Abstract

The autonomic nervous system (ANS) drives different non-voluntary responses, which can be investigated by multiple sensors. We propose a modular hardware prototype for the noninvasive acquisition, processing and transmission of biological signals to analyze the ANS in synchrony with the video recording of the pupil. The implementation includes 1) two noninvasive sensors, a pulse oximeter and an electrodermal activity sensor, 2) a module able to collect the information and send it to the PC via USB and 3) a graphic user interface for visualization, synchronization and data saving. A series of experimental tests were performed to investigate the effect of different stimulations: light, dental occlusion, transcutaneous electrical nerve stimulation (TENS) and mental efforts. They indicate the reliability of the system and the importance of the joint detection of more signals for discriminating different states of the ANS. Specifically, heart rate, Galvanic response and pupil size were compared, showing some coherence in their oscillations and a different ability to discriminate between the stimulation conditions. Their joint detection is thus important for discriminating different states of the ANS.

Keywords: Pulse oximetry, Electrodermal Activity (EDA), Galvanic Skin Response (GSR), Pupillogram, Autonomous Nervous System (ANS), Transcutaneous Electrical Nerve Stimulation (TENS), Embedded systems.

1 1. Introduction

The autonomic nervous system (ANS) is the portion of the central nervous system that controls unconscious activities, such as visceral functions and homeostasis [1]. It is divided into two main branches, the sympathetic and the parasympathetic, the first promoting the activation of a physiological response and the other inhibiting it. The ANS is profoundly affected by emotions and somatosensory inputs and plays an important role in pain and stress modulation and perception.

Autonomic testing finds application in the clinical assessment of neurological disorders, particularly those affecting predominantly small nerve fibres [2]. Many studies have been devoted to the quantitative assessment of the ANS response, dating back to more than 3 decades [3][4][5]. However, most of the literature takes into account just one of the numerous physiological systems that are affected by the ANS in turn.

Very frequently the works that have dealt with ANS in different disorders 15 related to its dysfunction have focused on cardio-circulatory parameters [6]. 16 However, there are many other potential peripheral effects of ANS which 17 could be deepened. For example, a physiological system related to the ANS 18 can be investigated measuring skin conductance, reflecting the sweating of 19 the sweat glands [7]. Moreover, pupil is strongly affected by the ANS [8]. The 20 study of mydriasis and myosis (i.e., the dilation and contraction of pupil) is 21 usually done in a different context (vestibular system). However, recent stud-22 ies have indicated the possibility of characterizing the condition of the ANS 23 in healthy or pathological conditions, by analyzing the nonlinear pupil oscil-24 lations [9][10][11][12][13][14]. Moreover, the study of pupillary dynamics was 25 considered useful for evaluating the arousal state during mental effort due to 26 cognitive tasks [15][16], in relation to the involvement of reward systems [17] 27 and in the development of Human-Machine Interfaces [18]. Furthermore, it 28 has been suggested that the use of different ANS parameters, including pupil 29 size, may be useful for better characterizing and quantifying the emotional 30 component linked to the autonomous response [19]. Moreover, further evi-31 dence was provided that pupil can be used to evaluate the state of emotional 32 arousal as well as the generic activation of the ANS [20]. 33

One of the limitations of the study of various ANS responses is the use of different instruments for the analysis of different signals. However, it was argued that pupillogram could provide useful information for the study of the arousal state and that it would receive a valid contribution from the association with signals already used for this purpose, such as skin conductance and electrocortical activity [21]. These observations would involve an important expansion of the combined and synchronous study of various parameters associated with pupillography to aspects not only of pathology, but also related to the emotional / affective state. Thus, important outcomes could be expected both for clinical patients and for any study involving the psychic assessment of the arousal state.

Only recently, more reactions of the ANS have been investigated simul-45 taneously [22][23]. The signals that have been often analyzed are the cardiac 46 pulse and the variations of skin conductance. In this study, we are inter-47 ested in the investigation of those signals jointly with the pupil response. 48 A modular hardware prototype is developed for the noninvasive acquisition, 40 processing and transmission of biological signals and is synchronized with 50 a commercial system for pupil investigation. Our present implementation 51 includes: 52

- two noninvasive sensors, a pulse oximeter and an electrodermal activity sensor (both often used in the study of the responses of ANS [24][25][26]);
- a module able to collect the information and send it to the PC via USB;
- a graphic user interface (GUI) for visualization and data saving.

⁵⁸ Pulse oximetry and skin conductivity are acquired in synchrony with the ⁵⁹ video recording of the patient's dilation and constriction of the pupil (ac-⁶⁰ quired by a commercial system [27]). The system was developed to keep low ⁶¹ the production cost and energy consumption. It was tested in experiments ⁶² from healthy subjects under different stimulations: light, dental occlusion, ⁶³ transcutaneous electrical nerve stimulation (TENS) and computational task.

⁶⁴ 2. Design and Implementation

The recording system is shown in Figure 1. Two sensors, described below, are developed and are used together with a commercial system for pupil investigation [27].

Figure 1: A) General scheme of the instrumentation used. B) Commercial system for pupil investigation [27]. C) Acquisition system recording photoplethysmogram and skin conductivity level.

68 2.1. Design of the sensors

69 2.1.1. Pulse oximeter.

The first sensor measures the absorption of red and infrared lights that 70 pass through a patient's finger by light sensors. The light is generated with 71 2 LEDs that are controlled alternately. A photodiode receives both ambient 72 and modulated light from the LED and generates a current that is related 73 to the oxygen saturation and the cardiac frequency [28][29][30]. The pulse 74 oximetry signal (photoplethysmogram - PPG) has an amplitude of aprox-75 imately 300 nA and a frequency range related to the heart rate (which is 76 about 1 Hz), with maximum frequency contributions of a few Hz [31]. The 77 signal is affected by the line interference (50 Hz), the neon lamps that are 78 usually used in offices and laboratories (giving an interference at 100 Hz) 79 and motion artifacts (notice that high performance professional oximeters 80 are stable to ambient light and motion artifacts [32], but our low cost system 81 had to rely on simple solutions). The circuit design is shown in Figure 2A 82 and B. The current signal is transformed into a voltage signal in the 0.1 V-83 0.3 V range using a transimpedance amplifier with a gain of 820 kV/A. An 84 initial bandpass filter with cut-off frequencies of 0.8 and 15 Hz was imple-85 mented; however powerline and neon lamps interferences were still visible in 86 the resulting signal, therefore two notch filters were added to remove their 87 contributions. A final active low-pass filter with a gain G = 30 V/V was 88 added to make up for losses in amplitude through the filtering stages, result-89 ing in a total gain of 5 MV/A. For the actual implementation, the sampling 90 frequency of the PPG is 220 Hz. Notice that this sample rate is very high 91 (e.g., 100 Hz is usually used in clinical settings, but 25 Hz was found to be 92 sufficient to get a reliable estimation of the pulse rate variability [33]): thus, 93 it could be decreased for saving energy or memory. 94

95 2.1.2. Skin conductivity level sensor.

There are two skin resistance responses due to the electrodermal activity (EDA): the tonic and the phasic levels. The tonic level is the absolute level of resistance at a given moment in the absence of a measurable phasic response and is referred to as Skin Conductance Level (SCL). The phasic level or Skin Conductance Response (SCR) is superimposed on the tonic level and corresponds to the response to stimuli. The sum of the tonic and phasic response is the Galvanic Skin Response (GSR).

The skin conductance is obtained by measuring the current flow through the skin in response to a constant applied voltage. The circuit design is

shown in Figure 2C. For bipolar recordings, 0.5 V is recommended [34]. For 105 a resolution of 0.01 μ S (the minimum variation of the SCR [35][36]), the 106 minimum current to be amplified is of 5 nA. The maximum input current of 107 the amplifier is 15 μ A (related to the maximum SCR and SCL), therefore 108 the transimpedance of the circuit must be of 333 k Ω . This circuit has two 109 independent outputs that allow the analysis of each component separately 110 (however, their combination, i.e., the GSR, was considered in our tests shown 111 in the following). The sampling frequency is 170 Hz. Notice that this sample 112 rate is far beyond the Nyquist limit (even if some literature has suggested 113 even to further increase it to allow to apply more easily complex analysis or 114 advanced smoothing procedures [37]), so that it could be decreased if needed 115 (e.g., to save power consumption or memory storage). 116

Table 1 summarizes the data acquired, the filters used and their frequency ranges, and the adopted sampling frequencies.

Signal	Filtered Frequency Range	Sampling Frequency
Pulse oximeter	0.8 Hz - 15 Hz	220 Hz
	Using a band-pass filter	
	and additional 50 Hz and	
	100 Hz notch filters	
Skin Conductivity Level (SCL)	0 - 15 mHz	170 Hz
	Using a low-pass passive	
	filter	
Skin Conductivity Response (SCR)	10 mHz - 1 Hz	170 Hz
	Using a decoupling capacitor	
	and an active low-pass filter	

Table 1: Signals acquired, frequency range of the signals and sampling frequency.

119 2.2. Digital signal processing and transmission

The information coming from the analogue sensors was converted into 120 digital form, acquired, pre-processed and transmitted via USB to a PC. The 121 microcontroller Atmel ATmega 16 accomplished these tasks [38][39]. Such 122 a microcontroller was chosen as it is cheap and it has a high speed, a small 123 code size and an analog multiplier (which can be used to implement digital 124 filters). The connection of the microcontroller to the system is shown in Fig-125 ure 3. Notice that the internal 10-bit ADC was used for sampling the skin 126 conductance, whereas an external 16 bits analog-to-digital converter (ADC) 127 was included to sample the PPG (the considered external ADC is AD7715, 128

Figure 2: A) Schematic of the photoplethysmograph (abbreviations: PPG - photoplethysmogram; TIA - Transimpedance amplifier; LPF - low-pass filter; HPF - high-pass filter). B) Schematic of the LEDs driver. The signal from the microcontroller unit (MCU) controls which of the 2 LEDs is ON. C) Schematic of the skin conductance sensor. The 2 outputs are for the Skin Conductance Response (SCR) and the Skin Conductance Level (SCL).

which is a 16-bit Sigma-Delta ADC that can be interfaced with microcon-129 trollers using the Serial Peripheral Interface, SPI). The ADC requires up to 130 195 μ s for a single conversion, thus setting the sampling frequency of the 131 signals once they have been converted to approximately 5 kHz. To remove 132 noise added by the ADC, an average filter (of 5 samples for pulse oximetry 133 and 20 samples for the Galvanic skin response) was implemented in the mi-134 crocontroller. The filtered samples were then transmitted to the PC with 135 the USART (Universal Synchronous/Asynchronous Receiver/Transmitter), 136 which was interfaced with a USB transceiver. 137

The red and infrared lights for the pulse oximetry sensor must be ON in different cycles: the signal period was 1 ms, with a duty cycle of 0.25 and the phase between the two lights was 0.5 ms. The state of the LEDs was controlled using timer interrupt.

To manage the data, a software interface was developed in Visual Basic, with the following main functions.

- Registration of patient's information. The user should also be able to import the information from the database of pupillograms.
- Visualization of the signals. The charts update constantly to show the signals while they are being acquired.
- Storage of the signals. The information was stored in a file. This file contains the patient's information, the starting time of the acquisition (with a resolution of 10 ms), the time of each sample (recorded as lag from the starting time of acquisition) and the samples of the signals.

152 2.3. Pupillometry.

Images of the pupils were acquired by the Oculus system (Inventis srl, Padova, Italy), using two infrared CCD cameras (resolution 720x576 pixels, 256 grey levels) mounted on a light helmet (1.5 kg), with sampling frequency of 25 frame/s. The eyes were illuminated with an infrared diode with 880 nm of wave-length; moreover, during experiments on pupil dynamics under constant light conditions, illumination was provided by a yellow-green LED with 740 nm of wave-length.

Figure 3: A) General schematic of the digital processing unit. B) Microcontroller general flow diagram.

¹⁶⁰ 3. Experimental tests

In order to assess the reliability of our acquisition system, a pilot study on a few healthy subjects was performed. Specifically, signals were acquired, synchronized and then processed, extracting some descriptors to characterize different experimental conditions.

165 3.1. Signal acquisition

Three signals were acquired and then synchronized for subsequent processing. Specifically, videos of the pupils were acquired by a commercial system (Section 2.3), whereas pulse oximetry and variations of sweat were monitored with the system described in the previous sections, considering the PPG and the GSR time series.

¹⁷¹ 3.1.1. Synchronization of the signals.

The software of the considered system for pupil investigation [27] does not allow any kind of modifications or access. However, it allows to record the machine time in which each frame is acquired. The data from our prototype were recorded on the same PC. The starting time of the acquisition was saved (as mentioned above), with a resolution of 10 ms. Given that the sampling period of the pupillogram was 40 ms, this resolution was enough to synchronize the two systems.

179 3.1.2. Experimental set up.

The subjects were sitting in a high-back chair. The environment was kept at a constant temperature of 21°C. Visual predominance was determined. The acquisition system was then connected to the patient's non dominant hand. The helmet was applied and was maintained until the end of the recording. This phase took about 4 minutes.

The correct procedure and execution of tests was first explained to the subjects. Then, they were asked for brief tests to make sure that the instructions were well understood. This phase took about 2 minutes.

¹⁸⁸ Two operators worked within the experimental set. The first took care ¹⁸⁹ of the subject (pretest and test instructions, helmet handling, check of the ¹⁹⁰ correctness of execution), the second controlled hardware and software.

191 3.1.3. Experiments.

A few experimental tests were performed on 8 young and healthy subjects 192 (age 25.1 ± 1.1 years; 6 females, 2 males). Small stimulations were admin-193 istered to the participants, to test the ability of our prototype to register 194 reliable data characterizing the response of the ANS. Specifically, stationary 195 conditions of one minute duration which require a different involvement of 196 the sympathetic and parasympathetic controls were considered, separated by 197 5 minutes rest. The following conditions were investigated: neutral position 198 of the jaw (rest position: RP) and habitual dental occlusion $(HDO)^1$, in light 190 or darkness condition; moreover, a test was performed during a computa-200 tional task, which was assumed to induce a detectable stress of the subject. 201 These 5 conditions (tested in the following order: RP in light and dark-202 ness, HDO in light and darkness and computational task in darkness) were 203 performed before, during and after the application of low-frequency Transcu-204 taneous Electrical Nerve Stimulation (TENS), which was expected to induce 205 relaxation. TENS was applied as in previous studies [40], using a J5 My-206 omonitor TENS Unit device (Myotronics-Noromed, Inc., Tukwila, WA, USA) 207 with disposable electrodes (Myotrode SG Electrodes, Myotronics-Noromed, 208 Inc., Tukwila, WA, USA). Synchronous and bilateral stimuli, with amplitude 209 adjusted in the range 0–24 mA and duration of 500 μ s, have been delivered 210 over the cutaneous projection of the notch of the fifth pair of cranial nerves 211 (grounding electrode in the center of the back of the neck) at 0.66 Hz. 212

213 3.2. Signal processing and results

214 3.2.1. Pre-processing of recorded data.

Pupillometric recordings were processed through the algorithm of strongly connected components [41] to measure frame by frame the area of the pupil, expressed as the number of pixels covering it. The area of the pupil was then low-pass filtered under 2 Hz (non-causal, zero-phase, Butterworth filter of order 2). This frequency range is enough to characterize the response of the ANS of our interest, which mainly includes the following frequency ranges: low-frequency (LF) 0.04–0.15 Hz and high-frequency (HF) 0.15–0.5 Hz [9]. The local maxima in the BBC were used to identify the heartheats from

²²² The local maxima in the PPG were used to identify the heartbeats, from

¹During dental occlusion, the effect of muscle fatigue and the massive involvement of the autonomic system were excluded by avoiding prolonged teeth clenching. Subjects were asked to swallow and then to contact the teeth lightly without clenching. Attention was paid to check the activity of mimic muscles.

which the heart rate (HR) was estimated as the reciprocal of the inter-pulse interval.

²²⁵ The GSR was low-pass filtered under 2 Hz.

226 3.2.2. Estimation of indexes.

The following simple descriptors were estimated from the pre-processed data (pupillogram, i.e., pupil size over time), HR and GSR.

• The mean and standard deviation (STD) were computed to explore average values and variability, respectively.

• The linear trend was estimated as a basic indicator of the evolution in time of the signals (the trend was defined as the slope of the interpolation line of the data after scaling the time to range between 0 and 1 and normalizing the time series to have zero mean and unit STD).

235 3.2.3. Statistical analysis.

The indexes mentioned above were used as descriptors of the signals in the different experimental conditions. The two-sided Wilcoxon signed rank test (considering paired data) was then applied to investigate differences of each of the indexes in specific pairs of conditions of interest, after pooling data: RP in darkness compared to the computational task, RP compared to HDO (in darkness), pre-TENS compared to TENS or post-TENS conditions. The significance level was set to p < 0.05.

243 3.2.4. Results.

Examples of recorded signals are shown in Figure 4. The pupil shows an 244 irregular oscillatory behavior, as also the HR. There is a decreasing trend 245 in both HR and GSR. The figure shows also the spectral coherence of the 246 pupilogram and the HR at frequencies lower than 1 Hz. The two signals were 247 found to be coherent in subjects under controlled breathing conditions, where 248 a respiratory component was visible in both the pupillogram and the HR [8]. 249 Here, the considered normal breathing and the short acquisitions resulted in 250 significant coherence (over 0.5) only in a few subjects and conditions. 251

The significance of the differences of indexes extracted from the signals recorded in different conditions is shown in Table 2. Different indexes have a greater discriminatory value comparing different conditions:

• an index from the HR showed the maximal significance (i.e., minimum p value) in discriminating computational task and RP in darkness (which can be considered as a rest state);

- indexes estimated from the pupillogram had the maximal significance
 in distinguishing light and darkness, RP and HDO, or pre-TENS and
 TENS conditions;
- 261 262
- indexes extracted from GSR were the most statistically different in the conditions pre-TENS versus post-TENS and TENS versus post-TENS.

Specifically, HR and mean pupil size increased when comparing computa-263 tional task with RP in darkness (due to the mental stress induced by the 264 task). The subject started sweating during the computational task, as indi-265 cated by the high positive trend of GSR. Pupil was the only system showing 266 significant differences between HDO and RP: pupil size increased as a result 267 of HDO stimulation [9][10][11]. Moreover, it was the only system showing 268 significant differences comparing light and darkness conditions (obviously, 269 increasing the diameter in darkness). 270

Pupil also indicated the relaxation induced by TENS (there is a significant reduction of pupil size during and after the application of TENS). On the other hand, GSR increased during and after TENS, with respect to the pre-TENS condition.

275 4. Discussion

The ANS controls many different visceral functions, including heart rate, perspiration, digestion, salivation, respiratory rate, pupillary dynamics, micturition (urination), sexual arousal, breathing and swallowing. The joint acquisition of different autonomic responses could be useful for a deeper insight into ANS physiology and pathology. For example, the study of the autonomic response is important in the following situations [42]:

- sympathetic and parasympathetic lesions after surgical procedures;
- drug's collateral effects;
- diagnosis and follow-up of ANS diseases;
- poisoning;
- involuntary reactions of the patient.

Figure 4: A) Example of data (pupillogram, PPG from which the HR is obtained, GSR), with the subject at rest position of the jaw in darkness. The HR was computed as the reciprocal of the inter-pulse interval. Each HR value was located in the average time between the two instants used to compute it, obtaining a time series (sampled not uniformly). Then, this time series, PPG and GRS were interpolated at 25 Hz (i.e., the sampling frequency of the pupillogram). B) Power spectrum densities (PSD) of pupillogram and HR (using Welch's overlapped segment averaging estimator, considering 8 segments with 50% overlap) and magnitude squared coherence.

The diagnosis in most of these situations is currently vague [43][44][45]. 287 The joint investigation of different autonomic responses could help in clar-288 ifying the complex dynamics of the ANS in such conditions. One of the 289 problems when designing an experimental setup is being constrained by the 290 functionalities of commercial systems, which are usually closed and allow only 291 specific protocols. Here, we were interested in investigating synchronously 292 the joint responses of the heart (i.e., the cardiac pulse), the skin (i.e., sweat 293 production) and pupil. Some devices have been developed for the joint ac-294 quisition of different ANS responses: both research prototypes [46][47][48] 295 and commercial products (Q sensor, MOXO, Feel^{TM} , UP4, VIVOGRAPH, 296 Microsoft Band, E4, Embrace) have been proposed. Despite the interest in 297 the study of pupillary dynamics, at present there are no tools that are able to 298 simultaneously obtain the acquisition and processing of pupillary dynamics 299 and those of other systems such as the cardiovascular (e.g., through pulse 300 oximetry) and sudorific system (through skin conductivity). Being able to 301 expand the analysis to several systems in a synchronous way would allow 302 a better knowledge of the coupling pathways between somatosensory and 303 affective / emotional needs and responses of the whole of the ANS in physio-304 logical and/or pathological conditions, probably indicating the activation of 305 different autonomous circuits in different conditions. 306

In this work, we have designed an experimental setup able to record in 307 synchrony the video of pupil (done with a commercial system [27]) and dif-308 ferent responses of the ANS. A modular sensor network was designed and 309 implemented to acquire, process and transmit via USB some biomedical sig-310 nals reflecting the state of the ANS. Two sensors have been included in the 311 prototype, for pulse oximetry and skin conductivity. However, it is feasible 312 for being extended to include more body sensors, miniaturized and embedded 313 in a portable system. This could be important for future extension of the 314 work, as body sensor networks are finding many applications in the continu-315 ous monitoring of sensitive people [49][50][51][52][53]. Indeed, many different 316 sensors are available to monitor physiological data and could be included: 317 accelerometer, blood glucose sensor, electrodes for bioelectric signals, blood 318 pressure sensor, gyroscope, carbon dioxide gas sensor, etc. [53][54]. 319

The developed system, even if it is only a prototype, provided robust estimations of the electrodermal activity and of the pulse oximetry, which was then processed to investigate the heart inter-beat interval. Note that the PPG is immune to electrical artifacts, which could be observed on the electrocardiogram during TENS application (however, it is less precise in detecting the HR, as it also depends on the pulse wave velocity). Thus, our system is adequate for the study of the ANS response to TENS reflected in the HR.

Preliminary experimental tests are shown. Some trends have been ob-327 served. For example, both HR and GSR are decreasing during the experi-328 ment shown in Figure 4. This could reflect that the subject was relaxing, as 329 the recordings were acquired in a rest condition (i.e., rest position of the jaw 330 in darkness). Moreover, GSR slowly increased during the experiments, with 331 the results that its mean value was larger during and after TENS, with re-332 spect to the pre-TENS condition, even if TENS should relax the participants 333 (as indicated by variations in pupil size). Possibly, this trend of GSR was 334 only due to an accumulation of sweat during the experiment, as the sensors 335 were kept fixed for all its duration. 336

However, some consistent outcomes were also observed. Specifically, even 337 if we considered only short recordings, weak ANS stimulations (dental oc-338 clusion, light, TENS and a computational task) in healthy subjects and we 339 extracted simple indexes (mean, STD and trend), we have shown statisti-340 cally significant variations of at least an index in each pair of conditions. 341 This indicates that the overall information provided by the joint recordings, 342 not just that of each individual signal, should be used for the discrimination 343 of the ANS responses in the different considered conditions. The results are 344 in line with our expectations: HDO and computation elicit the sympathetic 345 response (which should result in HR and GSR increasing and pupil dilation), 346 TENS induces relaxation (determining a decrease of HR, GSR and pupil 347 size). The sensory amplitude TENS that we administered has been shown 348 to induce the response of different branches of the ANS, as the salivary [55], 349 the cardiovascular [56], the neuromuscular systems [57] and, in particular, 350 the one that governs the static and dynamic dimension of the pupil [40]. The 351 effects of the sensory trigeminal TENS stimulation are probably to be at-352 tributed to a central system that modulates the mechanisms of arousal and, 353 therefore, the autonomous efferent response [58][59] (that was observed in 354 this study). 355

Pupil appeared to be the most sensible system, as it reflected even the small stimuli given by HDO or TENS. HR showed significant variations only in a few conditions (e.g., mean HR was significantly increased only by the computation task). GSR showed an important trend during computation, but it was prone to accumulation effects.

Our study has some limitations: a few experiments have been conducted and all on healthy volunteers; only three signals have been included; our

system for the recording of PPG and GSR is a simple prototype, which is 363 surely more delicate and less stable than engineered commercial products. 364 However, it pointed out the importance of integrating information from dif-365 ferent systems controlled by the ANS, in particular pupil (which was the most 366 sensitive to weak stimulations). Further studies are then suggested, both to 367 improve and extend our preliminary results. For example, other tests and 368 advanced processing techniques could provide specific indications in physi-369 ology or pathology, in future joint acquisitions of different responses of the 370 ANS. Additional measures to guarantee reproducibility of the tests need to 371 be developed, such as careful preparation in order to stabilize hemodynamic 372 parameters. Moreover, additional sensors or stimulation signals could be 373 included in the proposed device, due to its modular architecture. 374

375 5. Conclusions

We discuss the implementation of a modular system for the acquisition 376 of different signals reflecting the responses of the ANS to stimulations. The 377 signals were synchronized to the pupillogram recorded by a commercial sys-378 tem, showing the joint variations of pupil size, Galvanic response and pho-379 toplethysmogram. Small stimulations were given to the participants and 380 only considering all different recorded signals the different responses of the 381 ANS could be discriminated. Thus, these preliminary results suggest the 382 importance of recording jointly multiple data in order to better characterize 383 autonomic responses. 384

Light	$\frac{Mean\ area\ of\ nunil\ (n < < 0\ 001)}{Mean\ area\ of\ nunil\ (n < < 0\ 001)}$	
Light	L: $2987(2545, 3981) - D: 7312(6613, 9059)$	
versus	STD of pupil (p << 0.001)	
	L: $417(333, 539) - D: 220(161, 283)$	
Darkness	Trend of pupil (p=0.014)	
	L: $0.23(-0.79, 1.29) - D: 1.70(0.21, 2.32)$	

Table 2: Statistical analysis of the data using Wilcoxon sign rank test. Mean, standard deviation and trend of data were considered (L: light; D: darkness). Median and quartiles of the indexes showing significant differences (p<0.05) are reported (in order of increasing p). Pupil size is indicated in pixels, HR in Hz, GSR in μ S; their trends are measured in arbitrary units (they were computed on normalized data and time).
