A Lattice Boltzmann scheme for electrolytes by an extended Maxwell-Stefan approach

Jens Zudrop,* Sabine Roller,† and Pietro Asinari‡

This paper presents an extended multicomponent Lattice Boltzmann model for the simulation of electrolytes. It is derived by means of a finite discrete velocity model and its discretization. The model recovers momentum and mass transport according to the incompressible Navier-Stokes equation and Maxwell-Stefan formulation respectively. It includes external driving forces (e.g., electric field) on diffusive and viscous scales, concentration dependent Maxwell-Stefan diffusivities and thermodynamic factors. The latter take into account non-ideal diffusion behavior, which is essential as electrolytes involve charged species and therefore non-ideal long and short range interactions among the molecules of the species. Furthermore, we couple our scheme to a Finite Element Method to include electrostatic interactions on the macroscopic level. Numerical experiments show the validity of the presented model.

I. INTRODUCTION

In the last decade Lattice Boltzmann models became a popular numerical method to solve reduced kinetic models, in particular for the incompressible Navier-Stokes equation. In the following years it has been applied successfully to a number of complex problems in science and engineering [1], [2], [3], [4], [5]. A promising research area for Lattice Boltzmann methods seem to be multicomponent flows in complex geometries, e.g. porous media. In contrast to standard continuum based models, e.g. [6], [7], their algorithms are well suited for complex setups on high performance computers. However, a straight forward extension of Lattice Boltzmann BGK models to multicomponent flows fails due to the fact the a proper way of interaction between the species has to be defined in the kinetic formulation. Over the last years a number of different models have emerged: Some models properly take into account the momentum exchange between the species by pseudo-potential interactions [8], [9], [10], [11]. Others define free energies [12], [13], [14], [15], while [16], [17] adopt a force coupling in the momentum equations, derived from a linearized kinetic term and further [18], [19], [20] avoid a linearization by two collision operators. In [21] another LB scheme has been proposed aiming to minimize a proper H function defined on the fully discrete lattice.

Our work is a further extension of the models proposed in [20], [22] (which are based on [23]). Therefore, it inherits most of the basic properties as the indifferentiability principle, its main idea to exchange momentum among the species according to the Maxwell-Stefan formulation and the fact that the diffusion equations are recovered even when the mixture averaged diffusion approximation does not hold [24]. For further detailed comparison of existing models we refer the reader to the previously mentioned publications and references therein.

However, in this work a number of extensions for electrolytes and electrodialytic processes is presented: Compared to ideal mixtures, where any interaction between two species is the same, electrolytes show additional non-ideal diffusion behavior (due to significant deviation from spherical molecule shape, variations in molecule size, long-range electrostatic interactions between molecules, short-range van-der-Waals interactions) and thus only parts of the ionic species might be active. Even in diluted electrolytes the deviation from ideal behavior becomes apparent [25]. The Maxwell-Stefan closure relation incorporates these effects by the so-called thermodynamic factors [26], a coefficient matrix which is determined by concept of activity coefficients. To the knowledge of the authors it is the first time that thermodynamic factors (and therefore non-ideal diffusion processes) are considered in the context of mixture Lattice Boltzmann models. Electric forces are the main driving force for convection and diffusion in electrolytes/electrodialysis processes, therefore we present a proper inclusion of these driving forces in our FDV model. In comparison to [22] our approach requires no additional correction terms, works in presence of thermodynamic factors and is applicable in nonelectronneutral regimes, where strong diffusive driving forces apply (as long as the diffusive asymptotic limit is applied). Since the Maxwell-Stefan diffusivities for electrolytes show a significant dependence on species’ concentrations [27], we consider variable diffusivities in our FDVM. The model recovers the governing conservation equations asymptotically in the diffusive limit [28], [29]. The correct nonlinear hydrodynamic mixture behavior is
recovered even in regimes where diffusion velocities are large (and mixture velocity is small). Furthermore, our model recovers the Maxwell-Stefan equations in terms of molar quantities (which is more common for electrolytes) and it avoids the utilization of non-defined quantities for liquid electrolytes (e.g. partial pressures, etc.).

This paper is structured as follows: In paragraph II we present the equations of motion for an electrolyte solution. The following section III presents a simplified kinetic model, a Finite Discrete Velocity Model (FDVM), that recovers the equations of motion for an electrolyte asymptotically. Section IV provides simulation results of a fully discrete Lattice Boltzmann scheme derived by integrating the FDVM along its characteristics. Finally, section V gives a conclusion and an outlook to future work.

II. GOVERNING EQUATIONS OF MULTICOMPONENT ELECTRO-HYDRODYNAMICS

In this section we are concerned with the equations of motion for a mixture composed of \( N \) distinct ionic species in the regime of vanishing Mach number, influenced by external electric and gravitational fields, \( \mathbf{E} \) and \( \mathbf{g} \) respectively. Its mass balance for species \( k \) in terms of its the molar concentration \( n_k \) is given by

\[
\partial_t n_k + \nabla \cdot (n_k \mathbf{w}) = -\nabla \cdot \mathbf{J}_k. \tag{1}
\]

The molar and density averaged mixture velocities are defined by

\[
\mathbf{w} = \sum_k \frac{n_k}{m_k} \mathbf{v}_k, \quad \mathbf{v} = \sum_k \frac{\rho_k}{\rho} \mathbf{v}_k. \tag{2}
\]

Additionally we define the mixture molar weight and number density fractions by

\[
m = \frac{1}{N} \sum_k n_k m_k, \quad \chi_k = \frac{n_k}{n} \tag{3}
\]

with \( m_k \) the molar mass of species \( k \) and find the following relation between molar fraction \( \chi_k \) and mass density \( \rho_k \): \( \chi_k = \frac{m_k \rho_k}{\rho} \). The mixture’s momentum conservation is given in terms of an incompressible Navier-Stokes equation with external forcing term

\[
\partial_t \rho \mathbf{v} + \nabla \cdot (\rho \mathbf{v} \otimes \mathbf{v} + p \mathbf{I}) = \nu \nabla^2 (\rho \mathbf{v}) + \rho \mathbf{g} + \rho \mathbf{F}. \tag{4}
\]

Here, \( \mathbf{F} \) denotes the total mixture force per unit volume. The equations of motion are well posed when an additional closure relation for the diffusive fluxes \( \mathbf{J}_k \) is provided.

It has been shown by experiments that the analytic predictions of an extended Maxwell-Stefan closure relation leads to reasonable results in case of electrolytes and electrodealytic processes ([30], [31]). In our case, we consider the following extended Maxwell-Stefan model ([32], [33]) (where \( F \) denotes the Faraday constant, \( \mathbf{E} \) the electric field and \( z_k \) the ionic charge of species \( k \), \( V_k \) its molar volume and \( y_k = \rho_k / \rho \) denotes its mass fraction)

\[
\left( \sum_i \Gamma_{ik} \nabla \chi_i \right) - \mathbf{F}_k + \frac{y_k V_k - y_k \nabla p}{nRT} = \sum_{i \neq k} \frac{1}{D_{ki}} (\chi_i \mathbf{J}_i - \chi_i \mathbf{J}_k) \tag{5}
\]

where the external diffusive forcing term \( \mathbf{F}_k \) for species \( k \) is defined by:

\[
\mathbf{F}_k = \frac{1}{nRT} \rho_k \left( \mathbf{g} + \frac{z_k \mathbf{E}}{m_k} \right) - \frac{y_k}{nRT} \sum_{l=1}^N \rho_l \left( \mathbf{g} + \frac{z_l \mathbf{E}}{m_l} \right)
\]

Please notice, that by definition of \( \mathbf{F}_k \) the sum of the external diffusive forces cancels out. Additionally, in case of an electroneutral mixture (zero charge of the mixture) we have

\[
\rho = \sum_{l=1}^N \rho_l = \sum_{l=1}^N \rho_l z_l = 0
\]

and so the electric forcing term in the summation part of \( \mathbf{F}_k \) vanishes. In general, the external diffusive forces \( \mathbf{F}_k \) can be decomposed into two parts: The total external force for species \( k \) (i.e. \( \rho_k (\mathbf{g} + \mathbf{E} z_k \mathbf{F} / m_k) / (nRT) \)) and the fraction of the total mixture force acting on the species \( k \) (i.e. \( y_k (\sum_l \rho_l (\mathbf{g} + \mathbf{E} z_l \mathbf{F} / m_l)) / (nRT) \)). By subtracting these two parts, \( \mathbf{F}_k \) contains only that part of the external forces acting exclusively on species \( k \). The total mixture force is added to the momentum equation that leads to a transport of all species by advection of the mixture (cf. equation (3)).

The binary Maxwell-Stefan diffusivities in (4) can be calculated in an electroneutral electrolyte solution by [27], [34]

\[
D_{ij} = \tilde{D}_1 (i, j) + \tilde{D}_2 (i, j) \cdot n_{i+j} + \tilde{D}_3 (i, j) \cdot n_{i+j}^{3/2} + \tilde{D}_4 (i, j) \cdot n_i^{1/2} \cdot \sqrt{n_{i+j}}, \tag{6}
\]

where \( \tilde{D}_1 (i, j), \cdots, \tilde{D}_5 (i, j) \) are species dependent coefficients and \( n_{i+j} \approx n_i + n_j \) denotes the combined number density of species \( i \) and \( j \). For non-electroneutral conditions we use properly adapted rules for binary Maxwell-Stefan diffusivities , as given in [34] and we refer the reader to this publication for a detailed discussion. Appendix A1 and A2 provide numerical values for aqueous NaCl and H₂SO₄ solutions. It is worth pointing out that even in simple electrolytes, e.g. aqueous NaCl mixture, diffusivities show a significant dependence on
ionic concentrations in the liquid, as $\dot{D}_1(\text{Na, Cl}) = 0$. Furthermore, it is easy to check that according to equation (6) Maxwell-Stefan diffusivities itself might be negative. Although this is seems to been wrong intuitively, it is sufficient to ensure a positive-definite condition of the Maxwell-Stefan diffusivity matrix to ensure well-posedness. A detailed investigation is given in [35] and we refer to it in section IV A, equation (14).

The left hand side of equation (4) is coupled by a matrix $\Gamma$ that contains the thermodynamic factors [26]. The thermodynamic factor matrix is related to the concept of activity coefficients $\gamma_k$ and for electrolytes its functional dependence is given by [36]

$$
\Gamma_{k,i}(x, t) = \delta_k + \chi_k(x, t) \cdot \frac{\partial \ln \gamma_k}{\partial \chi_i}(x, t).
$$

A short derivation of the thermodynamic factors from thermodynamic principles is given in appendix B. From the physical point of view, activity coefficients take into account the deviations from ideal behavior in a multi-component fluid in the following sense: In an ideal mixture, any interaction between two species is the same, hence properties of the mixture may be expressed directly in terms of species’ concentrations or partial pressures. However, in non-ideal mixtures, as electrolytes, these concentrations have to be scaled properly by activity-coefficients. Even at very low concentrations electrolytes show a significant deviation from ideal behavior, an effect that is already known for long time [25], and though activity coefficients play an important role in mathematical models of such mixtures. A number of different models for the evaluation of activity coefficients/thermodynamic factors exist. Theoretical activity coefficient models are the Deby-Hückel model [25] and its extensions, e.g. Davies [37], Pitzer [38], TCPC [39]. For concentrated electrolyte solutions activity coefficient models can also be evaluated by correlating relational factors, e.g. MOSCED, (e)NRTL, UNIQUAC, UNIFAC. We refer the reader to [36] for a complete overview of these models. It should be noted that all these models are consistent with the Maxwell-Stefan without thermodynamic factors in the limit of vanishing concentrations, i.e. $\gamma_k \to 1$ when $\chi_k \to 0$ or $\chi_k \to 1$.

The electric potential $\psi$ (and hence the electric field $E = -\nabla \psi$) are obtained by

$$
-\Delta \psi = \frac{F}{\epsilon_{\text{mix}}} \sum_{k=1}^N n_k z_k. \quad (7)
$$

In combination with properly defined boundary conditions (Neumann or Dirichlet) the upper equation provides a well-posed potential equation for the electric potential, where $\epsilon_{\text{mix}}$ denotes mixture’s permittivity.

### III. A SIMPLIFIED KINETIC MODEL FOR MULTICOMPONENT ELECTRO-HYDRODYNAMICS

In this section we present a simplified kinetic model, a finite discrete velocity model (FDVM), consistent with the electrolyte’s equation of motion. It recovers them in the asymptotic limit of vanishing Knudsen and Mach number. Additionally, this FDV model will be the starting point for our Lattice Boltzmann model (LBM) that will be derived by spatial and temporal discretization in section IV.

In the BGK-FDV model we restrict the full Boltzmann equation to a finite set of $M$ discrete velocities and replace the collision operator by its BGK version [40] (where $m \in \{0, \ldots, M - 1\}$):

$$
\partial_t f_k^m + \mathbf{u}^m \cdot \nabla f_k^m = \lambda_k (f_k^{eq,m} - f_k^m) + d_k^m
$$

(8)

The collision parameter $\lambda_k$ is defined by $\lambda_k = BK/p'$ where $B$ denotes a collision frequency, $p'$ denotes an upper limit of the mixture pressure variations and $K$ the bulk modulus of the liquid mixture measuring the mixture’s resistance to uniform compression. Numerical values for some electrolytes relevant in electrodialysis can be found for example in [41]. In particular, we obtain $c_s^2 = K/p$ and for later use, we define the ratio of background density to pressure fluctuations by $C = Bp/p'$. Obviously, we assign the same relaxation parameter to all the species in our model. As already shown in [20], this does not restrict us to a single independent diffusion parameter, as momentum exchange among the species is modeled by $\rho_k \mathbf{V}_k$ in $f_k^{eq,m}$, cf. (9). The forcing term $d_k^m$ is directly related to the diffusive driving forces and mixture forces in (4) and (3). In the FDV model density and momentum can be obtained by:

$$
\rho_k = \sum_{m=0}^{M-1} f_k^m, \quad \mathbf{j}_s = \sum_{m=0}^{M-1} \mathbf{u}^m f_k^m
$$

The right hand side of equation (8) is the collision operator of the BGK model and relaxes the species probability density function $f_k^m$ towards its thermodynamic equilibrium with a given relaxation parameter $\lambda_k$ to achieve the desired macroscopic behavior. We define

$$
(\rho_k \mathbf{V}_k)^* = \left( \rho_k \mathbf{V}_k + \sum_i \Gamma_{k,i}^{-1} \rho_i \sum_\zeta \frac{B_k \zeta}{C} \phi_1 (\mathbf{V}_\zeta - \mathbf{v}_l) \right)
$$

(9)

where $B_{k,l} = 1/D_{k,l}$ are Maxwell-Stefan resistivities and set the thermodynamic equilibrium as follows (where $k$ is the species index):

$$
f_k^{eq,m} = \omega_m \left( \rho_k s_m^k + \frac{1}{c_s^2} (\mathbf{u}^m \cdot \rho_k \mathbf{V}_k^*) \right.
$$

$$
\left. + \frac{\rho_k}{2c_s^2} (\mathbf{u}^m \cdot \mathbf{v})^2 - \frac{\rho_k}{2c_s^2} \mathbf{v}^2 \right)
$$

(10)
The modifications, compared to [20], [22], are twofold: First, we make use of a modified velocity in the bilinear part of the collisions. This allows us to recover thermodynamic factors in the Maxwell-Stefan equations. In contrast to [20], in our model \( \sum_k p_k v_i^k \neq \sum_k p_k v_k \) due to the inclusion of the thermodynamic factors. In section III A, we show that a slightly generalized condition holds true (cf. equations (12), (13)). Second, we replace the velocities in the quadratic equilibrium part by the mixture averaged velocities. Hereby, we recover the correct mixture Navier-Stokes equation even in regimes where the mixture averaged diffusion approximation does not hold. In addition we choose \( s_k^i = \frac{1}{s^i_0} + (1 - \frac{1}{s^i_0}) \phi_k \), \( s_{m \neq 0}^k = \phi_k \).

The coefficient \( \phi_k \) defines the equation of state in our FDV model, i.e. \( p_k = c^2 \phi_k / \rho_k \). In general any equation of state is possible in our model, but two restrictions have to be considered: The equation of state should depend on the slow mass diffusion times scale and its corresponding quantities solely, e.g. \( \rho_k^{(0)} \) cf. section III B. From the numerical point of view it should be bounded by 1 to guarantee stability of the model. In the following we set \( \phi_k = \min_{\omega} m_\omega / m_k \leq 1 \). The weights \( \omega_{\omega} \) are chosen to guarantee lattice isotropy conditions, e.g. as defined for the D2Q9, D3Q15 or D3Q19 lattice [29].

It is worth emphasizing that the upper model satisfies the indifferentiability whenever the activity coefficient model satisfies \( \gamma_k \rightarrow 1 \) for \( \chi_k \rightarrow 0 \) and \( \chi_k \rightarrow 1 \).

### A. Diffusive driving forces and collision invariants

Similar to the decomposition of the external forces into diffusive driving forces (slow mass diffusion timescale, cf. section II) and mixture forces (fast viscous timescale), we split the mesoscopic forcing term in (8) into \( d^{m,1}_k \) and \( d^{m,3}_k \) respectively. We relate the forcing term in the FDVM to (5) by

\[
\begin{align*}
  d^{m}_k = & \min_{\omega} m_\omega \omega_{\omega} u_m \cdot \sum_l \Gamma_{l,k} \left( F_l - \frac{n_l V_l - y_l \nabla p}{nRT} \right) \\
  = & \left[ d^{m,(1)}_{k} \text{(diff. driv. forces)} \right] \\
  & + \frac{\omega_{\omega}}{c^2} u_m \cdot (p_k g + F n_k z_k E) \\
  = & d^{m,(3)}_{k} \text{species' mix. force fraction}
\end{align*}
\]

The mixture pressure gradient \( \nabla p \) can be obtained by a centered finite difference with second order accuracy on the compact Lattice Boltzmann stencil. Of course, this finite difference correction is not necessary whenever \( \Gamma_{i,j} = \delta_{i,j} \) cf. [42].

It should be noted that most activity models do not provide a formal dependency of the pressure and therefore the partial molar volume \( V_k = \partial g / (\partial n_k \partial p) \) cannot be obtained (\( g \) denotes the molar Gibbs free energy). This is due to the fact that in practice correlation based activity models would require a large amount of parameters. Hence, additional density models for electrolytes have been developed and applied. A detailed discussion and our density model of choice is given in [43]. Besides this technical discussion, the upper density model fixes the equation of state, as it provides a formal dependency \( V_k = f(n_1, \ldots, n_N, p, T) \).

Compared to the previous work in [22], no correction term for the stress tensor in presence of external forcing \( F_k \) is necessary in equation (11) (even in case that \( F_k \) in nonzero) due to the fact that the spurious terms cancel out by construction. Therefore, derivatives of the forcing terms are unnecessary. This can be easily checked by considering the asymptotic limit of the FDVM.

Although it has been shown in [20] that \( J_k \neq \sum_m u^m f_{eq,m} \), we can furthermore check that in our model

\[
\sum_m c^{m}_k (f) = 0, \quad \sum_m d^{m,(1)}_k = 0 \quad (12)
\]

and

\[
\sum_m u^m \left( c^{m}_k (f) + d^{m,(1)}_k \right) = 0 \quad (13)
\]

are satisfied. These three relations guarantee that each mixture state is possible in our model, but two restrictions have to be considered: The equation of state should depend on the slow mass diffusion times scale and its corresponding quantities solely, e.g. \( \rho_k^{(0)} \) cf. section III B. From the numerical point of view it should be bounded by 1 to guarantee stability of the model. In the following we set \( \phi_k = \min_{\omega} m_\omega / m_k \leq 1 \). The weights \( \omega_{\omega} \) are chosen to guarantee lattice isotropy conditions, e.g. as defined for the D2Q9, D3Q15 or D3Q19 lattice [29].

It is worth emphasizing that the upper model satisfies the indifferentiability whenever the activity coefficient model satisfies \( \gamma_k \rightarrow 1 \) for \( \chi_k \rightarrow 0 \) and \( \chi_k \rightarrow 1 \).
which is equivalent to (13). Physically the upper technical discussion proves that the presented FDVM ensures vanishing total diffusive driving forces (no matter whether the driving forces are internal or external).

B. The asymptotic limit of vanishing Mach and Knudsen number

The presented mesoscopic FDV method of the previous section recovers the electro-hydrodynamic equations of section II asymptotically, in the limit of small Knudsen and Mach number, with second order in space and first order in time. This can be shown rigorously by considering the diffusive asymptotic limit [28], i.e. scaling as $\Delta x = \epsilon \Delta x$, $\Delta t = \epsilon^2 \Delta t$. A lot of effort has been spent in the last years to analyze LBM like schemes rigorously and we refer the reader to [29] and to the previous work in [20], [22], [42] for mixture models based on the work of [23]. In the following we provide only the key concepts to connect (8) to (1), (4), (5), (3) and point out the differences to the mentioned publications. We adopt the notation of [20] in the following. The diffusive asymptotic limit is usually considered for analyzing continuum low Mach limit in Hilbert expansions [28] and provides a direct mathematical relation between the Boltzmann equation and incompressible Navier-Stokes equation. However, alternative scalings, as well as expansions are possible [44] and therefore the following analysis serves as a mathematical example in the low Mach and continuum limit.

Considering the diffusive mass transport in the proposed FDV model, cf. equations (47), (49) in [20], we obtain

$$\nabla \rho_i^{(0)} = \sum_{m=1}^{M} \frac{u_m d_m^{m,(1)}}{\phi_k c_s^2} + \frac{\lambda_k}{\phi_k c_s^2} \sum_{j \geq 0} \sum_{i=1}^{n_m} \left( \rho_j^{(1)} v_j^{(1)} - \rho_k^{(1)} v_k^{(1)} \right).$$

After some algebra and inversion of the thermodynamic factor matrix, it can be shown that this equation ensures that (1) and (4) are satisfied. By construction of $(\rho_k v_k)^*$ and $d_k^{m,1}$ the recovered Maxwell-Stefan formulation includes thermodynamic factors $\Gamma$ and diffusive driving forces $F_k$. Furthermore, it should be noted that the calculation of the Maxwell-Stefan diffusivities, according to (6), and the thermodynamic factors, is solely based on the slow scales and corresponding quantities, e.g $n_k^{(0)}$. Overall, we recover for the diffusive transport

$$\left( \sum_{i} \frac{\Gamma_{k,i} \nabla \chi_k}{n^{(0)}} \right) - F_k + \frac{\rho_k^{(0)} V_k - y_k^{(0)}}{n^{(0)} R T} \nabla \rho = \sum_{l \neq k} \frac{1}{D_{k,l} n^{(0)}} \left( \chi_k^{(0)} J_l^{(1)} - \chi_l^{(0)} J_k^{(1)} \right).$$

It is worth emphasizing that the baro-diffusion term in $d_k^{m}$, obtained by a centered finite difference, is usually small in the diffusive asymptotic limit.

Regarding the mixture momentum transport the following observations can be made: In comparison to equation (54) in [20] we obtain a slightly different momentum flux tensor for each species. When summing over the species index $k$, the result is a correct nonlinearity of the mixture Navier-Stokes equation

$$\sum_{k,m} u_m \otimes u_m f_k^{m,(2)} = c_s^2 \sum_k \phi_k \rho_k^{(2)} I + \rho_k^{(0)} v_k^{(1)} \otimes v_k^{(1)}$$

$$+ \frac{1}{c_s^2} \left( \nabla \rho_k^{(0)} v_k^{(1)} + \left( \nabla \rho_k^{(0)} v_k^{(1)} \right)^T \right).$$

Thus, we recover the correct hydrodynamic behavior of the electrolyte solution (i.e. (3) with $\nu = 1/c_s$), even when the diffusive fluxes are large and the mixture averaged diffusion approximation is not satisfied.

Independent of the asymptotic scaling under consideration, a few general remarks with respect to the external forcing terms can be given. By formally expanding the forcing term $d_k^{m,0} = \sum_{l \geq 0} e^l d_k^{m,(l)}$, different orders of forcing become apparent. Diffusive driving forces are large, appearing on $d_k^{m,1}$ scales, while mixture forces are small (i.e. $d_k^{m,(3)}$ in case of diffusive asymptotic limit). However, it is important to ensure that $\sum_k \sum_m u_m (C_k^{m,(f)} + d_k^{m,(0)}) = 0$ (for $i \leq 2$ for diffusive asymptotic analysis) to guarantee consistency to the low-Mach assumption. It is worth emphasizing that (11) guarantees this by construction for the diffusive asymptotic limit (to the knowledge of the authors this question has not been addressed rigorously so far, cf. discussion below (39) in [22]). Our model ensures this condition in the diffusive limit even when the mixture is not electroneutral and in presence of strong electric driving forces, a situation that is likely to occur in boundary layers of electrolysis processes, the so called diffusive double layer [33]. In fact the correct coverage of this phenomena is mandatory to study strongly nonlinear effects as electro-convective vortices [45], [46].

IV. NUMERICAL EXPERIMENTS

To derive a fully discrete model, we integrate the FDVM along its characteristics [47], [48]. While left hand side of (8) is integrated analytically, the particular fully discrete model is obtained by choosing a specific approximation for the integral of the collision term. We choose a trapezoidal rule, due to stability and accuracy reasons [20]. After applying a reformulation in terms of the transformed variable $f_k^{m} = f_k^{m} + \frac{\delta t}{2} \left( f_k^{m} - f_k^{m,q^{\text{eq}}(m)} \right)$ an explicit, Lattice Boltzmann scheme is obtained

$$f_k^{m}(x + u_m \delta t, t + \delta t) = f_k^{m}(x, t) + \frac{\delta t}{\lambda_k + \frac{\epsilon}{2}} \left( f_k^{m,q^{\text{eq}}(m)}(x, t) - f_k^{m}(x, t) \right) + d_k^{m}(x, t).$$

A few remarks on the upper discrete algorithm can be made: after each time step the the electric potential equa-
tion (7) is solved numerically to compute the external driving forces; density distributions are used to evaluate activities, diffusivities and the finite difference correction for the baro-diffusion term. To complete the assembly of the right hand side of the upper discrete scheme, we solve an elemental linear equation system to recover the correct momentum \( \mathbf{j}_k \) from the transformed variables

\[
\mathbf{j}_k = (1, \mathbf{u}^m, \mathbf{f}_k^m) = \mathbf{j}_k + \frac{\delta t \lambda_k}{2} (\mathbf{j}_k - (1, \mathbf{u}^m, \mathbf{f}_k^eq, m))
\]

\[
= \mathbf{j}_k - \frac{\delta t \lambda_k}{2} \sum_{i} \mathbf{j}_i \sum_{\zeta} \Gamma^i_k \xi \frac{B_{i,l}}{C} \phi_{\zeta} \chi_l
\]

\[
+ \frac{\delta t \lambda_k}{2} \sum_{l} \mathbf{j}_l \sum_{\zeta} \Gamma^l_k \xi \frac{B_{l,k}}{C} \chi_{l} \phi_{\zeta} l.
\]

After these steps, collision and streaming can be carried out to complete the time step. In contrast to the implementation described in [20], the presented method considers variable diffusivities and thermodynamic factors and hence the elemental variable system changes in each iteration. Therefore, no pre-computation of the inverse can be done. In the course of our numerical experiments in IV A and IV B, the elemental linear equation system has been well-posed in every time step.

The presented Lattice Boltzmann scheme is coupled to a nodal, first order FEM (Finite Element Method, [49]) to solve the electric potential equation on the same domain as the Lattice Boltzmann Method. The coupling is achieved by a simple first order accurate interpolation in both directions (from vertex (FEM) to barycentric (LBM) based values and vice versa). Both meshes have similar spatial resolutions. Due to the simplicity of the presented Lattice Boltzmann Method most of the time is spend for the solution of the electric potential equation by the FEM.

A. Thin diffusive double layer for H$_2$O – NaCl

We consider a mixture of NaCl and H$_2$O. The deviation of the Maxwell-Stefan diffusivities, activity coefficients and thermodynamic factors from ideal Maxwell-Stefan coefficients as a function of Na$^+$ mole fraction are given in figures 1 and 2, respectively. The Maxwell-Stefan diffusivities have been computed according to model (6) and the parameters of table I. According to the given diffusivity model it is obvious, that for low concentrations the Maxwell-Stefan diffusivities of $D_{Na^+, Cl^-}$ might become negative. The effect is well known and has been discussed several times, e.g. [50]. The authors point out that the only relevant restriction on the diffusivities arises from the fact that the overall entropy production has to positive (including all driving forces) and this can be ensured whenever

\[
0 \leq \left( \sum_{i,j,k} \chi_i \chi_k \frac{D_{i,k}}{D_{i,k}} \right) \left( \sum_{i,j,l} \chi_j \chi_l \frac{D_{j,l}}{D_{j,l}} \right) - \left( \frac{\chi_k \chi_l}{D_{k,l}} \right)^2
\]  

(14)

holds true for all $k$ and all $l$ with $k \neq l$. Essentially, the upper equation is a constraint on the positive definiteness of the diffusivity matrix and can be satisfied even for negative Maxwell-Stefan diffusivities [50]. In our simulations equation (14) has always been satisfied. The geometrical setup is a simple micro channel of length $L$ in $x$ direction (periodic in $y$ direction), homogeneously filled with a mixture of H$_2$O, Na$^+$, Cl$^-$, initially. We denote the initial values by $\chi_{H_2O}^0, \chi_{Na^+}^0, \chi_{Cl^-}^0$ in the following.

To create a non-electroneutral, thin diffusive double layer, we apply a drop in the electric potential by imposing Dirichlet boundary conditions

\[
\psi(0, t) = V_0, \quad \psi(L, t) = 0.
\]

Initially the electrical, external driving force moves opposing boundary conditions.

FIG. 1: Ratio of non-ideal (i.e. concentration dependent) and ideal (i.e. constant) Maxwell-Stefan diffusivity for Na$^+$, Cl$^-$ as function of Na$^+$ mole fraction in an electro-neutral mixture of H$_2$O, Na$^+$, Cl$^-$, according to model (6) and the parameters of table I.

FIG. 2: Activity of Na$^+/Cl^-$ as function of Na$^+$ mole fraction in an electro-neutral mixture of H$_2$O, Na$^+$, Cl$^-$ (predicted by NRTL model).

In an ideal mixture all lines would equal zero. Due to symmetry only the relevant entries of } \mathbf{\Gamma} \text{ are shown.}
\end{align*}

pletely charged species into opposite directions and creates non-electroneutral regimes. The process continues until driving forces due to gradients in chemical and electrical potential equilibrate; a thin non-electroneutral layer at the boundaries, the so-called diffusive double layer is formed.

At first we consider low electrolytes concentrations. In this regime non-ideal effects are small and we can compare the coupled simulation results to existing, leading order analytical predictions \cite{51, 52, 53}. The resulting concentration profiles for Na\textsuperscript{+} and Cl\textsuperscript{−} are shown in figure 4. Figure 5 shows a close up of the non-electroneutral region. The thin double layer is clearly visible close to the boundary. Around the center region, where concentration gradients are very small, the mixture is electroneutral, due to the strong electrostatic interactions among the species. In leading order approximation the concentration profile of the ionic species in the double layer region is given by $\chi_i(x) = C_i^0 \cdot \exp(C_i^2 x) + \chi_i^0$ (where $C_i^2 < 0$ and the sign of $C_i^2$ is determined by the charge of the species $i$). For the electric potential in the double layer region we obtain in leading order $\psi(x) = C_i^0 \cdot \exp(C_i^2 x) + C_i^3 x + C_i^4$. For a detailed analysis, we refer the reader to \cite{51, 52, 53}. Overall the coupled Lattice Boltzmann - Finite Element simulation results are close to the leading order predictions (cf. figure 5).

Figure 6 shows a comparison of simulations at high electrolyte concentrations, where non-ideal effects are important, among different Lattice Boltzmann models: The presented model, the presented model without finite difference correction for the baro-diffusion term and the model in [20], suited for ideal gas phases. Obviously, the presented model leads to much larger boundary layers than the model suited for ideal gas phases due to the following fact: Thermodynamic factors weight the driving forces $\nabla \chi_i$ in the Maxwell-Stefan formulation (cf. figure 3 and equation (4)). As the potential drop across the channel is prescribed, the main driving forces of the system, i.e. chemical and electrical driving forces, equilibrate at smaller concentration gradients with larger double layer size.

**B. Large molecular weight ratio (H\textsubscript{2}O – H\textsubscript{2}SO\textsubscript{4})**

In this section we consider a setup similar to the previous section, but test our model with a high molecular weight ratio of $m_{SO_4^{2-}}/m_{H^+} > 95$. The corresponding Maxwell-Stefan diffusion coefficients are calculated by the coefficients from table II. Furthermore, an adapted eNRTL model for H\textsubscript{2}O – H\textsubscript{2}SO\textsubscript{4} has been applied. A close up of the resulting concentration profiles for H\textsuperscript{+}
Sivities. A fully discrete scheme is derived by integration of the baro-diffusion and "ideal" diffusion in the double layer region of the μ-channel.

V. CONCLUSION AND FUTURE WORK

In this paper we have presented a new finite discrete velocity model for electrolytes. It recovers mass conservation, incompressible Navier-Stokes equation and Maxwell-Stefan equations. The building blocks of the extension to electrolytes are the rigorous coverage of external driving forces, the inclusion of thermodynamic factors for non-ideal diffusion and concentration dependent diffusivities. A fully discrete scheme is derived by integration along the characteristics and numerical experiments are presented.

VI. ACKNOWLEDGEMENT

This work was funded by the German Federal Ministry of Education and Research (Bundesministerium für Bildung und Forschung, BMBF) in the framework of the HPC software initiative in the project HISEEM. PA acknowledges the support of the Italian Ministry of Research (FIRB grant RBFR10VZUG).

Appendix A: Maxwell-Stefan diffusivities for electrolyte solutions

The concentration dependent Maxwell-Stefan diffusion coefficients for a liquid NaCl and H₂SO₄ solution have been estimated in [34] using equation (6). The results are obtained by experimental data from [27]. Parameter values for $\tilde{D}_{i,j}$ are summarized in table I and table II respectively.

1. Liquid NaCl solution

The correlation (6) can be applied for a NaCl concentration range of $0..5000 \text{ mol/m}^3$.

Appendix B: Thermodynamic factors in the Maxwell-Stefan formulation

In the following we briefly review the derivation of the formal shape of equation (4) from irreversible thermodynamics. A detailed version can be found in [32]. The diffusive driving forces $d_k$ for species $k$ are related to the diffusive fluxes by

$$nRTd_k = \sum_{\ell \neq k} \frac{RT}{D_{k,\ell}} (\chi_k J_{\ell} - \chi_{\ell} J_k).$$

The driving forces are proportional to gradients in the electro-mechanical-chemical potential

$$nRTd_k = n_k \nabla \mu_k^{e,m,c} = n_k \nabla \mu_k - y_k \nabla p - F_k.$$

The chemical potential of each species can be obtained by molar Gibbs free energy $g$ by $\mu_k = \partial g/\partial n_k$. In addition the chemical potential is given by

$$\mu_k = \mu_0 + RT \ln a_k = \mu_0 + RT \ln \gamma_k n_k$$

where $a_k$ is the species’ activity and $\gamma_k$ its activity coefficient. Hence

$$n_k \nabla \mu_k = nRT \sum_i (\delta_{k,i} + \chi_k \frac{\partial \ln \gamma_k}{\partial \chi_i}) \nabla \chi_i + n_k V_k \nabla p$$

where we used $V_k = \partial \mu_k / \partial p$.
