1. Introduction

The standard configuration of space solar power systems is based on triple junction III-V solar cells on a Ge substrate, that acts as a bottom sub-cell, but also provides mechanical structure and a barrier between the solar cell structure and the metal from the contacts. Devices with the thin-film architecture, on the other hand, are becoming increasingly relevant for space application studies, due to its reduced weight, flexibility [1–4] and possibility of wafer reuse [5–7], which would result in a significant reduction of costs to the system. An important point of concern for the application of thin-film devices in space, however, is the application of a copper foil as a conductive carrier to the back of the cells. Copper is known to be a fast diffuser in many semiconductors, and upon the challenging conditions of space, it may be harmful to the solar cells’ performances [8,9].

Currently, most of the space solar power applications are directed towards communication satellites operating in Geostationary Earth Orbits (GEO) or in satellite constellations in Low Earth Orbits (LEO) [10]. However, new advances in satellite technology, such as elliptical orbits that partially operate in the vicinity of the Van Allen radiation belt, require the understanding of solar cell degradation upon higher levels of radiation exposure [11]. Electron irradiation is the most commonly studied characterization method to replicate cell performance under irradiation damage in the space environment [12–18]. Using this method, a pre-defined equivalent irradiation dose of 1-MeV electrons is used to simulate the displacement damage from electrons, protons, ions and neutrons of different energies throughout the entire mission. The equivalent fluence usually associated to GEO missions is achieved with $1 \times 10^{18}$ 1-MeV electrons/cm$^2$, while 5 to 10 times lower doses are required for the simulation of LEO missions. The solar cells degradation constants for performance prediction available in literature, however, differ significantly [11,19,20]. Commonly, degradation is described in terms of experimentally determined parameter remaining factors which are valid for one particular cell architecture rather than for...
the applied absorber material in general [21].

In a recent study [22], a combined experimental and theoretical analysis of the performance of GaAs solar cells with multiple architectures subjected to electron irradiation fluences equivalent to GEO missions is reported, and a consistent physical model for cell performance simulations (CPS) is proposed. An important finding from this modeling study is that, besides the increase in Shockley-Read-Hall (SRH) recombination, which reduces the minority carriers SRH lifetimes, the electron irradiation strongly affects the quality of hetero-interfaces, characterized by a linear increase in the interface recombination velocity ($S_{p(0)}$). Therefore, in addition to the SRH lifetime degradation constant ($K_{p(0)}$), the model considers a linear increase in $S_{p(0)}$ and an interface recombination velocity degradation constant ($K_{Sp(0)}$) is also introduced. As a result from the CPS model fit, a coherent set of material-dependent damage constants is derived. Furthermore, this study showed that exposure to electron irradiation does not introduce additional defects to devices with the thin-film architecture, which have a Cu-foil applied as a conductive carrier. In fact, a thin-film solar cell with a shallow junction geometry showed the highest end-of-life (EOL) performance, with an efficiency equivalent to 82% of its initial value. But even though the copper was shown to comply well with the incidence of electrons, it is not known whether the incidence of different charged particles will have adverse effects to the metal-semiconductor interface, applied in direct contact to the epi-structures in this architecture.

In the present study, the previously developed CPS model is further validated for 1-MeV proton irradiation, and includes more harmful particle fluences than the equivalent to the standard GEO mission (up to $5 \times 10^{12}$ 1-MeV H$^+$/$cm^2$). Proton irradiation is a less used characterization method, and the equivalent doses are not as well defined. It has been established that the degradation of the solar cells short circuit current density ($J_{sc}$) upon irradiation depends primarily on the fluence, while the impact of radiation on other cell parameters such as the non-radiative recombination in the space charge region and the $V_{oc}$ is dependent on the particle type. As compared to electrons, protons have shown to cause relatively higher damage in GaAs solar cells $V_{oc}$ and have a very irregular damage profile for lower energy particles [23,24].

A broad variation of cell architectures is applied in order to isolate the radiation damage to the hetero-interfaces from effects in the bulk of the absorber. These include devices with different junction depths (i.e. shallow and deep-junction devices) as well as cells with and without their native substrate included in the final device structure (i.e. substrate-based and thin-film cells). Moreover, the comparison between substrate-based and thin-film solar cells with otherwise identical structures allows the identification of any possible copper-related defects resultant from proton irradiation. The direct conversion of the previously reported electron irradiation degradation constants, based on the particle equivalent displacement damage dose (DDD), resulted in a good representation of the experimentally obtained dark and illuminated $J-V$ and external quantum efficiency (EQE) curves. Furthermore, an earlier reported voltage-dependency of the photocurrent [11] is seen in the irradiated cells.

2. Methods

All solar cells used in this study were grown by low-pressure MOCVD on 2 inch diameter GaAs wafers with (1 0 0) 2 off to (1 1 0) orientation. The structures consist of solar cells with either a thin n-doped emitter and a thick p-doped base, here called shallow junction (SJ) geometry, or a thick n-doped emitter and a thin p-doped base, here called deep junction (DJ) geometry. In order to evaluate the effect of irradiation on solar cells with reduced thickness, thinner DJ devices were also produced. Schematic depictions of the studied cell structures are shown in Fig. 1a–c, indicating the cells active layers thickness and acceptor and donor doping densities ($N_A$ and $N_D$). Additionally, all structures have a 20 nm AlInP window and 100 nm InGaP back surface field (BSF) on the top and bottom of the active layers. The top most layer in all cells consists of a 300 nm n-GaAs contact, which provides low resistance ohmic contact.

The cells were processed either in the substrate-based form (SB) or into thin-film (TF) devices. For the thin-film solar cells, the first grown layer consists of an etch-stop AlGaInP layer, in order to limit the etching into thin-film (TF) devices. For the thin-film solar cells, the first grown layer consists of an etch-stop AlGaInP layer, in order to limit the etching of the wafer, followed by a p-AlGaAs contact layer. The wafer was

![Fig. 1. Schematic depiction of a) the shallow junction, b) the deep junction and c) the thinner deep junction active layers thicknesses and acceptor and donor doping densities ($N_A$ and $N_D$), and a representation of the solar cell structures processed into d) substrate based (SB) and e) thin-film (TF) devices.](image-url)
removed with an aqueous citric acid and hydrogen peroxide solution (5:1 in volume) and the etch-stop layer was removed in HCl 37%. This simplified chemical etching procedure is more time-efficient and has a better yield than the more elaborative epitaxial lift-off (ELO) method, both important aspects, considering the large amount of samples required for the irradiation tests. The final thin-film devices resulting from chemically removing the substrate, however, do not differ in quality from cells produced by the ELO method, and therefore their resilience to radiation should be equivalent.

A 200 nm thick Au rear contact/mirror was electron-beam evaporated onto the rear side of the cell, and a copper foil that acts as a conductive foreign carrier was electroplated to the back of the cell. In the substrate-based devices, the back contact consists solely of 100 nm thick electron-beam evaporated Au.

The cells all have 200 nm thick Au electron-beam evaporated front contacts. This front grid includes a large contact pad to facilitate easy placement of electrical probes for cell measurements, resulting in a surface coverage of 16.6%. The 5 × 5 mm² individual cells were defined by a MESA etch using an ammoniacalhydrogen peroxide solution for the GaN layers and either an HBrBr₂H₂O solution (for the thin-film cells) or HCl 37% (for the substrate based cells) for the phosphide layers. The n-GaAs contact layer between the grid fingers was removed also using an ammoniacalhydrogen peroxide solution. Finally, an anti-reflection coating (ARC) consisting of 44 nm ZnS and 94 nm MgF₂ was thermally evaporated on the top surface of all cells. A schematic depiction of the processed substrate based and thin-film devices is shown in Fig. 1d and e.

From each 2 inch wafer, 38 regular solar cells and 6 cells with an open grid dedicated for optical characterization were fabricated. The latter cells, instead of a grid, only have a square shaped contact frame at the outer edge of the front surface. The wafers were cleaved in quarters consisting of 11 solar cells and mounted to copper plates to be subjected to a specific radiation dose. The substrate-based cells were fixed to the plates using Kapton tape at the corners of the wafer. In this way an electrical contact between the rear contact of the cell and the copper plate is induced that allows convenient electrical probing of the cell with both probes at the front side. The thin-film devices were mounted to the copper plate using double sided tape, as their rear contact can be easily reached from the front side at any location between the individual cells (see Fig. 2).

The samples were exposed to proton fluences of 5 × 10¹⁰, 2 × 10¹¹, 5 × 10¹¹, 2 × 10¹² and 5 × 10¹² H⁺/cm² of 1-MeV radiation, performed at the Center of Nuclear Science and Materials Science (CSNSM) of Paris-Sud University with a Van der Graaf accelerator. The used proton flux is equal to 1 × 10⁶ H⁺/cm²/s for the lower two doses and 1 × 10⁷ H⁺/cm²/s for the higher three doses.

Illuminated J – V, dark J – V and External Quantum Efficiency (EQE) characteristics were measured before and after exposure to radiation. Illuminated and dark J – V characterization of the solar cells were performed using an ABET Technologies Sun 2000 Class AAA solar simulator set-up, equipped with a Keithley 2601B source meter, and ReRa Tracer3 software for data acquisition. The solar cells were kept at 25°C during measurement using a heating/cooling water thermostat and a Pt100 temperature sensor. The light intensity was set and corrected using an NREL calibrated reference cell before each measurement series. Because at higher voltages the series resistances cause the dark curve to bend downwards, a set of Jₑ – Vₑ data points measured under different light intensities was used in the dark characteristics analysis, as the series resistance is excluded under these conditions [25]. EQE measurements were performed with a ReRa SpekQuest Quantum Efficiency system. The system uses both a Xenon and Halogen light source to address all wavelengths present in the solar spectrum, a monochromator to generate quasi-monochromatic light and a chopper for intensity modulation. Due to shadow losses in the front grid, the EQE curves were corrected based on their Jₑ values obtained by the analysis of the illuminated J – V.

The cells illuminated performances are modeled based on the 1D analytical Hovell model, including light reflection and photon recycling [26-29], as described in a previous publication [22]. The reflectance of the cells’ front surface was calculated from the intended thickness of the ARC layers. Because there may be some difference between the intended and the actually deposited thickness, there is a level of uncertainty in the EQE fitting process, resulting in some deviations between the modeled and measured values. The main trends and shape of the curves are, however, modeled correctly.

The dark currents are in the first place analyzed as two diodes in parallel, which after de-embedding the possible influence of the parasitic series and shunt resistances, can be expressed as:

\[
J_{\text{dark}} = J_{\text{01}} \left( e^{\frac{qV}{kT}} - 1 \right) + J_{\text{02}} \left( e^{\frac{qV}{2kT}} - 1 \right)
\]

where \( q \) is the electron charge, \( k \) is the Boltzmann constant, \( T \) is the temperature and \( J_{\text{01}} \) and \( J_{\text{02}} \) are the saturation current densities at the 1\( kT \) and 2\( kT \) components of the curve, respectively. At higher voltages, the dark curve is dominated by \( J_{\text{01}} \), which is composed by the diffusion...

Fig. 2. Example of one quadrant of a 2-inch wafer containing multiple 5 × 5 mm² cells with the a) substrate based and b) thin-film architectures, to be subjected to a specific radiation dose. Note the large front contact pads to facilitate easy probing of the individual cells and the difference between the cells with regular grid and frame contacts for J – V and EQE analysis, respectively.
and radiative recombination current densities at the quasi-neutral regions (QNR).

The \( J_{QNR} \) component, on the other hand, involves the non-radiative recombination that takes place predominantly in the space charge region (SCR) and the perimeter of the cell, dominating the dark current at lower voltages. The contribution from the SCR can usually be modeled according to the Shockley-Read-Hall theory \([26,30]\), with analytical or semi-analytical formulations available under the assumption of a single mid-gap defect level \([30]\) and for the more realistic case of multiple trap levels \([21]\). In the case of the solar cells in this study, however, their relatively small size results in a large contribution from perimeter recombination to the dark curves \([31,32]\), which cannot be theoretically determined with sufficient accuracy. Therefore, while \( J_{QNR} \) was also calculated as reported in a previous publication \([22]\), the \( J_{QNR} \) values used for simulating the cells dark and illuminated \( J-V \) curves, both at BOL and upon irradiation, were experimentally obtained.

The BOL interface recombination velocities in the hetero-interfaces emitter-window (\( \mathcal{S}_n \)) and base-BSF (\( \mathcal{S}_p \)) were estimated by the comparison of the theoretically calculated \( J_{01} \) to the extracted values from the experimental dark curves, using equation (1). These values were then more finely adjusted by the fitting of the EQE curves.

3. Results and discussion

3.1. Solar cell performance at the beginning of life

The solar cells average illuminated \( J-V \) parameters at BOL are displayed in Fig. 3, as well as the maximum and minimum obtained values. The cells produced from a single epi-structure presented a high reproducibility in performance, with the thin-film devices showing a slightly larger spread of the parameters due to the increased number and less routinely applied processing steps. Overall, the short-circuit current of the thin-film solar cells is higher than the equivalent substrate-based devices due to the reflectance at the rear mirror of the long wavelength portion of the incident light that is not absorbed in the first pass through the active layers. Furthermore, the relatively large front grid coverage (16.6%) causes the solar cells current density, and efficiency \( \eta \), to be proportionally reduced, as compared to previously reported cells \([25,33]\). If the \( J_{sc} \) is corrected for the active area, the devices’ approximated average efficiencies range from 24.6% (thin SB-DJ) to 27% (TF-DJ). These efficiencies indicate high material quality, for which the BOL collection and mobility parameters are well approximated by the theoretical models \([28,34]\).

The BOL dark saturation current densities \( J_{01} \) and \( J_{02} \) are deduced from the best fit of equation (1) to the cells dark characteristics and \( J_{sc} - V_{oc} \) data under different light intensities. The extracted values are displayed in Table 1, together with all the relevant calculated BOL parameters for the five solar cell structures. The reason for the differences in minority carrier mobility values between the shallow and deep junction cells is due to the doping dependence of the diffusion coefficient \([34]\) and the fact that the two geometries have different doping concentration of the emitter and base layers.

If \( \mathcal{S}_n \) and \( \mathcal{S}_p \) are assumed to be negligible, the calculated \( J_{01} \) values show a considerable discrepancy to the experimentally deduced values. From this, it could be deduced that, for all cells the interface recombination is limiting the dark curves at the \( 1kT \) region, with values ranging between \( 1 \times 10^{10} \) and \( 5 \times 10^{10} \) cm/s. With the analysis of the cells’ EQE curves, \( \mathcal{S}_n \) and \( \mathcal{S}_p \) can be more precisely determined, and the resulting recombination velocities are depicted in Table 1.

3.2. Solar cell performance degradation upon proton irradiation

The averaged remaining factors of the illuminated \( J-V \) parameters of the cells upon proton irradiation, normalized to the BOL values, are shown in Fig. 4, together with the modeled curves. It is clear that both thin-film and substrate-based devices with a SJ geometry are less sensitive to irradiation damage than the cells with the DJ geometry, and the thinner DJ cells present a much lower degradation than their thicker counterparts, in particular for lower fluences.

The \( J_{sc} \) and \( V_{oc} \) remaining factors overlap for both thin-film and substrate-based devices with similar junction depth, even though the absolute values are different due to the higher BOL performance of the TF cells, indicating that there is no additional Cu-related defects caused by the incidence of protons. This indicates that the use of copper foil as a convenient low-cost carrier and rear contact for thin-film solar cells does...
not require reconsideration because of the encountered proton irradiation in space applications.

Because proton irradiation exposure is expected to create uniform damage throughout the GaAs active layers, the radiation-related degradation is expected to be material dependent, creating displacement defects and reducing the average minority carriers lifetime. All changes in performance should, therefore, be caused primarily by reduction of the minority carriers lifetime and degradation of heterointerfaces [22], being independent of solar cell geometry and processing steps. Because of this, the changes in dark $J - V$ and EQE characteristics of the thin-film cells upon irradiation are highly similar to those of the substrate-based cells, and therefore only the latter are shown in Figs. 5 and 6.

The performance degradation mechanism is well illustrated by the EQE curves, shown in Fig. 5. The differences between the SJ and DJ geometries are related to the fact that the absorption of light into the cell decreases exponentially, so the largest fraction of light is absorbed in the upper part of the cell. In the SJ cells (Fig. 5a), most of the photo-generated free carriers, therefore, only have to diffuse over a short distance to the $p - n$ junction to be drifted towards the right electrode and be collected. For longer wavelengths a smaller fraction of the light is able to penetrate deeper into the cell and consequently generate some minority carriers deeper in the base, which have to travel further before reaching the $p - n$ junction. Upon irradiation, these carriers face an increased SRH recombination probability, decreasing the EQE at longer wavelengths. In DJ cells (Fig. 5b), on the other hand, most of the minority carriers generated in the thick emitter have to diffuse over a long distance before reaching the $p - n$ junction, with the exception of the small fraction generated deeper in the cell. Therefore, the collection efficiency in these cells is basically reduced over the entire wavelength, being only slightly higher for the longer wavelength portion of the light.

Fig. 4. Average remaining factors of a) $J_{sc}$, b) $V_{oc}$, c) FF and d) η of the four different structures subjected to different radiation doses. The markers in these figures represent the experimental results and the lines are the modeled curves.
The degradation of the thinner SB-DJ cells (Fig. 5c) has a similar profile, but the reduced emitter thickness results in a smaller average distance between the location where light is absorbed and the SCR, and therefore the reduction of the EQE is less extreme than for the thicker devices.

In Fig. 6 the measured dark curves (dark blue lines of connected markers) and the $J_{sc}$, $V_{oc}$ values under different illumination intensities (red markers) are shown, as well as the best 2-diode model fits (equation (1)) to these measured quantities. The extracted parameters $J_{01}$ and $J_{02}$ of the irradiated cells are displayed in Fig. 7. It is important to note that, in particular for the DJ solar cells, there may be some uncertainty with regards to the $J_{01}$ values of the irradiated cells, since the dark curves are dominated by the $2kT$ component. The $J_{01}$ increase for the different cell geometries is consistent with the degradation in EQE as described above, with a large difference between the saturation currents of the SJ and the DJ cells. The increase of $J_{02}$, on the other hand, is much more uniform between the solar cell architectures. This illustrates that, while the radiation-induced degradation of the perimeter and SCR affects the different cell geometries in a similar way, the junction depth determines how strongly the QNR and hetero-interfaces degradation will reduce the performance.

The total damage that the incidence of charged particles will generate in the semiconductor material is proportional to the incident particle non-ionizing energy loss (NIEL) \([35,36]\), or the amount of energy deposited by the particle passing through the material and resulting in displacement processes. It is possible to calculate the absorbed NIEL dose (or the displacement damage dose, DDD) of different types of irradiation by:

$$DDD = \phi \times \text{NIEL},$$  \hspace{1cm} (2)

where $\phi$ is the charged particle fluence. The NIEL values calculated by Baur et al. \([36]\) for a displacement threshold energy of 21 eV, are $\text{NIEL}_{e} = 1.125 \times 10^{5} \text{ MeVcm}^2/\text{g}$ for 1-MeV electrons and $\text{NIEL}_{p} = 4.967 \times 10^{-2} \text{ MeVcm}^2/\text{g}$ for 1-MeV protons. Using equation (2), the $J_{sc}$ of the studied solar cells is presented as a function of DDD in Fig. 8. For comparison, the data from previously reported GaAs solar cells subjected to electron irradiation \([22]\) is also presented in this figure.
Furthermore, the DDD value equivalent to the electron radiation dose of $1 \times 10^{15} \text{e^{-}/cm}^2$, usually associated to GEO missions, is highlighted by the dotted line in the figure as a reference.

Although the active layer thickness of the various cell configurations evaluated in the previous study were slightly different, overall the $J_{sc}$ remaining factors from the proton and electron irradiated cells as a function of DDD show a good correlation. For the SJ cells, the small variations in thickness between the different studied cell structures do not impact the degradation, resulting in a near perfect overlap of results in the DDD range that is covered by each of the two irradiation studies. For the DJ cells, on the other hand, the degradation is very sensitive to the small changes in active layer thickness, resulting in small discontinuities between the curves following from $\text{e^{-}}$ and $\text{H}^+$ irradiation. For the thinner DJ cells, the reason for the increased resilience to irradiation of

**Fig. 6.** Dark $J-V$ characteristics of a) shallow junction and b) deep junction solar cells in the substrate-based architecture after exposure to different levels of proton radiation. The isolated red circular markers represent the measured $J_{sc}-V_{oc}$ values under different light intensities, the square blue markers that appear as continuous lines are the measured dark curves and the dashed lines show the curves deduced from the 2-diode model (equation (1)). (For interpretation of the references to colour in this figure legend, the reader is referred to the Web version of this article.)

**Fig. 7.** Dark curve parameters a) $J_{01}$ and b) $J_{02}$ extracted from the dark curves of the solar cells subjected to different doses of proton irradiation, using the two-diode model (equation (1)). The lines in these figures are merely a guide to the eye.

Furthermore, the DDD value equivalent to the electron radiation dose of $1 \times 10^{15} \text{e^{-}/cm}^2$, usually associated to GEO missions, is highlighted by the dotted line in the figure as a reference.
The \( K'_{\text{pro}} \) values used for fitting the experimentally obtained EQE and dark \( J - V \) characteristics upon proton irradiation are the direct results from the equivalence proposed in equation (5). As a starting point, a similar conversion was made to \( K'_{\text{pro}} \), but since this latter value was found to vary between the different geometries of the electron irradiated cells [22], it was adjusted to improve the fitting of the curves. The resulting lifetime and interface recombination degradation constants used in the model are stated in Table 2.

Fig. 9 depicts the reciprocal lifetime values of the SB-DJ and SB-SJ cell geometries simulated using these constants, for a large range of DDD, equivalent to proton fluences from approximately \( 2 \times 10^8 \) to \( 2 \times 10^{13} \) \( \text{H}^-/\text{cm}^2 \). The equivalent DDD of the studied proton and electron [22] irradiation doses are marked. For high irradiation doses, the cells’ minority carrier lifetime is limited by the \( K'_{\phi} \) component from equation (3), which is also highlighted in the figures, independent of their BOL values.

Aside from \( J_e \) and \( V_m \) degradation, the fill factor (FF) of the solar cells also decreases upon irradiation (see Fig. 4c). The shape of the illuminated \( J - V \) curves of the irradiated cells presents an effect resembling that of a reduced shunt resistance (see example in Fig. 10b), yet the dark characteristics of the cells, shown in Fig. 6, do not indicate the same effect. This difference between the illuminated and dark characteristics was also observed in a study by Salzberger et al. [11], where the voltage dependency of the space charge region width is suggested to explain the voltage-dependent photo-current. We can model the width of the emitter \((w_E)\) and base \((w_B)\) fractions of the space charge region by Ref. [37]:

\[
w_E = \frac{2\varepsilon_0 \varepsilon_r N_A}{q d (N_A + N_D)} (V_m - V)
\]

and

\[
w_B = \frac{2\varepsilon_0 \varepsilon_r N_D}{q d (N_A + N_D)} (V_m - V)
\]

where \( \varepsilon_0 \) is the vacuum permittivity, \( \varepsilon_r \) is the relative permittivity of GaAs and \( V_m \) is the built in potential of the junction. The proportions to which \( w_E \) and \( w_B \) are reduced upon the application of a voltage larger than zero, for the DJ and SJ geometries, are visualized in Fig. 10a. The effect of this reduction on the shape of the curve is illustrated in Fig. 10b, where the illuminated \( J - V \) curve of an irradiated SB-DJ cell is simulated considering either a constant SCR width, equal to the width at BOL and \( J \) (equation (3)), which is also highlighted in the figures, independent of their BOL values.

Aside from \( J_e \) and \( V_m \) degradation, the fill factor (FF) of the solar cells also decreases upon irradiation (see Fig. 4c). The shape of the illuminated \( J - V \) curves of the irradiated cells presents an effect resembling that of a reduced shunt resistance (see example in Fig. 10b), yet the dark characteristics of the cells, shown in Fig. 6, do not indicate the same effect. This difference between the illuminated and dark characteristics was also observed in a study by Salzberger et al. [11], where the voltage dependency of the space charge region width is suggested to explain the voltage-dependent photo-current. We can model the width of the emitter \((w_E)\) and base \((w_B)\) fractions of the space charge region by Ref. [37]:
devices the reduced SCR width affects more strongly the bottom portion of the cells, which has a lower carrier generation rate, the effect of proton irradiation on the FF of cells with this geometry is smaller. The good agreement between the model simulations and the experimental curves, shown in Figs. 4, 5 and 8, further validates the previously developed CPS model to proton irradiation. The damage constants to the SRH lifetimes used in this study were directly converted from the previously extracted to electron irradiation, and minor adjustments were made to the interface recombination velocity damage constants. The present study clearly demonstrates that these constants can be converted and applied to predict cell performance degradation under proton irradiation, which suggests that the approach can probably be used to any particle type and energy with a known NIEL value. The performance degradation of a multitude of solar cell structures can therefore be simulated to the specific application conditions, providing a good quality of the epilayers at BOL.

4. Conclusions

In this study, a recently developed method to simulate the performance degradation of GaAs solar cells upon electron irradiation is applied to analyze the effects of proton irradiation exposure to the devices. In order to isolate the radiation damage to the bulk of the absorber from effects in the hetero-interfaces, solar cells with a broad range of architectures were subjected to proton irradiation fluences up to $5 \times 10^{12} \text{H}^+/\text{cm}^2$.

The reported degradation of the quality of the hetero-interfaces, characterized by an increase in interface recombination velocities, is also observed in this study. Furthermore, a NIEL-based conversion of the minority carrier lifetime as well as the interface recombination velocity degradation constants derived from the electron irradiation studies is sufficient to obtain a good correlation between experimental and theoretical results, further confirming the validity of the model. These degradation constants are material dependent, being quite insensitive to the cell’s geometry and processing steps, allowing performance
prediction of GaAs solar cells of different architectures, not limited to the structures used in this study.

Because the utilized fluences are representative of more extreme radiation doses than the equivalent for GEO missions, a strong degradation in performance of all solar cell geometries is observed. It is shown that, similarly to electron irradiation, the incidence of protons affects the performance of the solar cells mainly by reducing the minority carrier lifetimes. Therefore, the distance from the space charge region to the location where carriers are generated is the determining aspect with regard to the cell’s resilience to radiation. Since for the DJ cells upon irradiation the hole diffusion length is much smaller than the emitter thickness, the collection of generated carriers is strongly reduced, and this geometry presents a much larger decrease of $J_{sc}$ as compared to SJ devices. Furthermore, a pronounced voltage dependency of the photocurrent is introduced in all cell structures, reducing the cell’s fill factor by up to 20%.

The main advantage of the thin-film geometry, as compared to substrate-based devices, is that the presence of a rear reflector allows the production of thinner cells with comparable efficiency. Thinner devices are less sensitive to reduced diffusion length, resulting in higher resilience to radiation damage. High quality thin-film solar cells also have the potential to achieve higher performances at beginning-of-life due to increased photon recycling, representing an interesting geometry for space applications. Copper foil represents a convenient low-cost carrier and rear contact for such thin-film cells. Whereas copper diffusion can be a potential problem in semiconductor devices, the present study demonstrates that proton irradiation levels up to $5 \times 10^{23}$ H/cm$^2$ do not induce such problems.
