ABSTRACT

Although the formation of nanosized and defective δ-$MgCl_2$ is essential for the performance of Ziegler-Natta catalysts, the process has not sufficiently been elucidated due to certain limitations in characterization. Here, the formation of nanostructures and active surfaces of Ziegler-Natta catalysts were investigated in detail based on a multifaceted set of characterization techniques represented by X-ray total scattering and various spectroscopies, in correlation with chemical composition analysis and polymerization tests. Solid samples were extracted in the course of the catalyst preparation from $Mg(OEt)_2$, and subjected to the analysis. Several interesting results were found. The addition of $TiCl_4$ almost spontaneously converts $Mg(OEt)_2$ into $MgCl_2$ seeds mainly exposing the {001} basal surface, whose dimensions are below 2 nm; a large Ti amount stays on the material as physisorbed 4-fold coordinated $TiCl_x(OEt)_{4-x}$ species. The heating treatment removes the physisorbed $TiCl_x(OEt)_{4-x}$ and/or convert them into chemisorbed 6-fold coordinated $TiCl_x(OEt)_{4-x}$, while the subsequent addition of an internal donor (here dibutyl phthalate, DBP) promotes a substantial reconstruction and growth of $MgCl_2$ seeds to almost the same size as the final catalyst (ca. 6 nm), with the exposure of the more catalytically relevant lateral surfaces. DBP is in one part adsorbed on $MgCl_2$ surfaces and in the other part complexed with Ti sites. This complex is only partially removed in the following steps of the synthesis. The second $TiCl_4$ addition replaces the chemisorbed $TiCl_x(OEt)_{4-x}$ with 6-fold coordinated $TiCl_4$ species, but it also causes side reactions with DBP, as testified by the formation of phthaloyl chloride (POC). After activation by triethylaluminum (TEAl), the activity per Ti for ethylene was almost constant throughout the whole preparation process after the initial $TiCl_4$ addition, whereas the activity for propylene was negligible before the addition of the donor and increased dramatically in the subsequent steps of the preparation. This was further investigated based on spectroscopies for TEAl-activated samples, in order to individuate the active Ti species responsible for the catalysis and to monitor the fate of DBP

upon TEAl reaction. The multifaceted characterization approach allowed us to integrate information on the formation of δ-MgCl$_2$, their surfaces, and adsorbed species, providing us with deep insights into the meaning of each step within an industrial catalyst preparation method that has been empirically refined over a long history.

1. INTRODCUTION

After almost seventy years since Karl Ziegler and Giulio Natta broke the monopoly of Nature on the synthesis of stereoregular polymers, Ziegler-Natta (ZN) catalysts are nowadays responsible for 99% of the world polypropylene (PP) production as well as one fourth of that of high-density polyethylene (HDPE).[1] The economic turnover of this industrial process brushes the verge of 300 billion dollars in 2020 and is forecasted to still grow at a compound annual growth rate of 6 % in the next decade.[2]

From their original and quite simple composition, ZN catalysts have evolved along several generations characterized by a gradually improved activity and stereoselectivity, up to the current multi-component composition: TiCl$_4$ (the active phase) is dispersed with organic Lewis bases (the internal donors) on MgCl$_2$ (the support material) and activated by AlR$_3$ (the co-catalyst), together with other organic Lewis bases (the external donors).[3-6] The internal/external donors are considered to be located at the vicinity of the Ti active species and to improve stereospecificity through steric hindrance. Such complex composition allows, by means of catalyst design, finely controlling the structure of the produced polymer across multiple scales, from the molecular architecture of the polymer chains to its distribution critical for actual properties, and finally to the morphology of the polymer particles.

65   In industrial practice, two main routes have been developed to integrate $TiCl_4$, $MgCl_2$, and

66   an electron donor into a single solid material, usually called pre-catalyst.[3] Note that the electron

67   donor in the pre-catalyst is termed as internal donor to distinguish it from the external one,

68   which is added directly in the reactor along with the AlR_3 activator. The former route

69   (traditional) is based on the mechanical ball-milling of highly crystalline $MgCl_2$ (α form) with

70   the internal donor and/or $TiCl_4$.[7-13] The latter route (advanced) employs the chemical

71   transformation of a $MgCl_2$-precursor into nanostructured and highly defective $MgCl_2$ (δ form)

72   by $TiCl_4$ itself in the presence of the donor,[14-29] and generally leads to more disordered and

73   more active nanostructures.[30-32] In a typical chemical preparation route, all the components are

74   intimately connected to each other. $TiCl_4$ promotes the chlorination of the precursor into $MgCl_2$

75   and exerts a capping effect on the newly formed $MgCl_2$ nanoparticles.[33] The electron donor not

76   only influences the $MgCl_2$ morphology by stabilizing specific surfaces,[20, 22] but also interacts

77   with the Ti sites through direct coordination[34-37] or more plausibly through coadsorption.[38] By-

78   products formed during the chlorination must not be overlooked as these products could adsorb

79   on $MgCl_2$ surfaces, and work as catalytic poisons unless properly removed.[39]

80   All the above-mentioned events parallel in the catalyst preparation to determine the final

81   structure of ZN catalysts at multiple length scales and, in turn, the catalyst performance.

82   Therefore, monitoring the evolution of the catalysts along the synthesis is the only way to

83   elucidate all the inter-connections between their components, laying the groundwork for a

84   future rational design of new and more efficient catalytic systems. In this work, we focus on

85   the ZN catalyst obtained from a $Mg(OEt)_2$ precursor, using dibutyl phthalate (DBP) as an

86   internal donor. The $Mg(OEt)_2$-based ZN catalysts are among one of the most employed

87   catalysts in industrial PP production, because of their high activity and stereoselectivity. The

88   difficulties of this investigation rely not only on the chemical lability or air sensitivity of

89   samples, but also on the multi-technique approach needed to face such a multi-scale

90   complexity, ranging from the local structure of the Ti sites to the textural properties of $MgCl_2$

91   particles. Only a few pioneering works in the literature dealt with the evolution of the material

92   during the ZN catalyst synthesis from $Mg(OEt)_2$, where a series of samples were extracted from

93   the reactor, and characterized for their chemical composition, structure, and activity.[40-42]

94   According to Jeong et al., the activity towards propylene polymerization increases linearly with

95   the increase in the number of $TiCl_4$ addition, while the presence of an internal donor affects

96   drastically the stereospecificity of the catalyst (enhancing the isotacticity of the produced PP

97   from less than 50 % up to 95 % in *mmmm*).[40] More in details, Chumachenko et al. found out

98   that the reaction at early stages between $Mg(OEt)_2$ and $TiCl_4$ leads to a mixture of $MgCl_2$ and

99    $TiCl_3(OEt)$ with very high surface area (415 m^2/g) but low activity and stereospecificity, while

100   the subsequent addition of DBP causes the removal of inactive $TiCl_3(OEt)$, the growth of

101   $MgCl_2$ crystallites (the surface area decreases to 211 m^2/g), and a significant increase of the

102   overall activity and stereospecificity.[42] Finally, Kim et al. mostly focused on the mutual

103   reactions between $Mg(OEt)_2$, $TiCl_4$ and the benzoyl chloride (BzCl) used as an electron donor

104   or its precursor, demonstrating the high interchangeability of $(OEt)^-$ and Cl^- anionic ligands.[41]

105   Recently, we proposed a combination of cutting-edge characterization techniques to clarify

106   the identity of δ-$MgCl_2$, which includes X-ray total scattering for defining the nano-sized and

107   disordered structure,[30] and vibrational spectroscopies for determining the exposed surfaces and

108   their relative extension.[43] In this study, the same approach has been adopted, but complemented

109   by chemical analysis, polymerization tests and UV-Vis spectroscopy, in order to elucidate the

110   chemical reactions and structural evolution taking place during the ZN catalyst preparation.

111

112   **2. EXPERIMENTAL**

113   **2.1. Reagents**

114   Mg powder was purchased from Merck, KGaA. Ethanol (purity > 99.5%, Kanto Chemical)

115   was dried over 3A molecular sieve with N_2 bubbling. Iodine (I_2, purity > 99.999%, FUJIFILM

116   Wako Pure Chemical) was used as a halide initiator. *n*-Heptane (purity > 99.5%,), toluene

117   (purity > 99.5%), and di-*n*-butylphthalate (DBP, purity > 98%) were purchased from

118   FUJIFILM Wako Pure Chemical and dried over 4A molecular sieve with N_2 bubbling.

119   Triethylaluminium   (TEAl)   was   donated   by   Tosoh   Finechem.

120   Cyclohexylmethyldimethoxysilane (CMDMS) was purchased from Sigma-Aldrich and

121   purified by vacuum distillation. Propylene was donated by Japan Polychem Corp., and ethylene

122   was purchased from Sumitomo Seika Chemicals Co., Ltd.

123

124   **2.2. Catalyst Synthesis**

125   All the manipulations and storage were performed under a N_2 atmosphere to prevent moisture

126   contamination. The starting material, $Mg(OEt)_2$, was synthesized according to a previously

127   reported method.[44-46] Briefly, 2.64 mmol of I_2 and 25.0 g of ethanol were introduced to a 500

128   mL jacket-type flask equipped with a mechanical stirrer rotating at 180 rpm. After dissolving

129   I_2 in ethanol at 75 °C, 2.5 g of Mg powder and 25.0 g of ethanol were added. The same amount

130   of Mg powder and ethanol were repeatedly added with sufficient intervals between individual

131   additions. The total amount of Mg powder and ethanol were 25.0 g and 125 g. The resultant

132   solid product was recovered by washing with 200 mL of ethanol and dried in vacuo at below
133   40 °C.

134   The procedures for catalyst preparation and sampling are shown in Scheme 1. A three-necked

135   flask (500 mL) equipped with a mechanical stirrer and purged with N_2 was charged with 20 g

136   of $Mg(OEt)_2$ powder and 136 mL of toluene. 20 mL of $TiCl_4$ was dropwise introduced by

137   keeping the temperature of the mixture below –5 °C. The mixture was gradually heated, and

138   when the temperature reached 60 °C, 4.3 mL of DBP was dropped in the flask. The mixture

139   was further heated, and kept at 110 °C for 2 hours. The solid product in the flask was washed

140   with toluene twice by a decantation method, and then 16 mL of $TiCl_4$ and 68 mL of toluene

141   were introduced. The mixture was heated and aged at 110 °C for 4 hours. Note that the aging

142   time after the second addition of $TiCl_4$ is usually set to 2 hours, while the duration was extended

143   to 4 hours in this study for the sake of characterization. Finally the mixture was sufficiently

144   washed with toluene and *n*-heptane to obtain the catalyst. At several key points in the above

145   preparation, samples were extracted from the flask using a syringe. The amount of each

146   extraction corresponded to ca. 3 g of solid. The extracted solid was washed thoroughly with *n*-

147   heptane, dried in vacuum at 80 °C, and stored under N_2 for characterization. The timing of the

148   extraction and the corresponding sample codes are as follows: (**A**) after the first $TiCl_4$ addition,

149   (**B**) immediately before the addition of DBP, (**C**) when the temperature of the mixture reached

150   110 °C, (**D**) after being kept at 110 °C for 2 hours, (**E**) after 2 hours of the aging, and (**F**) the

151   final catalyst. All the extracted samples were adequately washed with dehydrated *n*-heptane

152   and then dried in vacuum at 80 °C.

2.3. Ethylene and Propylene Polymerization

Polymerization tests were carried out in semi-batch mode. A mechanically stirred 1 L autoclave reactor was charged with 300 mL of heptane and 3.0 mmol of TEAl for ethylene polymerization, or with 300 mL of heptane, 3.0 mmol of TEAl, and 0.30 mmol of CMDMS for propylene polymerization. Either ethylene or propylene was introduced to the reactor and saturated at 0.4 MPa and 70 °C. The polymerization was initiated by the injection of a catalyst (10–50 mg) into the reactor and continued for 30 minutes, where the temperature, the monomer pressure, and the stirring speed were maintained at 70 °C, 0.4 MPa, and 500 rpm, respectively. The obtained polymer powder was recovered by filtration and vacuum drying at 60 °C for 6 hours.

2.4. Catalysts Activation by TEAl

In order to investigate the activation process, some selected samples (**A**, **B**, **C**, and **F**) were separately reacted with TEAl. The activation of the catalysts was carried out in glove-box by impregnating at room temperature the powders with TEAl (diluted 10 v/v % in hexane) at an Al:Ti ratio of 2:1. Afterwards, the solvent was removed by degassing under vacuum.

2.5. Characterization

2.5.1. Chemical Composition

The chemical composition of the samples was analyzed as follows. The Ti content was measured by a colorimetric method, where ca. 50 mg of a sample was dissolved in an aqueous solution of HCl/H_2SO_4, and then H_2O_2 solution was added to develop the color. The absorption intensity of the band at 410 nm was recorded on a UV–vis spectrometer (V-670 JASCO), which was used to calculate the titanium content based on external calibration.[44] Organic contents were analyzed by ^{1}H NMR on a Bruker AVANCE III 400 MHz spectrometer according to our previous study.[39] 10–30 mg of a sample was dissolved in 0.7 mL of DMSO-d_6 with 40 μg of 1,1,2,2-tetrachloroethane as an internal standard. The morphology of the catalyst particles was observed by scanning electron microscopy (SEM, Hitachi Ltd., S-4500). In order to minimize the risk of moisture contamination during sample transfer, sputter coating was omitted. The acceleration voltage was set to 1 kV to suppress a charge-up effect.

2.5.2. Polymer Characterization

The obtained polymers were subjected to differential scanning calorimetry (DSC, Mettler Toledo DSC 822) under a nitrogen atmosphere. About 8 mg of polymer in an aluminum pan were heated to 230 °C and then cooled down to 25 °C (20 °C min^{-1}). The cooled sample was then heated up to 230 °C at a heating rate of 20 °C min^{-1} to determine the melting temperature (T_m) and the crystallinity (X_c) from the melting endotherm.

Gel permeation chromatography (GPC, Tosoh Co., HLC-8321GPC/HT) measurements were performed at 140 °C using o-dichlorobenzene as a mobile phase. Polystyrene standards were used for calibration.

2.5.3. X-ray Total Scattering

201   X-ray total scattering data were acquired at the BL04B2 of SPring-8 (Hyogo, Japan). Each

202   sample in the powder form was filled in a quartz glass capillary with a diameter of 2 mm and

203   a wall thickness of 0.01 mm, placed in a vacuum chamber, and irradiated with the X-ray beam

204   at an energy of 61.4 keV (λ=0.202 Å). The diffraction patterns were recorded in transmission

205   mode and in the horizontal scattering plane by using solid-state array detectors. The upper limit

206   of the scattering vector (Q) was 25.7 Å^{-1}. The measured X-ray scattering data were corrected

207   for polarization, absorption, and background. The contribution of Compton scattering was

208   subtracted using standard analysis procedures.[47] The calculated total structure factor $S(Q)$ was

209   converted into reduced pair distribution function (PDF) $G(r)$ via Fourier transformation with a

210   Lorch modification function.[48]

211

212   **2.5.4. IR Spectroscopy**

213   IR spectra were collected with a Bruker Vertex70 FT-IR spectrophotometer, equipped with

214   a DTGS detector for the Far-IR region and a MCT detector for the Mid-IR region (hereafter

215   generically referred to as IR).

216   For the Far-IR measurements, the samples were prepared directly inside a N_2-filled glove-

217   box as thin layers deposited on a highly pure Si wafer (from a suspension in hexane), and placed

218   inside a quartz cell with PE windows, allowing to measure the spectra without exposing the

219   samples to air. Far-IR spectra were acquired at a resolution of 4 cm^{-1}, and are shown after

220   subtracting the weak contributions of both the Si wafer and the PE windows.

221   For the IR measurements, the samples were diluted in anhydrous KBr, compressed in the

222   form of thin self-supporting pellets (with a resulting density of 10 mg of sample per cm^2) inside

223   the glove-box, and placed inside a quartz cell with KBr windows. The IR spectra were acquired

224   at a resolution of 2 cm^{-1}. The curve fitting of the spectra in the ν(C=O) region was carried out

225   by OPUS software (Bruker), imposing the Gaussian shape to the contributions.

226

2.5.5. DR UV-Vis Spectroscopy

UV-Vis spectra were collected in diffuse reflectance mode (DR), with a Varian Cary5000 spectrophotometer, equipped with a reflectance sphere. The powder samples were directly placed inside a bulb-shaped cell made of optical quartz (Suprasil) within the glove-box, and successively measured in N_2 atmosphere. The spectra have been collected in reflectance mode and then converted in the Kubelka-Munk function.

3. RESULTS AND DISCUSSION

In this study, we performed a multi-faceted characterization of solid samples extracted at different steps of catalyst preparation for addressing two key questions: 1) how catalyst nanostructures are generated and shaped during the preparation, and 2) which are the mutual interactions between all the catalyst components. The structure of the Section is as follows: in Section **3.1** the chemical composition of all the samples is discussed; Section **3.2** describes the performances of each intermediate as well as of the final catalyst in olefin polymerization after activation by TEAl; then the results of individual characterization methods are explained and discussed in Sections **3.3-3.6**, and finally all the results are combined to give a conclusive picture in Section **4**.

3.1. Chemical Composition

The evolution of the chemical composition along the ZN catalyst synthesis is summarized in Table 1. In general, it has been reported that $Mg(OEt)_2$ is chlorinated by $TiCl_4$ to produce $MgCl_2$ and $TiCl_x(OEt)_{4-x}$. The OEt group remains in the catalyst to a greater or lower extent due to both/either incomplete chlorination of $Mg(OEt)_2$ and/or persistence of surface $TiCl_x(OEt)_{4-x}$ species, which greatly reduces the activity and stereospecificity of the catalyst.

251 Here, the OEt group was quantified by the methylene peak in ^{1}H NMR, so the OEt residual can

252 be associated to either Mg(OEt)$_2$ or TiCl$_x$(OEt)$_{4-x}$. Initially (**A,B**), the Ti content is pretty high

253 (about 2.5 mmol g^{-1}) and the Ti:OEt molar ratio is about 1:1. By introducing DBP and heating

254 up to 110 °C, the Ti content is reduced to less than half (**C**), and to a further half by the aging

255 (**D**), whereas the Ti:OEt molar ratio is kept almost constant. Hence, it is plausible that in the

256 early stages of catalyst preparation, Ti is present almost exclusively as TiCl$_3$(OEt). Heating

257 with DBP causes a reduction in the amount of TiCl$_3$(OEt). The second TiCl$_4$ treatment has

258 almost no impact on the Ti content (**E,F**), but the OEt further decreases to below 0.2 mmol g^{-1},

259 suggesting that TiCl$_x$(OEt)$_{4-x}$ species are replaced by TiCl$_4$. Concerning DBP, its content at the

260 end of ZN catalyst synthesis (**F**) converges to about 0.6 mmol g^{-1}, which corresponds to a

261 molar amount comparable to that of Ti. Finally, it is worth noticing that in ZN catalysts

262 containing DBP as an internal donor, phthaloyl chlorides (POC) are known as typical by-

263 products, which are produced by a reaction of DBP and TiCl$_4$ at an elevated temperature. In

264 our analysis, POC were not observed during the first TiCl$_4$ treatment (**C,D**), but was slightly

265 observed (column Cl in Table 1) after the second TiCl$_4$ treatment (**E,F**), which suggests that

266 the fresh TiCl$_4$ is more reactive towards the surface adsorbates.

267

268 **Table 1.** Evolution in the chemical composition along the synthesis steps.

275

3.2. Performance in Olefin Polymerization

277   Samples **A**–**F** have been used as catalysts for ethylene and propylene homopolymerization

278 after activation by TEAl. Table 2 summarizes the activity data, while Figure 1 shows the

279 activity normalized per Ti-mol. The reactivity is completely different for the two monomers,

280 suggesting that the composition and structural features required for ethylene and propylene

281 polymerization are completely different. The ethylene polymerization activity (per Ti-mol) was

282 almost constant throughout the catalyst synthesis, i.e. insensitive to the composition and

283 structural features. In contrast, propylene polymerization was found to be sensitive to the stage

284 of the catalyst preparation: no polymer was obtained before DBP was added and heated up to

285 110 °C (**A**,**B**), but then the activity increased significantly along with the synthesis. The

286 characterization of all the produced polymers is summarized in Table S1 and Figure S1.
287

288 **Figure 1.** Ethylene and propylene polymerization activity of the samples extracted at different

289 stages in the course of catalyst preparation. Reaction conditions: monomer pressure = 0.4 MPa,

290 catalyst = 10–50 mg, *n*-heptane = 300 mL, TEAl = 3.0 mmol, 70 °C, 30 min, CMDMS (for

291 propylene polymerization) = 0.30 mmol.

14

3.3. Formation of Nanostructure Along the Synthetic Steps

3.3.1. PXRD

The solid samples extracted in the course of catalyst preparation (**A** to **F**), as well as the Mg(OEt)$_2$ starting material, were subjected to X-ray total scattering measurements. The X-ray diffraction patterns are shown in Figure 2. The pattern of Mg(OEt)$_2$ exhibits two strong peaks at $2\theta = 9$ and $11°$. The structure of Mg(OEt)$_2$ has not been clearly identified yet, but it is believed that it resembles that of Mg(OH)$_2$ (Brucite, P$\bar{3}$m1), where the H atoms are substituted with ethyl groups, and the split peaks correspond to (001) reflection.[27, 49, 50] That is, the O-Mg-O layers are stacked across a layer of -C$_2$H$_5$ groups, and hence the peaks at $2\theta = 9$ and $11°$ are most likely originated from the stacking of the O-Mg-O layers. A broad peak centered at $2\theta = 10°$ is also observed in the pattern of **A** (right after the first TiCl$_4$ addition), which suggests that the structure of **A** memorizes the layered structure of Mg(OEt)$_2$ to some extent. The same pattern, however, also contains weak reflections at $2\theta = 27$–$40°$ and $50°$, which correspond to the (012)/(104) and (110) reflections of MgCl$_2$, and indicate that the MgCl$_2$ seeds are already formed at the very initial stage of the synthesis. The peak at $2\theta = 10°$ becomes weaker when the temperature is increased up to 60 °C (**B**), and eventually disappears after the addition of DBP and heating up to 110 °C (**C**). Instead, the peak corresponding to the Cl-Mg-Cl stacking along the *c*-axis emerges at 15°. In the following steps of the preparation (from **D** to **F**), the broad peak in the 27–40° range becomes stronger, reflecting the growth of the MgCl$_2$ crystallites both in the lateral and vertical directions. The patterns of **C**–**F** are typical for δ-MgCl$_2$: three broad peaks are observed at around 15°, 27–40°, and 50°, which correspond to (003), (012)/(104), and (110) reflections. The broadness of the peaks indicates the nano size of MgCl$_2$ in all the dimensions, while the merge of the (012) and (104) reflections into a single broad peak (in particular for **C**) dictates the total lack of periodicity in the stacking of Cl-Mg-Cl layers.[8] Hence, PXRD measurements clearly indicate that the MgCl$_2$ crystallites or their

seeds are formed just after the first TiCl4 addition, and they gradually grew through the subsequent steps of preparation, maintaining a disordered structure along the Cl-Mg-Cl stacking direction.
Figure 2. Powder X-ray diffraction (PXRD) patterns of the samples extracted at different steps of the synthesis and of the Mg(OEt)$_2$ starting material. The X-axis was scaled with the wavelength of Cu Kα (λ=1.5418 Å) for comparison with the literature. The typical diffraction peaks of α-MgCl$_2$ are denoted by dotted lines. The patterns are vertically shifted for clarity.

The SEM images of the catalyst samples are shown in Figure S2. The spherical Mg(OEt)$_2$ is an aggregate of plate-like particles with a length of several micrometers.[51] The surface of **A**, just after contact with TiCl$_4$, is notably rough since the plate-like particles partially retain their shape. In **B**, the macroparticles became smoother and more spherical due to the fusion of plate-like particles. After adding the donor (**C**), the surface became even smoother, and the plate-like particles were completely fused. From **C** to **F**, no significant changes were observed. In

16

337   addition, the macroparticles seem to grow slightly from **A** to **C**, which is probably due to the

338   fusion of small $Mg(OEt)_2$ macroparticles or the growth of the catalyst primary particles. Such

339   ripening phenomenon has been reported previously, where the resultant catalyst particles were

340   about 10% bigger in diameter than the original $Mg(OEt)_2$ particles.[44, 52]

341

342   **3.3.2. PDF**

343   The total scattering data were converted into PDFs. Figure 3 shows PDFs of the extracted

344   samples (**A**–**F**) as well as of $Mg(OEt)_2$ and α-$MgCl_2$ in the long-range (part a) and short-range

345   (part b) regions. PDFs directly correlate with the atomic configuration in the real space: i) peak

346   positions correspond to atomic distances; ii) the broadness represents their distribution,

347   including the thermal vibration effect; iii) the relative abundance of the atomic pairs can be

348   estimated by the intensity of the peaks; therefore, the distance at which the amplitude becomes

349   completely negligible corresponds to the crystalline dimensions.[53] For $Mg(OEt)_2$, a weak

350   oscillation can be observed from around 0.5 to 6 nm; however, this is not due to the local atomic

351   configuration, but to density fluctuation originated from a nanostructure, that is most plausibly

352   caused by O-Mg-O layers.[54] The fact that limiting the Q_{min} to 1.0 $Å^{-1}$ completely diminishes

353   the fluctuation also supports this hypothesis (Figure S3). From **A** to **F**, the distance at which

354   the amplitude disappears gradually increases (as marked in yellow in Figure 3a), from r = ca.

355   2 nm (**A,B**) to ca. 4-5 nm (**C**) and to ca. 5.5-6.5 nm (**D,F**), suggesting that the $MgCl_2$ crystallites

356   slowly grow during the synthesis.

357   In the shorter region (Figure 3b), the pattern of $Mg(OEt)_2$ shows a prominent peak at 0.20

358   nm, which is attributed to the Mg-O atomic pair. For comparison, the distance between Mg and

359   O in $Mg(OH)_2$ is estimated at a very close value, ca. 0.21 nm. The PDF pattern of **A** does not

360   exhibit such peak, providing evidence that the Mg-O bond is immediately converted to Mg-Cl

361   by contacting $Mg(OEt)_2$ with $TiCl_4$. Although there is no traceable Mg-O in the PDF, there is

362 a remnant of the periodic structure formed by $Mg(OEt)_2$ in the PXRD. Such a memory of the

363 precursor structure on PXRD has also been reported in the formation of δ-$MgCl_2$ from

364 $MgCl_2$/Lewis base adducts.[55, 56] The positions of the most relevant peaks in the patterns of the

365 extracted samples are similar to those of α-$MgCl_2$, for example, the peaks at 0.25, 0.35, 0.58,

366 0.63, and 0.97 nm. This fact indicates that the local structures of the extracted samples were

367 almost identical to that of the α-$MgCl_2$ even at the stage of seeds formation (**A**). The relatively

368 weak peak intensity of **A** and **B** over $r = 0.5$–1.0 nm is due to its finite crystal dimension (<2

369 nm).

370

371
Figure 3. Part a) Atomic pair distribution functions (PDFs) of the extracted samples in the long-range region. Part b) Those in the short-range (part b) region. Q_{min} was set as 0.1 Å^{-1}. The PDFs of Mg(OEt)$_2$ and highly crystalline α-MgCl$_2$ (acquired at AichiSR, Q_{max}=15 Å^{-1}. See ref[30]) are also provided for comparison purpose. The patterns are vertically shifted for clarity.

3.3.3. Quantitative Structural Determination

The structure of δ-MgCl$_2$ in the extracted samples was quantitatively determined by PXRD fitting and cross-validated by PDF fitting, following the same approach discussed in our

381 previous work.[30] Table 3 summarizes the structural parameters of $MgCl_2$ nanoparticle models

382 as determined by PXRD fitting, where $L_a=L_b$ correspond to the lateral size in the *ab* plane, L_c

383 is the crystallite dimension in the basal direction, and P_c is the probability of finding α-$MgCl_2$

384 sequences as an indicator of the amount of stacking disorders ranging from 25 to 100%; the

385 accuracy of the fit is also provided in terms of R_w, defined as the residual between the

386 experimental and the simulated patterns. A typical fitting pattern is shown in Figure S4a.

387 In **A**, obtained just after contacting $Mg(OEt)_2$ with $TiCl_4$, the $MgCl_2$ seeds have a lateral

388 dimension of 1.8 nm and a vertical dimension of 0.3 nm, corresponding to a single Cl-Mg-Cl

389 layer. Heating up to 60 °C (**B**) brings no significant change in the structure of $MgCl_2$ seeds.

390 The addition of donor and heating up to 110 °C (**C**) significantly promotes the growth of the

391 $MgCl_2$ seeds both in the lateral and vertical directions (4.0 nm and 1.4 nm, respectively).

392 Further heating for 2 hours (**D**) induces further growth in the lateral direction (from 4.0 nm to

393 5.5 nm) as well as a decrease in the stacking disorder (P_c increases from 25% to 40%). The

394 second $TiCl_4$ addition and further aging (**E,F**) do not cause a significant structural change,

395 which is consistent with the fact that the amount of Ti and phthalate on $MgCl_2$ is almost kept

396 constant from **D** to **F** (Table 1). It is likely that the presence of DBP (only in the first $TiCl_4$

397 treatment) is a primary factor to promote the growth of $MgCl_2$.

398 The obtained $MgCl_2$ nanoparticle models were cross-validated using PDF fitting. Simulated

399 patterns and fitting parameters therein are shown in Figure S4b and Table S2. All the PDF

400 patterns are reasonably fitted with the PXRD-determined nanoparticle models. The fitting

401 accuracy for **A** and **B** was relatively poor ($R_{w,PDF}$ = 0.374 and 0.377), which is likely attributed

402 to the relatively low periodicity (i.e. weaker signals).

403

404 **Table 3.** $MgCl_2$ nanoparticle models derived via PXRD fitting and cross-validated by PDF

405 fitting with the aid of software, DISCUS,[57] PDFgui,[58] and DShaper.[59] $L_a = L_b$: lateral size in *ab*

406 plane; L_c: crystallite dimension in the basal direction; P_c: indicator of stacking disorder; R_w:

407 indicator of the fitting accuracy.

| Sample Name	$L_a = L_b$ [nm]	L_c [nm]	P_c [%]	$R_{w,PXRD}$	$R_{w,PDF}$
A	1.8	0.3	n.a.[a]	0.162	0.374
B	1.8	0.3	n.a.[a]	0.106	0.377
C	4.0	1.4	25	0.151	0.318
D	5.5	1.4	40	0.115	0.278
E	5.8	1.4	46	0.165	0.270
F	6.1	1.4	49	0.143	0.221

408 [a] P_c was not specified as the particle model is composed of a single Cl-Mg-Cl layer.

409

3.4. Morphology of MgCl₂ Nanoparticles Along the Synthetic Steps

411   Far-IR spectroscopy has been applied to all the extracted samples to retrieve information on

412 the morphology of the $MgCl_2$ nanoparticles. As a matter of fact, we have previously

413 demonstrated that the vibrations in the region of $600 - 100$ cm^{-1}, which are due to both intra-

414 layer displacement of the atoms in the *ab* plane and inter-layer displacement along *c* axis, are

415 sensitive to the relative extension of the different $MgCl_2$ surfaces.[43] Moreover, vibrations

416 involving Ti-Cl, Ti-O and Mg-O also fall in this spectral range, so that Far-IR can provide

417 information also on the adsorbates at $MgCl_2$ surfaces, including the Ti species.

418   Figure 4 displays the evolution of the Far-IR spectra along the synthetic steps, together with

419 the spectrum of the $Mg(OEt)_2$ starting material.
Figure 4. Far-IR spectra of the extracted samples and of the $Mg(OEt)_2$ precursor. The spectra are vertically stacked for clarity.

The Far-IR spectrum of $Mg(OEt)_2$ is characterized by two main absorptions centered at 330 and 450 cm^{-1}, very broad and overlapping to each other. Similar bands have been already observed in the past for different $MgCl_2$ adducts with alcoholates and alkoxides, and assigned to the vibrations of Mg-O bonds.[60-62] As observed in the PDF analysis for the same sample, these bands are no more observed already at the first step of the synthesis, while they are replaced by the vibrational modes characteristic of $MgCl_2$. The spectrum of **A** shows a main absorption band centered at 235 cm^{-1}, together with two weaker bands at 525 and 360 cm^{-1}. The sharp band at 235 cm^{-1} is assigned to the basal (001) surface,[43] in well agreement with the PXRD analysis according to which the first $MgCl_2$ seeds are mostly formed as monolayers. The band at 525 cm^{-1}, instead, is attributed to the ν(Ti-O) vibrations of 4-fold coordinated $Ti(OEt)_xCl_{4-x}$ species (vide infra).[63] The relatively high intensity of this band is in well

22

435 agreement with the high and nearly equimolar Ti and OEt percentages in **A** (2.42 and 2.09

436 mmol g^{-1}, respectively). Finally, the band at 360 cm^{-1} is attributed to a few ethoxide residues

437 on the MgCl$_2$ seeds.

438 In the spectrum of **B**, the main absorption band is still located at 235 cm^{-1}, indicating that

439 even after heating at 60 °C MgCl$_2$ particles mainly expose the basal surface (001). The band at

440 525 cm^{-1} is no more observed, while a new band with similar intensity is present at 435 cm^{-1}.

441 This band is assigned to ν(Ti-Cl) of 6-fold coordinated Ti species,[11] and indicates that a fraction

442 of the Ti ethoxy chloride complexes are chemisorbed on the MgCl$_2$ seeds during the warm-up

443 process up to 60 °C. Unfortunately, the destiny of this band in the following steps of the

444 synthesis cannot be further investigated because of the drastic decrease of the Ti loading (to

445 0.56 mmol g^{-1} in **F**), which makes the band too weak in intensity.

446 The addition of DBP (**C**) causes a significant change in the Far-IR spectrum: the main

447 absorption band upward shifts to 250 cm^{-1} (with a shoulder at 280 cm^{-1}) and a sharp and intense

448 band appears at 365 cm^{-1} (with a pronounced hump at 405 cm^{-1}). According to previous

449 calculations, both manifestations can be associated to a morphological reconstruction of the

450 MgCl$_2$ crystallites, which now do not expose anymore exclusively the basal (001) surface. In

451 particular, the (110) surface is the principal responsible for the main signals at 250 and 365 cm^{-}

452 ^{1}, while both the (012) and (015) surfaces significantly contribute at 280 and 405 cm^{-1}.[43]

453 From **D** on, all the Far-IR spectra are similar to each other and to the spectrum of the final

454 ZN catalyst (**F**). The features of the spectra are the same as already discussed in our previous

455 work.[43] Briefly, with respect to the spectrum of **C**, the main absorption band at 250 cm^{-1}

456 undergoes a slight enlargement and the band at 365 cm^{-1} slightly decreases in intensity. Overall,

457 the spectrum indicates that MgCl$_2$ nanoparticles expose a large variety of surfaces, among

458 which the relatively most abundant is the (110) one. It is worth noticing that such a surface has

459 been claimed to be one of the most catalytically relevant ones.[64-67]

460

3.5. Surface Species Along the Synthetic Steps

The evolution of the surface species during ZN catalyst synthesis was investigated by IR spectroscopy in the Mid-IR region, as reported in Figure 5a. The spectrum of $Mg(OEt)_2$ is analogous to the spectra of Mg alkoxides already reported and described in literature.[68, 69] Briefly, most of the bands are due to the vibrational modes of the OEt moieties: the $\nu(CH_x)$ bands at 2800-3000 cm^{-1}, the $\delta(CH_2)$ and $\delta(CH_3)$ bands at 1450 and 1380 cm^{-1}, $\nu(C-O)$ at 1120 cm^{-1}, $\nu(C-C)$ at 1050 cm^{-1} and some rocking modes at 890 cm^{-1}. Below 600 cm^{-1} the tail of the absorption band due to the $\nu(Mg-O)$ vibrations, contributing in the Far-IR region, is also observed.

470
Figure 5. Part a) IR spectra of the extracted samples, normalized to the optical thickness of the pellets. Part b) Magnification of the **C-F** spectra in the $\nu(C=O)$ region. Part c) Curve fitting in the $\nu(C=O)$ region for **F** (the black curve is the sum of all the calculated contributions). Part d)

24

Evolution of individual $\nu(C=O)$ components along the synthetic steps. The components are liquid-like physisorbed DBP, DBP on MgCl$_2$ surfaces, DBP on defective Mg^{2+} sites, DBP on Ti^{4+}, and POC.

The original bands due to the Mg-ethoxide groups are no more observable in the spectrum of **A**. Nevertheless, the spectrum still contains intense bands in the $\nu(CH_x)$, $\delta(CH_x)$, $\nu(C-O)$ and $\nu(C-C)$ regions, which correspond well to those observed in the spectra of tetrahedral Ti(OEt)$_2$Cl$_2$ and Ti(OEt)$_3$Cl complexes.[63] Hence, at this stage most of the ethoxide groups look associated into TiCl$_x$(OEt)$_{4-x}$ species rather than incompletely chlorinated Mg(OEt)$_x$Cl$_{2-x}$. Beside the ethoxide bands, the spectrum of **A** displays a weak and broad band in the $\nu(OH)$ region (around 3400 cm^{-1}), which is due to a small amount of moisture contamination. The spectrum of **B**, obtained after heating **A** up to 60 °C, shows only small changes in the position of the bands ascribed to the ethoxide species, which are compatible with the chemisorption of the Ti ethoxide chloride complexes and a change in the coordination of the Ti cations from tetrahedral to octahedral.

The IR spectra radically change after the addition of DBP in the reaction mixture (**C**).[70] Most of the bands associated to the ethoxide groups drastically decrease in intensity after the addition of DBP (**C**), indicating that the ethoxide groups are mostly removed, in perfect agreement with the chemical composition of the sample in Table 1. The spectra of **C** to **F** are all dominated by the vibrational features of DBP, with the characteristic $\nu(C=O)$ band around 1700 cm^{-1} (as magnified in Figure 5b). The analysis of the $\nu(C=O)$ region allows to obtain information on the coordination modes of DBP at the MgCl$_2$ surfaces and hence, indirectly, on the types of exposed sites. A curve fitting of the $\nu(C=O)$ region has been performed for the spectra of **C-F**, as frequently reported in the literature, where each computed band has been assigned on the basis of the literature. By way of example, Figure 5c displays the curve fitting of the spectrum

499   of the final catalyst (**F**), which includes all the possible ν(C=O) contributions: for liquid-like

500   DBP at 1728 cm^{-1},[71, 72] DBP in interaction with different Mg^{2+} sites at 1657, 1680 and 1707

501   cm^{-1},[71-74] DBP in interaction with TiCl$_4$ at 1634 cm^{-1},[75, 76] and the POC produced by a side

502   reaction between DBP and TiCl$_4$ at 110 °C[42] at 1758, 1836 and 1862 cm^{-1} (identical bands were

503   observed by directly co-milling MgCl$_2$ and POC).[76, 77] The fit is completed by including the

504   two ring vibrations of the ortho-disubstituted phenyl ring at 1581 and 1595 cm^{-1},[78] and an

505   additional band at 1615 cm^{-1} ascribable to δ(OH) of water traces. Focusing on the three bands

506   due to DBP in interaction with different Mg^{2+} sites, the band at 1707 cm^{-1} can be assigned to

507   DBP both in a chelate configuration on 4-fold coordinated Mg^{2+} sites (the most

508   thermodynamically favored configuration for DBP on the (110) surface) and monodentate on

509   5-fold coordinated Mg^{2+} sites,[79, 80] the band at 1680 cm^{-1} is ascribed to monodentate DBP at 4-

510   fold coordinated Mg^{2+} sites,[79, 80] whereas the band at 1657 cm^{-1} is due to DBP on defect sites.[71,

511   73, 74] It is important to notice that, at a difference than what happens with ethylbenzoate, it is

512   not possible to quantify the DBP coordinated at 4-fold and 5-fold Mg^{2+} sites, but only to

513   discriminate between DBP adsorbed at MgCl$_2$ surfaces and defects.

514   By estimating the integrated areas of each ν(C=O) band in the series of spectra for **C-F**, it

515   has been possible to estimate in a semi-quantitative way the relative abundances of each species

516   at the different synthesis steps, as reported in Figure 5d.[81] A few conclusions can be drawn as

517   follows.

518   i.   As soon as DBP is added (**C**), some DBP molecules are trapped as liquid-like in the

519   interparticle pores of the material (blue line). This is compatible with the porosity data

520   reported by Chumachenko et al.[42] The amount of liquid DBP slightly decreases in the

521   following steps.

522   ii.   Moreover, as soon as DBP is added to the reaction mixture (**C**), a non-negligible

523   amount of a complex with TiCl$_4$ (orange line) is formed at MgCl$_2$ surfaces. The

524   thermodynamics driving this process was evaluated in the past by experimental

525   calorimetric measurements[82] and by theoretical calculations.[83] An analogous behavior

526   has been already observed upon dosing ethyl benzoate (EB) on $MgCl_2/TiCl_4$ from the

527   vapor phase.[84] According to the trend in Figure 5d, some of these complexes are washed

528   away during the successive steps of the catalyst synthesis, but not all of them.

529   iii.   DBP on $MgCl_2$ surfaces (grey line) are the most abundant species in all the samples,

530   although their amounts slightly decrease along the series in favor of DBP on defective

531   sites (light grey line), likely because their formation and stabilization is promoted by

532   DBP itself.[85]

533   iv.   Finally, after the second addition of $TiCl_4$ (**E**), some DBP molecules are converted into

534   phtaloyl chloride,[42] which was not present at all upon the first addition of $TiCl_4$. This

535   process increases over time upon aging the sample at 110 °C in the reaction mixture

536   (**F**).

537

3.5. Local Structure of the Ti Centers Along the Synthetic Steps

539   Finally, DR UV-Vis spectroscopy has been applied to monitor the evolution of the Ti species

540 from an electronic point of view during the ZN catalyst synthesis (Figure 6). Even though the

541 oxidation state remains the same (+4), the DR UV-Vis spectra change along the series,

542 reflecting changes in the titanium coordination sphere.
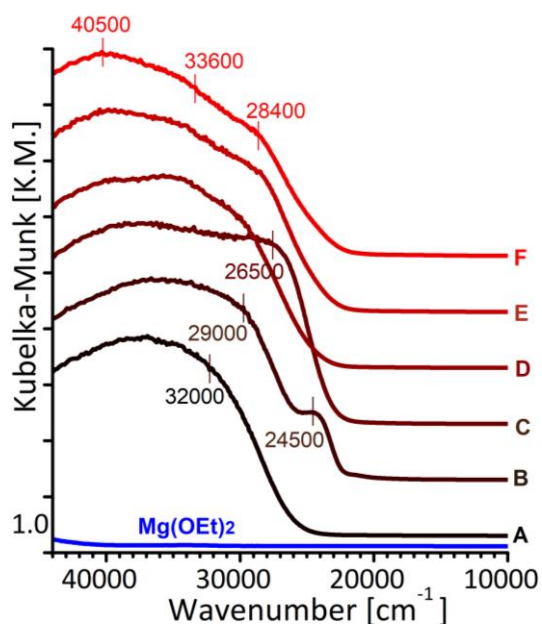

Figure 6. DR UV-Vis spectra of the extracted samples and of the $Mg(OEt)_2$ precursor. The spectra are vertically stacked for clarity.

Whereas the spectrum of $Mg(OEt)_2$ displays no absorption in the whole UV-Vis region, the spectra of the extracted samples are dominated by intense absorptions above 30000 cm^{-1}, due to several charge transfer (CT) transitions involving the Ti metal centers and their ligands. Since many contributions overlap to each other at high energy and hence cannot be clearly identified, the analysis will focus on the absorption band at lower energy, which is more easily identifiable and straightforwardly assigned to a $Cl(\pi) \rightarrow Ti(d)$ CT transition.[86, 87] Moreover, on this band the Jorgensen semi-empirical rule on the optical electronegativity of transition metals and their ligands can be applied.[88]

The spectrum of **A** shows the maximum of the first absorption at ca. 32000 cm^{-1}, which is compatible with a charge transfer transition from Cl^- ligands to a 4-fold coordinated Ti^{4+} (expected around 34500 cm^{-1} according to the Jorgensen rule).[88] This indicates that most of the Ti in **A** is present as physisorbed 4-fold coordinated $TiCl_x(EtO)_{4-x}$ species,[63] in fair agreement with both Far-IR and Mid-IR data, and compatibly with the sequence proposed by Brambilla et al. for $TiCl_4$ chemisorption on $MgCl_2$.[12] Then, after heating at 60 °C (**B**), the main absorption

560 downward shifts to ca. 29000 cm^{-1} and a new sharp band appears at 24500 cm^{-1}. The downward

561 shift of these bands is associated to a change in the coordination of the Ti ions from 4-fold to

562 6-fold (the theoretical value for the CT transition from Cl$^-$ ligands to octahedral Ti^{4+} is 28200

563 cm^{-1}),[88] indicating that 4-fold coordinated TiCl$_x$(EtO)$_{4-x}$ species at 60 °C have adjusted in the

564 more stable 6-fold coordinated octahedral configuration on the nascent MgCl$_2$ surfaces. This

565 is again in agreement with the analysis of the Far-IR and Mid-IR spectra. Notably, an analogous

566 trend was observed during TiCl$_4$ chemisorption from the vapor phase onto bare MgCl$_2$.[89] The

567 two bands, which differ of ca. 4500 cm^{-1}, might arise from the same Cl(π)→Ti(d) CT transition

568 localized on slightly different Ti species (for example with a different number of ethoxide

569 ligands) and/or from two Cl(π)→Ti(d) CT transitions on the same Ti cation from two different

570 Cl species (e.g. axial and equatorial Cl atoms with respect to the ethoxide ligands).[90]

571   The successive synthetic step (**C**) is dominated by the introduction of DBP, which not only

572 coordinates to the MgCl$_2$ surfaces and defects, but also directly to the Ti centers, as revealed

573 by the IR spectra in Figure 5c. The corresponding UV-Vis spectrum shows an intense band

574 peaked at 26500 cm^{-1}, which is always ascribed to a Cl(π)→Ti(d) CT transition for 6-fold

575 coordinated Ti sites, but with a slightly different environment than before. Indeed, IR

576 spectroscopy revealed that, at this step, most of the ethoxide ligands have been removed, and

577 TiCl$_4$-DBP complexes are formed. Most of the TiCl$_4$-DBP complexes are then removed from

578 MgCl$_2$ surfaces in the following steps of ZN catalyst synthesis because of the several washes

579 with toluene, and that absorption band is almost no more present in the following spectra.

580 Therefore, spectra of **D**, **E**, and **F** are all dominated by the absorption bands typical of

581 Cl(π)→Ti(d) CT transitions for Ti^{4+} in a 6-fold coordination, with small differences due to

582 slight distortions in the geometry and minor changes in the effective charge distribution.[86]

583

584 **3.6. Evolution of the samples upon TEAl activation**

585   TEAl activation has been investigated with an Al:Ti ratio of 2:1, in order to simulate the

586   excess of activator used in the polymerization tests in Section 3.2. Figure 7 displays some

587   significant results obtained by DR UV-Vis and IR spectroscopies.

588
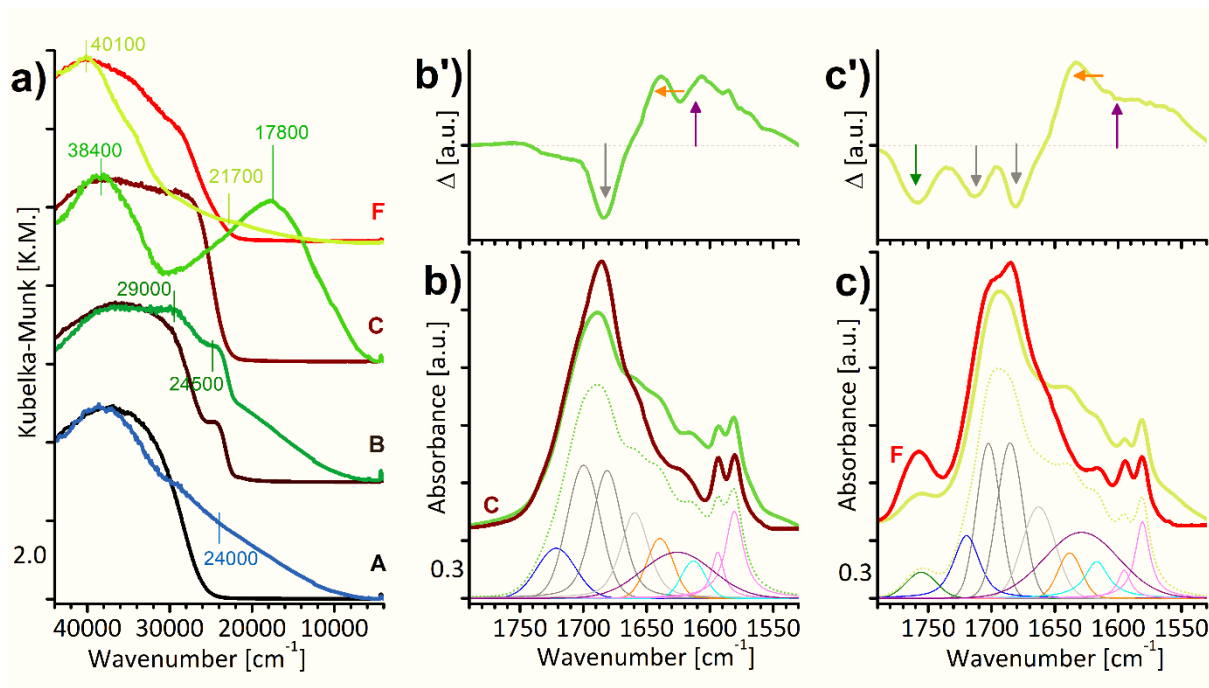

590   **Figure 7.** Part a) DR UV-Vis spectra of samples **A**, **B**, **C** and **F**, before and after TEAl

591   activation. Part b) Magnification in the ν(C=O) of the IR spectra of **C** before and after TEAl

592   activation. Curve fitting is also shown for activated **C**. Part b') Difference spectrum calculated

593   by subtracting to the spectrum of activated **C** the spectrum before TEAl activation. Parts c and

594   c') same as in parts b and b' for **F**.

595

596   In the UV-Vis spectrum of **A**, the position of the main absorption (that was assigned to a

597   Cl(π)$\rightarrow$Ti(d) CT transition) upward shifts at 38400 cm^{-1}, which is compatible with the

598   reduction of the Ti sites from +4 to +3 oxidation state.[88] At the same time, a broad absorption

599   grows up centered at about 24000 cm^{-1}, whose position corresponds to a Ti^{3+} d-d transition, but

600   whose intensity is much higher. Similar bands have been already observed in the past for TEAl-

601   activated ZN catalysts and assigned to intersite d-d transition involving two Ti^{3+} sites bridged

602   by a Cl^- ligand, thus assuming a partial charge transfer character;[91] for this reason, they have

603   been considered as proof of the formation of $TiCl_3$ clusters. In **A**, the formation of $TiCl_3$ clusters

604   is favored by the high mobility of physisorbed $TiCl_x(OEt)_{4-x}$ species.

605   An analogous trend is observed also in **B**, although in this case the two bands at 29000 and

606   24500 cm^{-1} remain unaltered, revealing that the fraction of 6-fold coordinated $TiCl_x(EtO)_{4-x}$

607   species responsible for those bands are evidently less reactive towards TEAl.

608   The spectrum of activated **C** is characterized by two very intense and well-defined absorption

609   bands at 38400 and 17800 cm^{-1}. The former is assigned to a $Cl(\pi) \rightarrow Ti(d)$ CT transition for a

610   Ti in the +3 oxidation state (as already discussed for **A**), while the latter is very peculiar, quite

611   different from the fingerprint of the $TiCl_3$ clusters typically observed in TEAl-activated ZN

612   catalysts. Instead, that band recalls the UV-Vis spectrum reported in the literature for a

613     $[TiCl_4(thf)_2]_1[MgCl_2(thf)_{1.5}]_2$ adduct after reaction with an Al-alkyl (trioctyl-aluminum, in that

614   case).[90] Therefore we can imagine the formation of DBP-bonded $TiCl_3$.

615   Finally, the DR UV-Vis spectrum of activated **F** is characterized by the almost complete

616   erosion of the bands at 33600 and 28400 cm^{-1} that were present before the reaction with TEAl,

617   leaving the place for an intense CT transition absorption band at 40100 cm^{-1} and a quite weak

618   band at 21700 cm^{-1}, which is attributed to isolated, 5-fold coordinated and alkylated Ti^{3+}

619   species (although the broadness of the band reveals a certain heterogeneity of the sites, in terms

620   of slightly different structural parameters and chemical surroundings).[92] According to the data

621   of polymerization activity shown in Figure 1, those species are thus the main responsible for

622   propylene polymerization.

623   On the contrary, IR spectroscopy provides new insights on the fate of the donor after TEAl

624   activation, which is one of main open questions in ZN catalysis. As a matter of fact, depending

625   on the temperature a more or less large fraction of DBP is known to be cleaned up by TEAl (a

626   minimal fraction at room temperature, almost the totality at about 100 °C),[93] but the state of

627   the molecules remaining on the catalyst surfaces is still unclear. Figure 7b and **Figure 7**c

628   display the magnification of the ν(C=O) region for **C** and **F** before and after TEAl activation

629   at room temperature, revealing an analogous trend for the samples corresponding to the initial

630   DBP addition and to the sample at the end of the synthesis (the quantification of the integrated

631   areas for all the individual ν(C=O) components are reported in Table S3).

632   The fraction of liquid-like DBP is roughly constant, indicating that DBP molecules trapped

633   within the pores during ZN catalyst synthesis are not washable and not accessible even for

634   TEAl. The fraction of DBP adsorbed on Mg^{2+} sites drops down (especially for surface Mg^{2+}

635   sites), together with the fraction of POC in **F**, in the face of the appearance of a new component

636   at ca. 1625 cm^{-1}, which can be reasonably assigned to DBP in interaction with the Al^{3+} centers,

637   coming from both the TEAl molecules in excess and the $AlCl_xEt_{3-x}$ by-products adsorbed on

638   the catalyst. Finally, the fraction of DBP in interaction with the Ti centers is almost constant,

639   but the position of the band shifts at higher frequencies (from 1634 to 1640 cm^{-1}), likely

640   because of the reduction from Ti^{4+} to Ti^{3+}. This suggests that the $TiCl_4$-DBP complexes that

641   are formed on the catalyst surface and remain after the following thermal and chemical

642   treatments, they do remain even after TEAl activation and are actually activated, so that a

643   possible role in the overall catalytic process cannot be discarded.

644

645   **4. Conclusions**

646   The multi-technique investigation presented in this work sheds light on the chemical

647   reactions and structural evolution taking place during the formation of an industrial-like

648   Ziegler-Natta pre-catalyst, starting from the $Mg(OEt)_2$ precursor and in the presence of DBP

649   as an internal donor. Five intermediate samples have been extracted from the glass reactor at

650   different stages, plus the final catalyst, and analyzed in terms of structure, morphology, and

651 surface species. All the techniques converge in demonstrating that as soon as $Mg(OEt)_2$ is

652 contacted with $TiCl_4$, all Mg-O bonds are converted into Mg-Cl ones, forming the first seeds

653 of $MgCl_2$, which appear as Cl-Mg-Cl monolayers with a lateral dimension of below 2 nm, and

654 releasing $TiCl_x(OEt)_{4-x}$ as by-products (first physisorbed as 4-fold coordinated, and then

655 chemisorbed as 6-fold coordinated). Those species efficiently polymerize ethylene but not

656 propylene.

657 The addition of the DBP electron donor significantly promotes the growth of $MgCl_2$ seeds

658 with the preferential exposure of lateral surfaces, including those relevant for the catalysis; as

659 a matter of fact, only after the DBP addition the catalyst becomes active in propylene

660 polymerization. Most of DBP is coordinated to $MgCl_2$ surfaces, corroborating the hypothesis

661 that the influence of the electron donors on the stereoselectivity of ZN catalysts is mostly due

662 to a steric modulation of the Ti surroundings. However, a non-negligible fraction of DBP is

663 actually complexed to the Ti ions, and some of these species remain in ZN catalyst even at the

664 end of the synthesis and can be effectively activated by TEAl (at least at room temperature,

665 further investigation will be needed to monitor the activation process at higher temperatures).

666 Finally, the second addition of $TiCl_4$ is mostly chemisorbed as 6-fold coordinated on $MgCl_2$

667 surface largely replacing the $TiCl_x(OEt)_{4-x}$ species, although a fraction of $TiCl_4$ is also

668 consumed in a side reaction with DBP, as testified by the formation of phthaloyl chlorides. The

669 newly formed Ti species are remarkably more active in propylene polymerization (the

670 production of polypropylene per hour per Ti mole almost triples at this step). It is worth

671 noticing that the aging at 110 °C allows a further rearrangement of the species in the material

672 (both in $MgCl_2$ morphology, and in DBP disposition, and in the local structure of the Ti sites),

673 further increasing the activity towards propylene polymerization, which is attributed to

674 isolated, 5-fold coordinated and alkylated Ti^{3+} species. This demonstrates the positive effect of

675 the final thermal treatment to afford truly performant ZN catalysts. All these findings are

676 schematically summarized in Figure 8.

677 　　More in general, this unprecedented knowledge of all the chemical reactions and structural

678 evolution at each step of ZN catalyst synthesis will drive the choices of the researchers from

679 both academia and companies that aim at the optimization of this complex multicomponent

680 material.

Author Contributions

A.P.[†] and T.W.[†] wrote the manuscript. A.P.[†] and A.A. acquired and analyzed the vibrational and electronic spectroscopies. T.W.[†] performed sample preparation, chemical analysis, and the synchrotron X-ray total scattering experiments. G.T. created some nanoparticle models and helped computational simulation. T.I. acquired SEM observation and interpreted the results. Z.D. performed DSC measurement and analysis. M.T. contributed to finalize the manuscript. P.C. designed and performed the polymerization tests. E.G. and T.T. conceived the concept and supervised the entire research.

[†]These authors contributed equally.

927   70.   Interestingly, even the slope of the spectra baseline changes from A and B to the other

928   intermediates: since the baseline in the IR spectra is correlated with the scattering properties of

the particles, such a change can be interpreted as a contraction of the nanocrystals aggregates, which gives rise to the interparticle porosity.
