 than for TBT and a number of dofs that is at least two orders of magnitude less than for high-  
17  
18 fidelity FE models based on commercial codes) demonstrate that RZT is strongly advisable as an  
19  
20 analysis tool for composite and sandwich beams. The results obtained in the present paper confirm  
21  
22 this observation and extend its applicability also to the buckling and nonlinear analysis of  
23  
24 geometrically imperfect sandwich beams.

### 30 Appendix A

31 In Eq. (6), the strain components dependence on the  $z$ -coordinate is expressed through the matrices  
32  
33  
34  
35

$$36 \mathbf{Z}_\varepsilon^{(k)} = \begin{bmatrix} 1 & 0 & 0 & 0 & z & \phi^{(k)} \end{bmatrix}$$

$$37 \mathbf{Z}_\gamma^{(k)} = \begin{bmatrix} 0 & 1 & 1 & \beta^{(k)} & 0 & 0 \end{bmatrix}$$

38  
39  
40  
41  
42  
43  
44  
45  
46  
47 whereas  $\mathbf{H}$  is the zero-one matrix

$$48 \mathbf{H} = \begin{bmatrix} 0 & 0 & 0 & 0 & 0 & 0 & 0 \\ 0 & 1 & 0 & 0 & 0 & 0 & 0 \\ 0 & 0 & 0 & 0 & 0 & 0 & 0 \\ 0 & 0 & 0 & 0 & 0 & 0 & 0 \\ 0 & 0 & 0 & 0 & 0 & 0 & 0 \\ 0 & 0 & 0 & 0 & 0 & 0 & 0 \end{bmatrix}$$

The matrix  $\Delta$  containing the stiffness coefficient in the nonlinear constitutive equations (Eq.15) is

$$\Delta = \begin{bmatrix} A_{11} & 0 & 0 & 0 & B_{12} & B_{13} \\ 0 & \bar{G}A & \bar{G}A & (G-\bar{G})A & 0 & 0 \\ 0 & (G-\bar{G})A & (G-\bar{G})A & (\bar{G}-G)A & 0 & 0 \\ B_{12} & 0 & 0 & 0 & D_{11} & D_{12} \\ B_{13} & 0 & 0 & 0 & D_{12} & D_{22} \end{bmatrix}$$

where

$$[A_{11}, B_{12}, D_{11}] \equiv \int_A E_x^{(k)} [1, z, z^2] dA$$

$$[B_{13}, D_{12}, D_{22}] \equiv \int_A E_x^{(k)} \phi^{(k)} [1, z, \phi^{(k)}] dA$$

$$\bar{G} \equiv \frac{1}{2h} \int_{-h}^{+h} G_{xz}^{(k)} dz$$

## Appendix B

The strain–displacement matrix,  $\mathbf{B}^e$ , for the two-node, eight-dof *constrained anisoparametric* element is given by [24]:

$$\mathbf{B}^e = \frac{1}{L^e} \begin{bmatrix} N_{1,\xi}^L & 0 & 0 & 0 & N_{2,\xi}^L & 0 & 0 & 0 \\ 0 & N_{1,\xi}^L & -\alpha \frac{L_e}{8} N_{m,\xi}^Q & -\alpha c \frac{L_e}{8} N_{m,\xi}^Q & 0 & N_{2,\xi}^L & \alpha \frac{L_e}{8} N_{m,\xi}^Q & \alpha c \frac{L_e}{8} N_{m,\xi}^Q \\ 0 & 0 & L_e N_1^L & 0 & 0 & 0 & L_e N_2^L & 0 \\ 0 & 0 & 0 & L_e N_1^L & 0 & 0 & 0 & L_e N_2^L \\ 0 & 0 & N_{1,\xi}^L & 0 & 0 & 0 & N_{2,\xi}^L & 0 \\ 0 & 0 & 0 & N_{1,\xi}^L & 0 & 0 & 0 & N_{2,\xi}^L \end{bmatrix}$$

and the matrix  $\mathbf{B}^{*e}$ , containing the derivatives with respect to the  $x$ -coordinate of the Lagrange parabolic polynomials, is

$$\mathbf{B}^{*e} = \frac{1}{L^e} \begin{bmatrix} 0 & 0 & 0 \\ N_{1,\xi}^Q & N_{m,\xi}^Q & N_{2,\xi}^Q \\ 0 & 0 & 0 \\ 0 & 0 & 0 \\ 0 & 0 & 0 \end{bmatrix}$$

where  $\xi \equiv 2x / L^e - 1$  is the non-dimensional axial coordinate ( $\xi \in [-1,1]$  and  $x \in [0, L^e]$ ).
