Abstract

Systemic diseases affect multiple tissues that interact with each other within a network difficult to explore at the body level. However, understanding the interdependences between tissues could be of high relevance for drug target identification, especially at the first stages of disease development. *In vitro* systems have the advantages of accessibility to measurements and precise controllability of culture conditions, but currently have limitations in mimicking human *in vivo* systemic tissue response. In this work, we present an *in vitro* model of cross-talk between an *ex vivo* culture of adipose tissue from an obese donor and a skeletal muscle *in vitro* model from a healthy donor. This is relevant to understand type 2 diabetes mellitus pathogenesis, as obesity is one of its main risk factors. The human adipose tissue biopsy was maintained as a three-dimensional culture for 48 h. Its conditioned culture medium was used to stimulate a human skeletal muscle-on-chip, developed by differentiating primary cells of a patient's biopsy under topological cues and molecular self-regulation. This system has been characterized to demonstrate its ability to mimic important features of the normal skeletal muscle response *in vivo*. We then found that the conditioned medium from a diseased adipose tissue is able to perturb the normal insulin sensitivity of a healthy skeletal muscle, as reported in the early stages of diabetes onset. In perspective, this work represents an important step toward the development of technological platforms that allow to study and dissect the systemic interaction between unhealthy and healthy tissues *in vitro*. © 2018 American Institute of Chemical Engineers *Biotechnol. Prog.*, 35: e2766, 2019.

Introduction

Systemic diseases disrupt the overall patient physiology, involving changes in multiple tissues.**1** Studying how they develop is a difficult task due to the high interconnectivity of the body system. For example, through blood circulation, endocrine signals from one tissue affect the physiological function of other tissues, even if remotely located.

In vivo, dissecting the cross-talk between tissues is complicated both by the difficulty to access human tissues and by the interplay between tissues, which prevents understanding the directionality of the phenomena. However, understanding which tissue is the most relevant target for therapeutic intervention is critical, especially during disease pathogenesis.

On the contrary, *in vitro* culture systems offer the advantages of controlled manipulation of experimental conditions for dissecting tissue-to-tissue communication and of accessibility to measurements.**2** The most used *in vitro* models to study the cross-talk between different tissues are based on no-contact coculture systems, called transwell, where different cell types are cultured on the same dish sharing the same culture medium, but physically separated by a porous membrane. One limitation of these systems is that they cannot be used to understand the directionality of the interactions. Another strategy commonly used is to culture each cell type in different dishes, and to mimic their interaction by putting the medium used to culture one type of cells on the

other cell type. The conditioned medium from the "upstream" cells will contain their secreted proteins, and will be used to understand the effect on the "downstream" cells in absence of a returning feedback.[3]

However, aiming at studying the cross-talk between tissues, the first requirement and current limitation in the field is that the *in vitro* tissue culture has to accurately mimic the relevant features of the tissue *in vivo*, in order to achieve an *in vivo*-like response. So-called tissues-on-chip are systems that integrate cells within microfluidic devices that promote their organization to mimic tissue functionality.[4-6] Miniaturization has been shown to be critical to favor the development of tissue-like structures *in vitro*, because the confined environment preserves the scale ratio of different molecular transport phenomena occurring during the reciprocal interaction between cells and surrounding microenvironment within tissues *in vivo*.[7]

Moreover, microfluidics has several other advantages. The small volume requires only few cells, and make possible to obtain multiple parallel cultures from a single tissue biopsy. Considering the limited access to human biopsies of tissues, especially from healthy patients, this aspect is very critical for *in vitro* studies of human biology. Another advantage of microfluidics is that it requires a little amount of medium for cell culture, few microliters instead of multiple milliliters, thus the same amount of conditioned medium from one tissue can be used to perturb the culture of many other target tissues.

Up to now, multiple tissues-on-chip have been developed,[4, 7] although the application of these technologies to human primary cells is more limited.[5, 8, 9] Some studies have been performed to understand the interaction between different tissues *in vitro*, but mainly cell lines have been used so far, as recently reviewed.[2, 10]

In this work, we study the cross-talk between adipose and skeletal muscle tissues using human primary cell sources, within the context of metabolic impairments. These two tissues are mainly responsible for glucose uptake from the blood stream in response to insulin after meals.[11] Their reciprocal interaction is strictly linked to the delicate equilibrium between diet and physical exercise, object of many studies especially at the organism level.[12, 13] Because obesity is known to be an important risk factor for the development of type 2 diabetes,[14, 15] here we study the effect of an adipose tissue from an obese nondiabetic patient onto a skeletal muscle from a healthy nonobese patient, in terms of perturbations of insulin signaling (Figure 1).

Toward this aim, we developed the first human *in vitro* model of skeletal muscle on a chip. In previous works a skeletal muscle cell line was used to develop a mouse model on chip.[16-18] We have previously demonstrated that inducing an aligned topology on a dish culture promotes human skeletal muscle-like functionality.[19, 20] Here, we extend these results to build a human skeletal muscle-on-chip, with an innovative technology to produce a cell-adhesive pattern in microfluidics.

We obtained human adipose tissue as a three-dimensional biopsy, preserving the *in vivo* organ structure, and we cultured it *in vitro* for only 48 h to obtain the conditioned medium for the cross-talk experiments. The data obtained showed the possibility to dissect *in vitro* the role of an impaired adipose tissue onto the insulin sensitivity of a healthy skeletal muscle.

In vitro studies of human tissue cross-talk are still very limited, but will be more and more relevant for understanding tissue interactions at the cellular level in the future. The possibility to use stem cells to develop tissues-on-chip will greatly favor these studies, given the current difficulty of collecting primary human tissue

biopsies.[7] In perspective, the use of microtechnologies, coupled with stem cell-derived tissues, will make possible not only to develop reliable *in vitro* models of human tissues, but also to understand the complexity of the whole body physiology by dissecting their interactions.

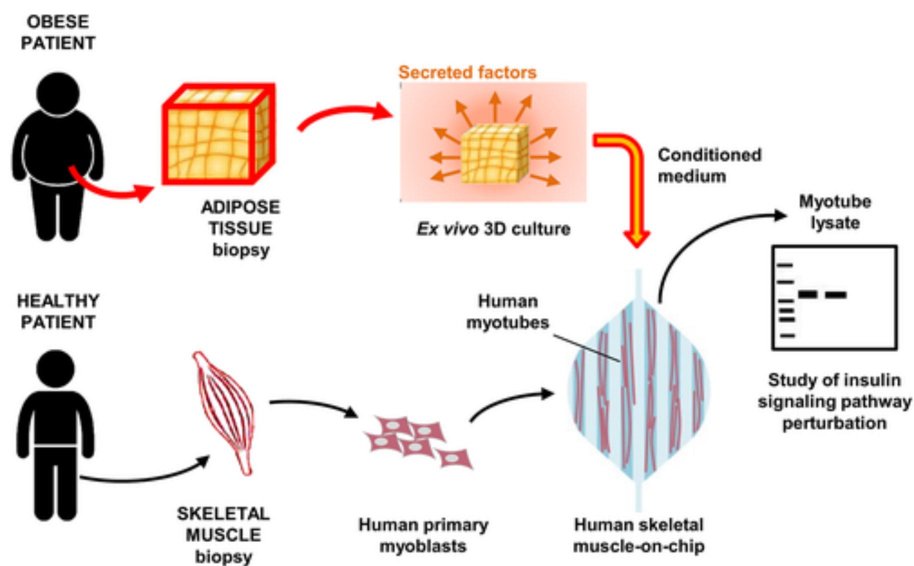

Figure 1
Study of the cross-talk between an adipose tissue from an obese patient and a skeletal muscle from a lean patient. A biopsy of human adipose tissue was maintained in a three-dimensional culture *ex vivo* for 48 h. A human skeletal muscle-on-chip model was developed from human primary myoblasts, which were induced to differentiate into mature myotubes within a microfluidic chamber by a combination of exogenous factors in the culture medium, concentrated cell secreted factors and surface topology control.

Materials and Methods

Microfluidic devices

The microfluidic devices used for culturing skeletal muscle cells were produced according to standard lithographic techniques.[21] The design of the devices was previously described.[16]

Surface micro-pattern within microfluidic culture chambers

Selected areas of the culture surface in the microfluidic chambers were made cell repellent by photo-patterning of linear acrylamide (Figure **2**a). After fabrication, microfluidic chambers were rinsed with isopropanol and distilled water, and treated with a 0.1 M NaOH solution for 1 h. A 0.3% solution of 3-acryloxypropil methacrylate (Acros) in ethanol and 5% v/v acetic acid was used to treat oxidized glass surface inside each microfluidic channel. After 5 min, channels were rinsed twice with ethanol and filled with an acrylamide solution (8% v/v acrylamide (Sigma-Aldrich), 50 mM HEPES, 10% v/v methanol solution with 35 mg/mL Irgacure 2959 (Ciba)). Then, microfluidic chips were placed on a transparency mask, printed with a pattern of 300-µm wide parallel lanes, and exposed for 2 min to UV light, generated by a collimated 50-W UV-lamp (Dymax Bluewave 50 W). Unreacted material was removed

by rinsing the channels twice with distilled water. Sterilization was performed by UV-light exposure for 20 min. Finally, a 4 °C-cold Matrigel (Becton-Dickinson) solution, 2.5% in Dulbecco's Modified Eagle Medium (DMEM, ThermoFisher Scientific), was injected into the micro-channels and incubated for 1 h at room temperature, producing a patterned cell-adhesive surface coating, due to linear acrylamide protein exclusion.

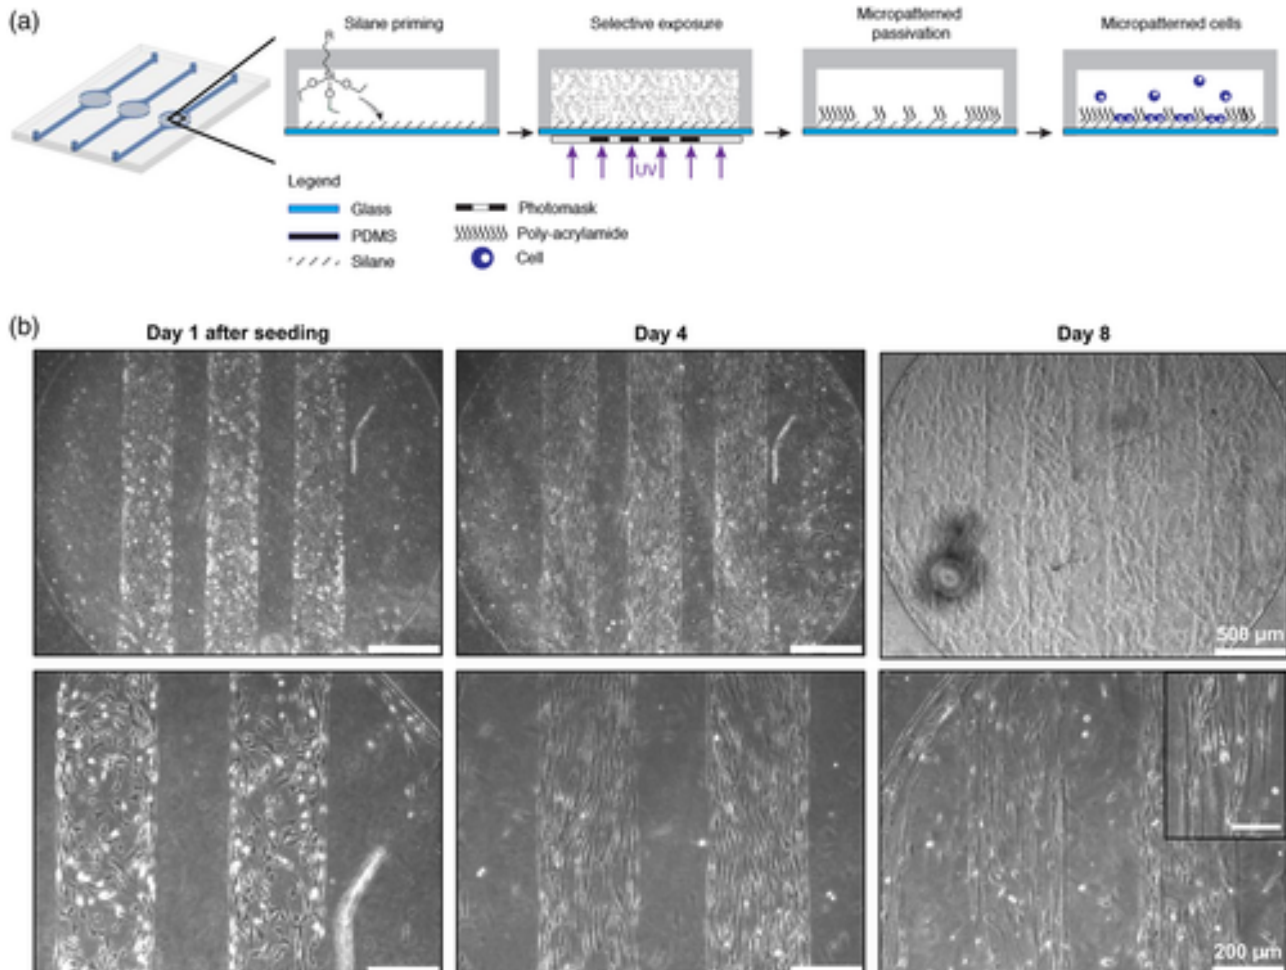

Figure 2
Human skeletal-muscle on chip development. (a) Schematic of adhesive pattern production and functioning. (b) Temporal evolution of human primary myoblast morphology within the patterned microfluidic culture chamber. Scale bars: 500 µm (top row), 200 µm (bottom row), and 100 µm (enlargement).

Human primary myoblast extraction and expansion

Human primary myoblasts were kindly provided by Dr. Karim Bouzakri (University of Geneva), isolated as previously described**22** from a skeletal muscle biopsy of nondiabetic patients undergoing surgery after informed consent by Ethics Committee. Briefly, after explant, the human skeletal muscle biopsy was maintained in 20 mL of physiological solution at +4 °C for 2 h to allow blood coagulation. It was then processed under sterile hood with a scalpel, to isolate single muscle fibers from connective, adipose, and blood vessel tissues. The isolated fibers were maintained in a solution 0.05% Trypsin–EDTA at 37 °C for 3 h to extract single-cell myoblast precursors. The

surnatant cell suspension was then transferred into a new tube, added of an equal amount of fetal calf serum (FCS, Life Technologies), and centrifuged at 200*g* for 5 min. The pellet was resuspended in 10 mL of skeletal muscle cell basal medium (PromoCell), and preplated in a bacterial Petri dish for 2 h, the time required to have fibroblast adhesion and therefore exclusion. Afterward, medium with myoblasts still in suspension was collected and myoblasts plated in a 25-mm**2** tissue culture flask. Human primary myoblasts were cultured for at least 7 days, with medium changes every 2–3 days. Cells were split before confluence by Trypsin–EDTA 0.05%.

Human myoblast microfluidic integration and differentiation

After Matrigel coating, microfluidic chambers were rinsed with skeletal muscle cell basal medium. A myoblast suspension was injected into the chambers for seeding at a final density of 200 cell/mm.**2** The microfluidic devices were then placed in a biological incubator at 37 °C and 5% CO_2. Medium was changed every 12 h. At cell confluence, differentiation of human myoblasts into myotubes was induced by switching to a differentiation medium, composed of DMEM with 2% horse serum (HS, Life Technologies). Thereafter, medium was changed every 24 h for 6–8 days.

Immunofluorescence analysis

For immunofluorescence analysis, myotubes were fixed in 4% (w/v) paraformaldehyde (PFA, Sigma-Aldrich) for 15 min, and stained with primary antibodies in PBS with 3% bovine serum albumin (BSA, Sigma-Aldrich) and 0.25% (v/v) Tryton-X-100 (Sigma-Aldrich). Primary antibodies: Myosin Heavy Chain II 1:100 (MHC, Sigma-Aldrich) and Desmin 1:100 (DAKO). Alexa488 and Alexa594 conjugated mouse secondary antibodies (1:200) were used (Life Technologies). Nuclei were stained with Hoechst 33342 (Life Technologies). Images were acquired with a DMI6000B epifluorescence microscope (Leica Microsystems) and with a TCS SP5 confocal microscope (Leica Microsystems).

Human adipose tissue isolation and culture

A biopsy of a visceral adipose tissue was collected from an obese individual undergoing surgery (sleeve gastrectomy) at the University Hospital of Padova (Italy), after informed consent. Collection and storage of biological samples was approved by the local Ethical Committee. After isolation, the biopsy was maintained in 5 mL of DMEM with 5-mM glucose (Life Technologies) for up to 3 h at room temperature. Then, it was washed with phosphate buffer saline (PBS, Life Technologies) and cut into 4-mm diameter slices with the aid of a sterile biopsy punch (Miltex) and a scalpel. Each slice was put in a 48-well plate with 300 μL of 5-mM glucose DMEM. Conditioned media were collected after 48 h of culture and stocked at −20 °C until use. These media were used as conditioned media for the stimulation of human myotubes in microfluidics.

Tissue cross-talk experiments

After myoblast differentiation into myotubes in the patterned microfluidic culture chambers, medium was changed to serum-free DMEM (5 mM glucose) the night before the stimulation. Next, adipose tissue-conditioned media were used for a 24-h preconditioning; control chambers were kept in DMEM (5 mM glucose), with or without TNFα (20 ng/mL). At the end of the 24 h, a 10-min stimulation was performed using DMEM with or without

insulin (100 nM). The whole experiment was performed using one adipose tissue and two skeletal muscle biopsies. Next, the microfluidic chambers were washed with cold PBS before lysate collection for Western blot analysis.

Western blot analysis

Microfluidic cultures were treated with 12-µL ice-cold lysis buffer: 5% deoxycholic acid (DOC, Sigma-Aldrich) in Tris-Buffered Saline (TBS), supplemented with Complete EDTA-free protease inhibitor (Roche) and antiphosphatase cocktail (Sigma-Aldrich). Lysis buffer was directly injected in each microfluidic chamber and whole cell lysate collected. PAGE was performed with 4–12% NuPAGE polyacrylamide gels and MOPS buffer (Life Technologies). Proteins were blotted on PVDF membranes (Life Technologies) and detected with Carestream films (Kodak). A 1:1000 dilution of primary antibodies for Phospho-Akt (Ser 473), Akt, Phospho-AS160 (Thr 642), AS160 (all from Cell Signaling), IRS-1 (Millipore), GAPDH (Abcam), and HRP-conjugated secondary antibodies (mouse, Bio-Rad; rabbit, Life Technologies) were used. Gel images were quantified by standard image analysis, and ANOVA was performed to identify statistically significant differences.

Results and Discussion

Micropattern integration in the microfluidic chip

The importance of topology in human skeletal muscle differentiation has been previously reported.[19, 20, 23] In particular, a substrate for myoblast culture with an elongated geometry pattern favors the alignment of differentiating myotubes and improves their functional maturation. In addition, performing myotube differentiation within microfluidic devices makes possible to take advantage of some strengths of this technology: specifically, the small volume and ease of parallelization. These features make microfluidics particularly attractive for performing screening studies starting with a small number of cells, and using a small amount of medium to test several conditions.

Micropatterning topology is difficult to integrate within microfluidic cell cultures. Few solutions were previously proposed and are described next. Folch's group performed a cell adhesive pattern on a culture substrate before attaching the microfluidic device on it;[17] however, the subsequent assembly of the microfluidic chip cannot be performed by plasma bonding as usual, and becomes more unpractical and less robust. More recently, micropatterning by pneumatic microfluidics have been suggested.[24] However, this method requires multilayer microfluidics coupled with a pneumatic system for controlling the production stages, and the whole design and production have to be changed in case of variations in the pattern geometry.

We successfully produced a defined pattern of cell adhesion directly inside the assembled microfluidic chip (Figure 2a). To topologically control cell-adhesive and repellent areas, linear acrylamide was photo-patterned according to the design of a photomask, placed between the acrylamide solution in the microfluidic chambers and a UV light source. This method is rapid and practical, and the pattern geometry can be easily changed by simply printing different designs in the photomask. After washing and sterilization, cells are seeded in the microfluidic

chambers and only adhere where the surface is free of the linear acrylamide pattern, with a resulting specific topology in culture.

For this study, a pattern of 300-μm wide lanes was produced. The width of the lanes was optimized in our previous works,[19, 20] which demonstrated that this width represents a trade-off between the accumulation of endogenous cell-secreted signals, which requires cell crowding, and the geometric effect for the myotube alignment, which is better promoted with thinner lanes.

Human skeletal muscle culture and characterization in the microfluidic chip

Human primary myoblasts were seeded and differentiated in the patterned microfluidic chambers. Cells were seeded on Matrigel, which introduces some uncertainty in the system due to the undefined and complex composition. However, during the 2-week cell culture before the perturbation experiments with conditioned media, cells deposited and remodeled their endogenous extracellular matrix and the effect of the original coating becomes less relevant for the purpose of the study. The protocol includes two stages: first, cells are cultured in a skeletal muscle basal medium until they reach confluence (after ~4 days from seeding); then, the medium is changed to one containing factors promoting differentiation and fusion of myoblasts into myotubes. The cells were cultured in the microfluidic device for up to 14 days. A longer culture period was prevented by myotube detachment due to spontaneous contractions.

Aside of medium composition, the culture conditions needed an optimized frequency of medium change. As we previously demonstrated, in microscale cultures the balance between exogenous factors introduced with the medium and endogenous cell-secreted factors is very critical in modifying cellular response.[8, 25] Conversely, conventional culture systems are quite insensitive to modifications to the frequency of medium change, as long as cell starvation is avoided, because cell-secreted factors are rapidly diluted in the large medium volume. The accumulation of cell-secreted factors occurring in microfluidics could be seen as a criticality because it makes the system over-sensitive, but it actually produces an increase in endogenous factor concentrations to the point that their role becomes biologically relevant, mimicking the self-regulation occurring within tissues *in vivo*. In this work, the following optimal frequencies of medium change were obtained: medium changes every 12 h during the first stage of cell proliferation, and every 24 h during the second stage of myotube differentiation. These conditions proved optimal to balance the higher demand of nutrients during the first proliferative stage, and the need of promoting cell self-regulation during differentiation.

The morphological progression during proliferation and differentiation on the microfluidic pattern with the optimized protocol is shown in Figure **2**b. At day 1 from seeding, cells are proliferating only within the adhesive surface of the pattern. After 4 days cells already show some alignment along the longitudinal direction. At day 8, elongated myotubes are visible, parallel to the lanes of the pattern.

Myotubes were further characterized by immunofluorescence assay for specific skeletal muscle proteins: Desmin and Myosin Heavy Chain (MHC), together with nuclei staining. These two proteins are components of the contraction machinery of the skeletal muscle, thus related to the main tissue functionality *in vivo*. Figure **3** shows myotubes as elongated multinucleated cells formed by the fusion of myoblasts. Immunofluorescence analysis

detected the expression of both Desmin and MHC. As highlighted in Figure **3**d, within our *in vitro* system, Desmin is not only expressed, but also properly localized within myotubes according to a regular pattern typical of a functional striated muscle.

Overall, this characterization shows the *in vitro* maturation of myotubes in microfluidics, according to multiple features characterizing the *in vivo* skeletal muscle. Thus, the *in vitro* system we developed could be a reliable model for studies of skeletal muscle response under external stimuli.

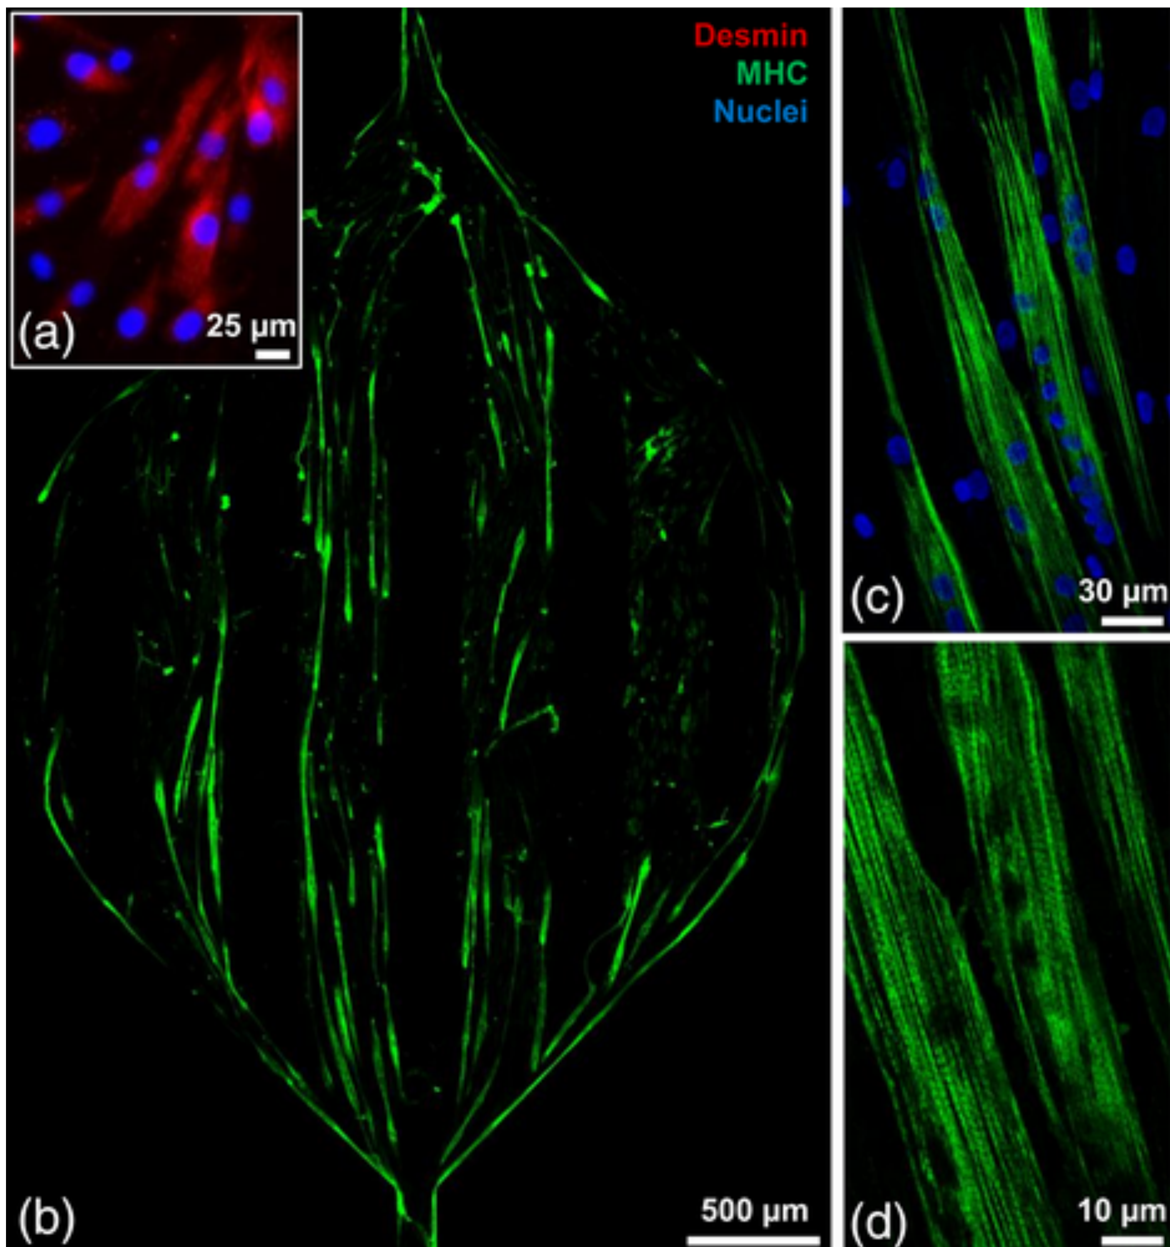

Figure 3

Characterization by immunofluorescence of myotubes within the skeletal muscle-on-chip system. (a) Desmin and nuclei staining. (b) Myosin heavy chain (MHC) staining of a whole patterned culture chamber. (c–d) Enlargement from (b), highlighting the skeletal myotube sarcomere organization into a striated regular pattern, with and without nuclear staining.

Adipose tissue and skeletal muscle cross-talk

Skeletal muscle is the tissue responsible for most of glucose uptake from the blood stream.[11] Insulin signaling pathway within muscle cells is a complex network of protein interactions that is activated in response to the presence of high concentrations of extra-cellular insulin, which is produced by the pancreas.[26] In this work, we focus on the specific subnetwork of the insulin signaling pathway shown in Figure 4a, where, after insulin binding upon its receptor, a cascade of protein phosphorylation events is generated, ultimately leading to the translocation of glucose transporter GLUT4 to the cell membrane. Once it reaches the cell surface, GLUT4 plays as a channel for glucose entrance into the cell. Thus, this subnetwork links extracellular insulin concentration to cell glucose uptake. To understand the impact of unidentified signaling molecules secreted by an obese adipose tissue on skeletal muscle insulin-stimulated glucose uptake, we pinpointed the targets within this subnetwork by means of Western blot analysis: specifically, IRS1, and Akt and AS160 both in their unphosphorylated and phosphorylated states.

Once myotubes had reached their functional maturation within the chip, they were cultured in adipose tissue-conditioned medium for 24 h and then stimulated, or not, for 10 min with an insulin concentration physiologically sufficient to activate the pathway. After this stimulus, the culture was stopped, cells lysed, and cell protein content from each microfluidic culture chamber collected for quantification of selected proteins. We compared these results with a negative control given by cells stimulated, or not, with insulin without prior exposure to adipose tissue-conditioned medium. We also compared these results with a commonly used positive control given by cells stimulated, or not, with insulin after been exposed to a medium containing TNFα, which is a protein, produced also by the adipose tissue especially in obese patients, known to induce *in vitro* insulin impaired response on healthy myotubes.[27] Thanks to the small number of cells required in each microfluidic platform, cells from the same patient could be used to test all these conditions in parallel.

The results of protein quantification at the end of the experiment are reported in Figure 4b-d. First, in the negative control condition, insulin stimulation does not affect IRS1 total content, and strongly induces Akt and AS160 phosphorylation. Thus, the *in vitro* skeletal muscle model we developed reproduces the known features of a normal insulin response.[26]

Second, in the positive control, TNFα does not affect the total IRS1 content (Figure 4b). IRS1 expression is known to have reduced expression in obese patients.[28] This result may point out the limitations related to TNFα use for mimicking the complexity of adipose tissue-skeletal muscle cross-talk in obesity. On the contrary, TNFα significantly decreases insulin-induced Akt phosphorylation (Figure 4c); however, despite reduced activation of Akt, AS160 phosphorylation is comparable to the negative control in this condition (Figure 4d). Due to the complexity of the overall insulin signaling network, it is not possible to discriminate between two possible scenarios: (i) the reduced activation of Akt is still not limiting for AS160 phosphorylation, and (ii) the network is redundant and another kinase can phosphorylate AS160 compensating for Akt reduced activity, as it occurs when AS160 is phosphorylated by stimuli other than insulin.[29] This result is in contrast with another study where TNFα was shown to decrease AS160 phosphorylation; however, due to the very different experimental design and duration of the stimulation, it is difficult to have a direct comparison between the two studies.[30]

Last, adipose tissue-conditioned medium more strongly disrupts skeletal muscle insulin response: IRS1 content is approximately halved (Figure 4b), and both Akt and AS160 show a limited response to insulin in terms of fraction of phosphorylated protein, while the basal (noninsulin stimulated) phosphorylated fraction is comparable in the three conditions with different preconditioning (Figure 4c,d). The comparable phosphorylation level of Akt between the adipose tissue-conditioned medium and TNFα containing medium, seems to support the second scenario suggested earlier, and we can speculate that, because multiple signals are secreted by the adipose tissue, the impact on the insulin signaling network occurs at different nodes, disrupting the redundancy of its functionality.31, 32

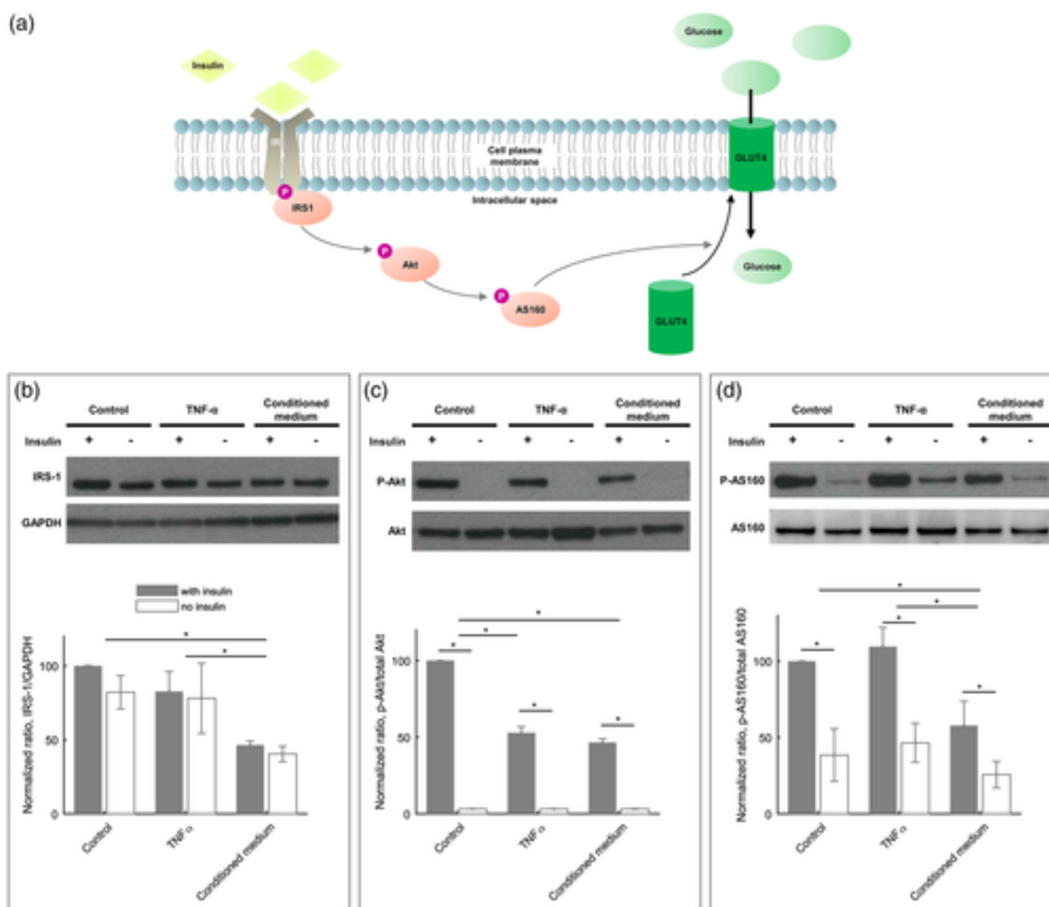

Figure 4
Results of the cross-talk between a human adipose tissue from an obese patient and a skeletal muscle from two healthy patients. (a) Schematic representation of insulin signaling pathway in a skeletal muscle cell, limited to the components of the pathway measured in this study: extracellular insulin binds to the insulin receptor (IR) and activates a phosphorylation cascade that ultimately induces the translocation of the glucose transporter GLUT4 to the cell plasma membrane. The main physiological effect of this pathway is the insulin-stimulated uptake of glucose by the skeletal muscle. (b–d) Quantification, by Western blot analysis, of insulin signaling-related proteins in myotubes after a 24-h preconditioning with TNFα or adipose tissue-conditioned medium, and a 10-min insulin stimulation.

Conclusions

In this study we reported the first *in vitro* human skeletal muscle-on-chip model. We characterized it morphologically, biochemically, and functionally, demonstrating its ability to respond to insulin stimulation. Besides the biological reliability of this model, miniaturization also decreases the requirements in terms of number of cells and amount of conditioned medium, favoring throughput and parallelization of experiments. Due to the high variability of biological systems, a design of experiments that tests several conditions on the same biopsy strongly enhances the statistical significance of the results.

In perspective, we envision that tissue-on-chips will be more and more used to bring physiological studies from the patient to the laboratory bench, in terms of tissue cross-talk. *In vitro* systems expand the parameter space of possible investigations respect to *in vivo* studies, helping the dissection of biological mechanisms. For example, here we could show the interaction between an adipose tissue from an obese patient and a skeletal muscle from a healthy patient, comparing this to the same tissue not subjected to the pathological perturbation. This kind of tissue cross-talk studies could be relevant in understanding disease pathogenesis with high accuracy at the molecular level, and ultimately developing tissue-targeted therapies.**6**
