Graphical Abstract:

HIGHLIGHTS:

- The porous shell in porous hollow silica nanoparticles (PHSN) resulted in significantly different particle physicochemical properties compared to solid silica nanoparticles (SSN) of similar size.
- Higher surface roughness in PHSN than that of SSN was responsible for the deviations in standard DLVO theory.
- High ionic strength (IS) and low pH decreased mobility and increased retention for both particle populations.
- Retention was 3-fold higher for PHSN compared to SSN at the highest IS and lowest pH.

ABSTRACT

Silica nanoparticles (SiO_2 NPs) are of increasing interest in nano-enabled agriculture, particularly as nanocarriers for the targeted delivery of agrochemicals. The direct application of these in agricultural soils may lead to the release of SiO_2 NPs in the environment. Although some studies have investigated transport of solid SiO_2 NPs in porous media, there is a knowledge gap on how different SiO_2 NP structures incorporating significant porosities can affect the mobility of such particles under different conditions. Herein, we investigated the effect of pH and ionic strength (IS) on the transport of two distinct structures of SiO_2 NPs, namely solid SiO_2 NPs (SSNs) and porous hollow SiO_2 NPs (PHSN), of comparable sizes (~200 nm). Decreasing pH and increasing ionic strength reduced the mobility of PHSNs in sand-packed columns more significantly than for SSNs. The deposition of PHSNs was approximately 3 times greater than that of SSNs when pH was 4.5 and IS 100 mM. The results are non-intuitive given that PHSN has a lower density and the same chemical composition of SSN but can be explained by the greater surface roughness and ten-fold greater specific surface area of PHSN, and their impacts on van der Waals and electrostatic interaction energies.

Introduction

Rapid advances in nano-enabled agriculture have been focused on making significant improvements in enhancing crop yields, mitigating energy and water footprints, and reducing unintended pollution from the use of fertilizers and pesticides [1-3]. The latter is achieved through precise delivery of pesticides and fertilizers using nanocarriers, which can dose these agents to plant tissues in a targeted manner and with a higher efficiency than traditional pesticide and fertilizer formulations [3-8]. Porous nanosilica is a promising candidate for pesticide and fertilizer nanocarriers because SiO_2 is an earth-abundant, biocompatible material [9, 10] that promotes plant growth, and provides resistance towards pathogens and unfavorable environmental conditions [10-12]. SiO_2 nanocarriers may be introduced to agricultural soils either through direct application or through indirect releases such as discharges to soils following foliar application [13-17]. It is important to investigate the mobility of silica nanocarriers to account for their environmental transport and that of their cargo. Although several studies have investigated the transport of SSNs in geologic deposits [18-21], it is unclear how the differences in particle structure, in particular the high porosity of silica nanocarriers, fundamentally influence their mobility in porous media.

Among studies on SSN transport, Wang, et al. [20] reported that particle size and concentration influenced the transport and retention profiles of SSN in porous media. Small SSN of 8 nm diameter caused higher retention and, thus, less mobility when compared to SSN with mean diameter of 52 nm. Moreover, that study showed that increased ionic strength reduced the overall SSN mobility in the porous medium. Zhang, et al. [22] reported that humic acid improved mobility of SiO_2 nanoparticles in saturated porous media because of enhanced electrostatic forces. HonetschlÄgerová, et al. [23] showed that coating nanoscale zerovalent iron (nZVI) particles with a SiO_2 shell enhanced their colloidal stability and mobility in porous media compared to bare nZVI, which have high aggregation tendency and thus are very colloidally unstable.

Common parameters that influence the mobility of nano- and micro-colloids in porous media are (i) particle surface charge and coating [23], (ii) particle size [20], (iii) ionic strength [24], (iv) pH [25], and (v) temperature [26]. However, few studies have analyzed the effects of the structure of nanoparticles. For SiO_2 nanoparticles, while most studies investigate the

transport of SSNs, most applications in agriculture focus on the use of mesoporous SiO₂, such as MCM-41 [27-31], and SiO₂ nanoshells, such as PHSN [32-36], which are structurally different from SSNs and, therefore, may lead to different transport profiles. Given the increasing use of silica nanocarriers in agriculture, and the increased potential for release into soils, there is a critical knowledge gap on the transport behavior of nanocarriers in natural porous media, and whether their transport differ from those of SSN which have been studied before.

The objective of this study was to evaluate how the porous structure of the SiO₂ NPs influences their mobility. Two SiO₂ NPs with very distinct structure and similar size were synthesized, namely (i) SSNs which are solid spheres and (ii) PHSNs which are porous and hollow and represent nanocarriers with high porosity. The synthesis methods ensured that the particles were composed only of SiO₂. Experiments were conducted to assess the colloidal stability and mobility of these two particles in saturated, acid-washed, sand-packed columns, over a range of pH and ionic strength (IS). Furthermore, theoretical Derjaguin-Landau-Verwey-Overbeek (DLVO) interaction energies and single collector contact efficiency calculations were performed to investigate how porosity and density differences in the two types of particles influenced colloidal stability and deposition on collector surfaces. A fundamental understanding of the impacts of particle structure on its mobility is essential before investigation of the effects of various environmental conditions and complex particle compositions.

Materials and Methods

Porous Media. White quartz sand with 50-70 mesh particle size (Sigma-Aldrich) was used as the porous medium in this study. Scanning electron microscopy was used to confirm the sand grain morphology and size (Figure S1). The average grain diameter of the quartz sand was 250 μm, with diameters ranging from 210 to 297 μm. Prior to use, the sand was treated with HNO₃ (70% v/v) for 16 hours to remove metal oxides and other impurities as reported elsewhere [37-40]. The acid-washed sand was thoroughly rinsed with DI water (ASTM Type 1, Thermo Fisher) followed by three 20-minute cycles of sonication in water bath. The cloudy

DI water was replaced at the end of each cycle. The electrical potential on the surface of the sand particles was quantified by measuring the zeta potential under varying conditions of pH and IS, remaining negatively charged across the board (Table S1).

SiO₂ Nanoparticles. SSNs were synthesized following a protocol based on the Stöber method [41]. A solution of anhydrous ethanol (200 mL, 100%, Commercial Alcohols, Canada) and NH₄OH (15 mL, 28% NH₃ basis, Sigma-Aldrich) was stirred under 400 rpm for 30 minutes to ensure complete mixing. Then, 10 mL of tetraethyl orthosilicate (TEOS 98%, Sigma-Aldrich) was added dropwise at a rate of 1 mL/min. After 5 hours, the reaction was stopped by drying the cloudy suspension overnight at 80°C. Finally, the nanoparticles were calcined for 5h under 500°C.

PHSNs were synthesized based on a protocol previously described [36]. In summary, a solution of DI water (125 mL), anhydrous ethanol (75 mL), NH₄OH (7.5 mL), hexadecyltrimethylammonium bromide (CTAB, 300 mg, Sigma-Aldrich) and Pluronic P123 (850 mg, Sigma-Aldrich) was stirred under 1000 rpm for 1 hour until reagents were completely mixed. Then, 10 mL of TEOS was added dropwise at a rate of 0.75 mL/min. After 5 hours, the reaction was stopped by drying the cloudy suspension overnight at 80°C. Finally, the nanoparticles were calcined for 5h under 500°C.

The morphology of the nanoparticles was characterized by TEM using a Philips model CM200 TEM at an acceleration voltage of 200 kV. The particle size distribution was characterized through DLS using Malvern Zetasizer Nano ZS (Malvern Instruments, UK). DLS analysis was conducted using SSN and PHSN suspended in DI water with a concentration of 100 ppm. The specific surface area was determined using the BET method through nitrogen sorption/desorption experiments using a Quantachrome Autosorb-1 (Quantachrome GmbH & Co., Netherlands). FTIR spectra were obtained for both SSN and PHSN with a Spectrum II (Perkin Elmer) Spectrometer with a single bounce diamond crystal. Spectra were recorded in the range from 4000 to 400 cm⁻¹ at a resolution of 1 cm⁻¹.

Solution Chemistry. 100 ppm of SSNs and PHSNs were prepared by suspending the dried SiO₂ powder obtained from the synthesis in DI water, followed by sonication in water bath for 30 minutes. IS was adjusted in the nanoparticle suspensions and background solutions

using NaCl (ACS grade, Sigma-Aldrich). The pH was adjusted dropwise with 0.1 M HCl and 0.1 M NaOH, and the counter-ions (Na^+ and Cl^-) were taken into account for the final IS of the system.

Column Experiments. A 10-cm long acrylic column (Chromaflex, Fisher) with internal diameter of 1 cm was packed with acid-washed sand using a wet packing technique described in Oliviera, et al. [42]. Prior to the addition of the acid-washed sand, the column was filled with DI water. Then, saturated acid-washed sand was deposited in increments of 1 cm layer at a time while vibrating the column for 20 seconds. This procedure was repeated until the saturated acid-washed sand occupied the whole space within the 10 cm long column, yielding a porosity of 0.391 from fitting the advection dispersion equation to the tracer breakthrough curve (BTC).

At the start of each run, 3 pore volumes (PVs) of DI water were introduced to the system with the aid of a peristaltic pump at a flow rate of 1.25 mL/min, which corresponds to a Darcy velocity of $2.64 \times 10^{-4} \text{ m s}^{-1}$ within our setting. The flow rate remained constant throughout the run and for all the different conditions. 10 PVs of background solution amended with NaCl (25 mM) followed to produce the breakthrough curve (BTC) for the tracer to ensure consistency and reproducibility of the column wet packing procedure. Then, 5 PVs of particle-free electrolyte solution at desired IS and pH, 10 PVs of the particle suspension at 100 ppm at the respective IS and pH. Then 5 PVs of the particle-free electrolyte solution and, finally, 3 PVs of DI water were injected. Ten different experimental conditions were carried out in triplicates as detailed in Table 1. The SiO_2 NP concentration of 100 ppm was selected based on concentrations employed in previous column transport studies for SSN [20] and concentrations relevant to foliar application of SiO_2 NPs [13].

NaCl and particle (SSN and PHSN) concentrations exiting the column were quantified in real-time by UV-Vis spectroscopy (Agilent Technologies, Model 8453) in a quartz flow-through cell (Hellma Analytics, GE, 10 mm path length, 300 μL volume) at wavelengths of 196 nm, and 350 nm, respectively. Particle size distribution and zeta potential at different experimental conditions were measured using a Zetasizer Nano ZS (Malvern Instruments). Size distribution was determined using the dynamic light scattering (DLS) mode and electrophoretic mobility mode [43].

1 **Table 1.** Particle characterization data and calculated DLVO interaction energies by nanoparticle type, pH, IS (mM, electrolyte NaCl),
2 and measurements of zeta potential (mV), Z-average diameter (nm), Polydispersity Index (PDI), depths of primary minima (Φ_{\min}), heights
3 of energy barriers (Φ_{\max}) and depths of secondary wells (Φ_{\sec}) for the DLVO energy profiles. Errors denote standard deviations
4 corresponding to measurement of 3 samples.

7 **Interaction Energies and Collector Efficiency.** The van der Waals forces and repulsive
8 electrostatics forces for SSN and PHSN for the different experimental conditions were
9 calculated to determine the particle-particle and particle-collector interaction energies
10 according to the classical DLVO model (Equation 1) using the expressions proposed by
11 Gregory [44] (full list of equations and theoretical considerations in Supporting Information).
12 Interaction energies due to Born were not accounted for because of their negligible
13 magnitudes [45-47]. The Hamaker constant was calculated using the expressions proposed
14 by Lipkin, et al. [48], and accounted for the contributions of water core and silica shell for
15 PHSNs The full list of physical properties used to compute the DLVO energy profiles for
16 SSNs and PHSNs can be found in Table S2. For PHSNs, the interior and exterior fluid
17 compositions were considered to be the same, thus the van der Waals energy profile was
18 calculated by subtracting the resulting forces generated by a particle with diameter
19 corresponding to the inner diameter of the PHSN from the resulting forces calculated for a
20 particle with diameter corresponding to the outer diameter of the PHSN [49, 50] as per
21 Equation 2.

$$V_{\text{tot}} = V_{\text{vdW}} + V_{\text{edl}} \quad (1)$$

22

$$V_{\text{vdW}} = V_{\text{vdW}}^{\text{out}} - V_{\text{vdW}}^{\text{in}} \quad (2)$$

23 The depths of primary minima (Φ_{min}), heights of energy barriers (Φ_{max}) and depths of
24 secondary wells (Φ_{sec}) for the DLVO energy profiles are summarized in Table 1.

25 The single collector contact efficiency was calculated based on the empirical expressions
26 derived from the following studies: Yao, et al. [51], Rajagopalan and Tien [52], Tufenkji and
27 Elimelech [53], Ma, et al. [54], Nelson and Ginn [55], Ma, et al. [56], and Messina and Sethi
28 [57]. The comprehensive list of expressions used in this step is presented in Table S3.

31

32 **Results and Discussion**

33 **SiO₂ NPs Characterization.** The TEM images in Figure 1 show that while the SSN
34 synthesized based on the Stöber method (Figure 1a and b) are solid with an average primary
35 particle diameter of 184 nm, the PHSN (Figure 1c and d) are hollow with an average diameter
36 of 205 nm. Figure 1b and 1d show a more magnified TEM image of singular particles of
37 SSN and PHSN. The shell thickness of the PHSN ranged from 22 to 38 nm. An important
38 difference in the surface characteristics of the two particle types is the significantly higher
39 surface roughness of PHSN created in part by the highly porous shell surface. The calculated
40 mass of the SSNs and PHSNs were very similar. Thus, the particle number concentration of
41 SSNs and PHSNs were very similar in all experiments.

42 The primary particle size distributions ($N = 100$) for SSN and PHSN represented in Figure
43 S2a and Figure S2b, respectively, show that both particles have a comparable size
44 distribution. The hydrodynamic diameter size distribution, obtained by DLS for SSNs
45 (Figure 2a) is slightly narrower than for PHSNs (Figure 2b) as reported in Table 1 represented
46 by the polydispersity index (PDI). The DLS measurements were obtained at pH 9.5 and IS 1
47 mM because optimal colloidal stability was obtained at these conditions. Overall, both
48 particle populations were successfully synthesized to yield comparable size and shape, to
49 enable direct comparison of their mobility in porous media.

50 The surface characteristics were investigated using BET and FTIR analyses (Figure S3).
51 Although, SSN and PHSN have relatively similar sizes, the specific surface area of PHSN
52 ($287 \pm 30 \text{ m}^2 \text{ g}^{-1}$) is approximately 10 times greater than the specific surface area of SSN (29
53 $\pm 8 \text{ m}^2 \text{ g}^{-1}$). This is due to the presence of micro-scale pores of around 2.5 nm in the PHSN
54 surface as characterized in previous work [36].

55 The chemical composition of the SSN and PHSN were identical with no chemical bonds
56 present other than those attributable to silica, as determined by FTIR analyses (Figure S3c).
57 Although both populations of SiO₂ nanoparticles have the same chemical composition, the
58 differences in their structure result in different Hamaker constants ($6.59 \times 10^{-21} \text{ J}$ for SSNs and
59 $5.79 \times 10^{-21} \text{ J}$ for PHSNs) and zeta potentials (Table 1). Given the higher surface area of

60 PHSN, there are more counter-ions around the PHSNs compared to SSNs, resulting in a
61 thinner solvation layer and zeta potential closer to zero [58].

62 **pH Effect of the Transport Behavior.** The effect of pH in the transport of SSNs and PHSNs
63 in saturated porous media was evaluated at IS 1 mM for both sets of nanoparticles. The BTCs
64 obtained for SSNs (Figure 3a) show that the values for steady-state relative effluent
65 concentration (at 9 PV) decreased as the pH also decreased, from 0.99 at pH 9.5, to 0.95 at
66 pH 6.5 and then 0.91 at pH 4.5, suggesting that transport of SSNs is slightly hindered as the
67 pH becomes more acidic, increasing retention of SSNs in the column. The changes in
68 mobility of SSNs with pH are consistent with another study showing reduced mobility of
69 SiO₂ nanoparticles in carbonate reservoirs at acidic pH [59]. It should be noted that the SSN
70 hydrodynamic diameter as measured by DLS increased slightly with pH decrease from 9.5
71 to 4.5 (from 201 ± 4.9 nm at pH 9.5 to 238 ± 1.9 nm at pH 4.5) suggesting limited aggregation.

72 The DLVO energy profiles for the SSN particle-particle (Figure 4a) and particle-collector
73 interactions (Figure 4c) at IS of 1 mM, show highly unfavorable attachment conditions.
74 Under these conditions, the repulsion forces between SSNs and between SSNs and the sand
75 collector surfaces resulted in elevated energy barriers and absence of secondary minima
76 (Table 1). The DLVO energy profiles for the SSN particle-collector interactions (Figure 4c)
77 support the observations of low retention of SSNs from the BTC trends discussed above
78 (Figure 3a). The calculated particle-particle energy barrier for SSN at pH 4.5 was far greater
79 than 15 k_bT, an approximate threshold for colloidal stability, and thus do not suggest
80 conditions favorable for SSN aggregation. However, the energy barrier was significantly
81 lower at pH 4.5 (120.2 k_bT) compared to pH 9.5 (373.2 k_bT).

82 The values for steady-state relative effluent concentrations in the BTCs for PHSN also
83 decreased with decreasing pH, from 0.94 at pH 9.5 to 0.85 at pH 6.5 and then more
84 substantially to 0.37 at pH 4.5. The extent to which the transport was hindered in PHSNs
85 with decreasing pH was much more significant than that in SSNs. As with SSNs, there was
86 also a small increase in DLS-measured hydrodynamic diameters with decreasing pH (221 ±
87 1.9 nm at pH 9.5 to 240 ± 1.1 at pH 4.5). Although the DLVO calculations suggest that the
88 primary maximum for particle-particle interactions of PHSN at pH 4.5 was small at 10 k_bT,
89 the measured hydrodynamic diameters suggest limited aggregation, comparable to SSNs.

90 At pH 4.5 and IS 1 of mM, the primary energy maximum for PHSN was the lowest (49.1 k_bT)
91 of the 3 pH conditions at the same IS, and thus the DLVO calculations are in qualitative
92 agreement with the experimental observation of significantly low mobility of PHSNs at pH
93 4.5. However, there was no secondary minima predicted by DLVO calculations. This
94 suggests that other parameters played a role in the transport of these nanoparticles. Straining
95 is unlikely to be a cause for the significantly higher deposition of PHSN, given that the SSN
96 have similar hydrodynamic diameters at corresponding pH, but had lower deposition.
97 Furthermore, straining is not expected when the colloid diameter (d_c) to sand grain diameter
98 (d_g) ratio (d_c/d_g) is below 0.008 [60]. Here, the d_p/d_g ratio is approximately 0.001 for both
99 SSN and PHSN. According to Xu, et al. [60], straining rates are negligibly small when d_p/d_g
100 < 0.008 and, in this work, such ratio is one order of magnitude lower. There is, however, a
101 gradual increase in C/C_0 with increasing pore volumes, suggesting some blocking or
102 detachment of deposited PHSNs. As a first layer of deposited nanoparticles is formed, the
103 trajectories of the subsequent nanoparticles are significantly impacted by this monolayer of
104 deposited particles, a phenomenon previously referred to as the shadow effect [61]. The
105 extent of the influence of the shadow effect in subsequent particle trajectory is directly related
106 to the hydrodynamic interactions and electrostatic double layer repulsion. Therefore, as the
107 conditions become unfavorable (lower pH and higher IS), repulsion forces decrease, thus
108 increasing both the surface coverage of deposited nanoparticles on the sand grains and the
109 blocking effects in the nanoparticle transport profiles.

110 **IS Effect on the Transport Behavior.** The effect of IS in the transport of SSNs and PHSNs
111 in saturated porous media was evaluated at pH 9.5 and at the same SiO_2 concentration of 100
112 ppm. The BTCs for SSNs (Figure 5a) showed that the values for relative effluent
113 concentration at 9 PVs decreased as the IS increased, from 0.99 at IS 1 mM, to 0.96 at IS 10
114 mM and then 0.92 at IS 100 mM, which was expected and is consistent with the literature
115 [20, 59]. The addition of salt increases the number of counter-ions migrating to the solvation
116 layer of the nanoparticles, thus decreasing the Debye-length and the repulsive electrostatic
117 forces. Although the total interaction energies calculated yielded a lowered energy barrier, a
118 weak secondary minimum ($-2 k_bT$) was obtained only at IS of 100 mM.

119 The values for relative effluent concentrations at 9 PV in the BTCs for PHSN (Figure 5b)
120 also decreased with increasing IS, from 0.94 at IS 1 mM to 0.88 at IS 10 mM and then 0.34
121 at IS 100 mM. Once again, the mobility PHSNs was much more affected by the change in IS
122 than for SSNs. The similarity in the BTC shape with changes in pH and IS suggests that
123 similar deposition processes are involved. As for the SSNs at pH 9.5 and IS at 100 mM, a
124 weak secondary minimum for PHSNs was calculated from the interaction energy profiles at
125 an IS of 100 mM.

126 Overall, low pH and high IS decreased the mobility of the nanoparticles in porous media. We
127 observed similar trends between SSN and PHSN: (i) As pH decreased, zeta potential also
128 decreased, which is expected because the isoelectric point of bare SiO₂ is around pH = 2 [62-
129 64]. (ii) As IS increased, zeta potential decreased as a result of the stabilization of the excess
130 ions in the electrical double layer of each nanoparticle by the counter-ions from the NaCl
131 added. In both cases, a decrease in zeta potential led to a decrease in the intensity of repulsion
132 forces between nanoparticles and between nanoparticles and sand. However, the increased
133 retention of PHSNs compared to the SSNs, which is non-intuitive because both particles have
134 comparable sizes (Figure 1) and surface chemical composition (Figure 2c). The DLVO
135 interaction energies calculated are qualitatively in agreement with the mobility trends for
136 SSN and PHSN, but the calculated values are not consistent in several instances. For
137 example, if we compare the particle-collector interaction resulting energy profiles for Exp. 5
138 (SSNs, pH 9.5, IS 100 mM, Figure 6c) with Exp. 10 (PHSNs, pH 9.5, IS 100 mM, Figure 6d)
139 the heights of energy barriers were comparable, and yet, the steady-state relative effluent
140 concentrations were 0.34 and 0.96 for PHSNs and SSNs, respectively. A theoretical analysis
141 of DLVO interaction forces between SSN or PHSN and collector surfaces suggested
142 relatively small differences in the magnitude of the interaction forces [50], and is in
143 agreement with the calculations in this study. It is likely that the surface structure differences
144 caused by the concave asperities in the PHSNs caused by the pores played an important role
145 in the mobility of these particles.

146 **Single Collector Contact Efficiencies (η_0) and Particle-Collector Attachment**
147 **Efficiencies (α_{pc}).** The η_0 values as a function of particle radius (a_p) for SSNs (Figure 7a) and
148 PHSNs (Figure 7b) were calculated based on expressions derived elsewhere [51-56]. The

149 expressions and parameters used to estimate the η_0 can be found in Table S3 and Table S4,
150 respectively.

151 The average η_0 predicted for SSNs ($a_p = 92$ nm) and PHSN ($a_p = 103$ nm) were 0.007 and
152 0.005, respectively. The η_0 were slightly greater for SSNs, which is contrary to observations
153 of lower mobility of PHSNs in the column experiments. To assess the size difference effect
154 between SSNs and PHSNs, the η_0 ratio was plotted as a function of particle size in Figure 7c.
155 For any particle radius below 100 nm, SSNs and PHSNs have very similar predictions for η_0 .
156 For any particle radius above 100 nm, the predicted η_0 for SSNs surpassed the predicted η_0
157 for PHSNs, indicating more chance of retention for SSNs than for PHSNs. Therefore, η_0
158 could not explain why such inconsistencies with the experimental data exist.

159 The α_{pc} values remained below 0.04 for all experimental conditions with SSNs, whereas they
160 reached 0.54 and 0.59 for PHSNs at pH 4.5 and IS 1 mM, and at pH 9.5 and IS 100 mM,
161 respectively, which were the conditions where retention was more pronounced. The α_{pc}
162 values (Table S5) were calculated with Equation (3) below.

$$\alpha_{pc} = -\frac{2}{3} \frac{d_c}{(1-n)L\eta_0} \ln\left(\frac{C}{C_0}\right) \quad (3)$$

163

164 **Surface Roughness and the DLVO Theory.** Deviations from DLVO predictions due to
165 nanoscale physical heterogeneity have been previously reported [65-74]. These deviations
166 happen because standard DLVO theory assumes that particle and collector surfaces are
167 geometrically smooth and homogeneous, when in reality colloid may possess some degree
168 of roughness [67]. Modeling and experimental data have demonstrated that surface roughness
169 reduces the repulsive energy barriers, and in some cases eliminates them altogether [67-69,
170 72]. For instance, Liang, et al. [71] observed enhanced retention of silver nanoparticles in
171 porous media with higher surface roughness (SR). Retention was 6.8-fold higher in relatively
172 rough sand particles (root mean square roughness, $S_q = 524$ nm) when compared to the
173 experimental condition using relatively smooth sand ($S_q = 93$ nm).

174 Specifically, two phenomena are relevant: (i) the concave asperities in PHSN surface, caused
175 by the presence of pores in the surface, result in the separation distance among particle-

176 particle and/or particle-collector surfaces becoming larger at the pores, when compared to
177 that of SSNs [69] as depicted in Figure 8. Generally, as the separation distance increases,
178 overall repulsive electrostatic forces generally decay faster than van der Waals interactions
179 [75], resulting in enhanced attraction to the collector surface. (ii) The roughness caused by
180 the asperities on PHSN surface alter the flow field around the particle during the column
181 experiments, enhancing resisting adhesive torque and diminishing applied hydrodynamic
182 torque [76]. These effects likely led to enhanced colloid immobilization on the collector in
183 this study.

184 It is also important to note that this work has assessed the transport behavior of SiO₂ NPs in
185 saturated sand, and thus, will differ from actual agricultural conditions. Agricultural soils are
186 generally unsaturated, with some exceptions, such as when the soil is irrigated or when it
187 rains. Agricultural soil may also contain high organic matter content and other types of
188 contaminants that could complex with the NPs and influence their mobility. These
189 conditions, however, are not replicated in our experimental setting. Nevertheless, the use of
190 saturated sand served as model towards a first step in assessing the fundamental differences
191 in the transport profile of SSNs and PHSNs and how their structure plays a role in their
192 mobility.

193 **Conclusions**

194 Herein, we synthesized, characterized, and investigated the mobility of SSNs and PHSNs in
195 a saturated sand-packed column in various pH and IS conditions. As expected, the zeta
196 potential of both sets of particles approached lower absolute values as pH became more acidic
197 and closer to the isoelectric point of SiO₂ nanoparticles. On the other hand, zeta potential
198 approached lower absolute values as IS increased. The decrease in zeta potential indicates a
199 decrease in the repulsive forces between nanoparticles, which in turn led to a small extent of
200 agglomeration, and higher PDI.

201 During the column experiments, deposition was enhanced by the decrease of pH and increase
202 of zeta potential, as such conditions deteriorate (acidic pH and high salinity) the overall
203 colloidal stability of SiO₂ nanoparticles in suspension. The PHSNs, however, experienced a
204 higher degree of deposition when compared to SSNs. DLVO energy profiles and single

205 collector contact efficiency values were unable to explain why such discrepancies existed,
206 and surface roughness likely contributed to the different extents of deposition. The surface
207 roughness was not factored into the DLVO calculations because of the high complexity of
208 the calculations and the many assumptions needed. The surface roughness related concave
209 asperities of the pores lowered the repulsive energy barriers and led to more deposition.

210 This study elucidates how nanoparticle architecture can influence their mobility in porous
211 media and highlights the importance of a thorough experimental analysis of the fate and
212 transport of nanoparticles of different architecture that are likely to be discharged in the
213 environment, such those intended for use in nano-enabled agriculture.

214 **Declaration of competing interest**

215 The authors declare that they have no known competing financial interests or personal
216 relationships that could have appeared to influence the work reported in this paper.

232 **Figure 1.** TEM images of (a and b) SSNs and (c and d) PHSNs. The images on the right
233 exhibit more magnified images of singular (b) SSN and (d) PHSN to show the different
234 features between both structures. Although both structures are spherically shaped, PHSNs
235 feature a hollow core and pores. The latter is directly responsible for the increased surface
236 area and roughness of PHSNs when compared to SSNs.

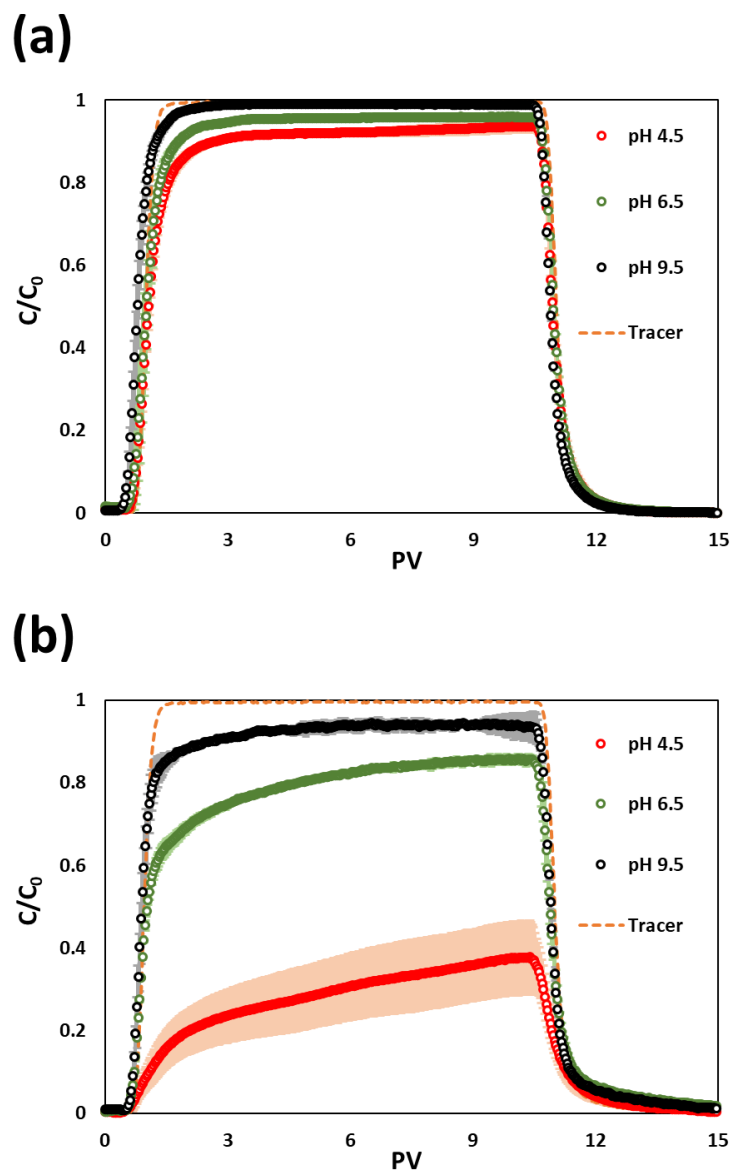

237

238

239 **Figure 2.** Particle size distribution at pH 9.5 and IS 1 mM of (a) SSNs and (b) PHSNs. The
 240 width of the PHSN size distribution is broader than that for SSN, indicating a higher PDI as
 241 confirmed in Table 1.

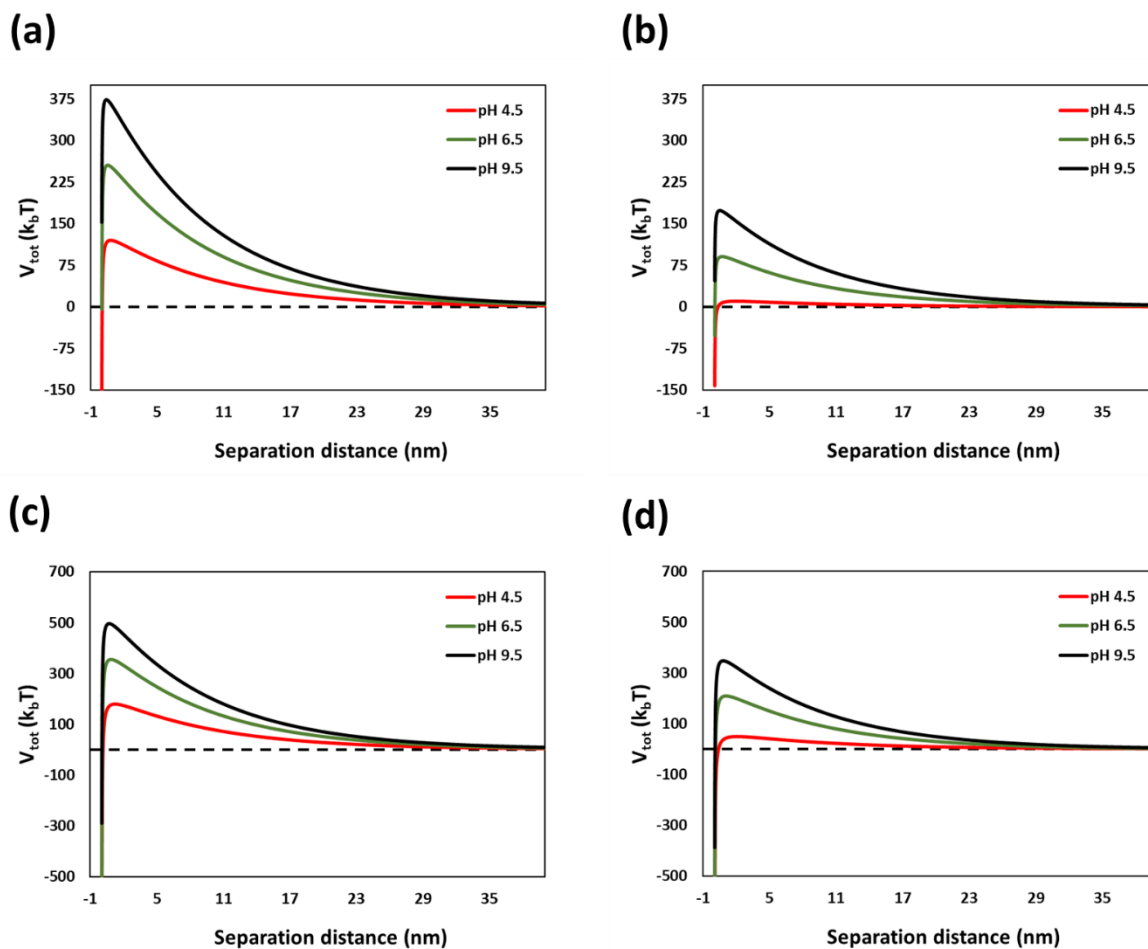

242

243

244 **Figure 3.** BTCs at fixed IS 1 mM and varying pH for (a) SSNs and (b) PHSNs. The shaded
 245 zones represent the standard deviation of the particle concentration run in triplicates. Wider
 246 shaded areas represent greater standard deviation among replicates. The conditions with no
 247 visible shaded areas represent runs with not relevant difference among replicates.

263 **Figure 6.** DLVO energy profiles at fixed pH 9.5 and varying IS for (a) SSN particle-particle
 264 interactions, (b) PHSN particle-particle interactions, (c) SSN particle-collector interactions,
 265 and (d) PHSN particle-collector interactions.

266

269 **Figure 7.** Estimates of η_0 for (a) SSNs and (b) PHSNs, and (c) the SSN-PHSN η_0 ratio.

270

271 **Figure 8.** Schematic representation of the distance between sites in the SSN (a) and PHSN
 272 (b), and a hypothetical surface. For SSNs, the distance from point a to the surface, h_a , and
 273 the distance from a relatively distant point a' to the same surface, $h_{a'}$, are approximately the
 274 same. Meanwhile, in PHSNs, the distances h_b , h_c and h_d may vary significantly, even if they
 275 are at the same distance as points a and a' in scheme (a). Effectively, the overall separation
 276 distance between rough spherical surfaces and a hypothetical surface is larger than the
 277 distance between smooth spherical surfaces and a hypothetical surface.
