The superconducting magnet system plays an important role in the framework of the design of the EU DEMO tokamak. In recent years, ENEA developed a prototype of cable-in-conduit conductor (CICC) with two low-impedance central channels to be used in the DEMO Toroidal Field (TF) coils with a graded winding pack (WP). In this paper, a model of a TF coil based on the thermal-hydraulic code 4C has been developed, including the WP, the steel casing with dedicated cooling channels (CCCs) and the two independent cryogenic circuits cooling the WP and the casing, respectively. The first part of the work analyzes the performance of the WP during a series of standard plasma pulses in normal operating conditions. In the second part different off-normal operating conditions during the plasma pulses are studied, namely the collapse of one or both central channel(s) in the most critical CCCs and the plugging of some CCCs at the most critical locations in the magnet.

1. Introduction

In the frame of the EU DEMO design activities [1], a big effort is being devoted in the Work Package Magnets (WPMAG) to the preliminary design of the Toroidal Field (TF) coils, resulting in the proposal of three different conductors and corresponding winding packs (WPs) by different European institutions [2,3]. These proposals are periodically updated and optimized taking into account the feedback from mechanical and thermal-hydraulic (TH) analyses, as well as, of course, the updates in the input from the EUROfusion Project Management Unit.

The TH code 4C [4] was already used to develop the first model of an entire EU DEMO TF coil, including structures and a simple cooling circuit [5], and applied, with the addition of quench lines in the model, to the quench analysis of the magnet [6]. In this paper, the previous model is updated to the new WP and conductor designs proposed by ENEA after the 2015 DEMO design review that increased the number of TF coil from 16 to 18 [7]. The model is then used first to assess the coil DC performance, considering, as a major difference with past works analyzing steady state burns [5,8,9], the standard pulsed operation currently foreseen for DEMO: several cycles are simulated, up to a periodic behavior of the coil. The value (and location) of the minimum temperature margin (ΔTmin) in the WP is computed and compared with the minimum acceptable value of 1.5 K [2]. The study is then repeated in off-normal conditions, i.e., considering the choking of the flow in the pressure relief channels of the most critical conductor or in some casing cooling channels (CCCs).

2. Conductor and WP

The most recent WP proposal by ENEA (the so-called WP2016#2) is an upgrade of the 2015 design [10] and consists of a double-layer (DL) wound WP, see Fig. 1a, that allows the grading of the SC cross section in the different DLs, depending on the magnetic field, thus optimizing the use of SC. The WP consists of six DLs where the jacket thickness of each conductor increases with the distance from the plasma to withstand the higher mechanical stresses [11]. The originally circular cable-in-conduit conductors (CICCs) are compacted and squeezed to a rectangular shape, see Fig. 1b, with two low-impedance cooling channels (“holes”) [10] delimited by spirals.

Each DL is constituted by a single conductor; the supercritical He at the nominal conditions of 4.5 K and 0.6 MPa is supplied to

the two layers of the same DL through a single inlet (a hole in the jacket). The inlet mass flow splits between the two layers, so that the He flows in counter-current in adjacent layers. In each layer, the He distributes among the three parallel cooling channels (i.e. the two holes and the bundle) according to their hydraulic impedance. The main geometrical parameters of the conductors are reported in Table 1.

3. The 4C model of the TF coil

The 4C model adopted here includes, as in [5], all DLs of the WP (see [12] for details), and the casing, thermally coupled to the WP across the ground insulation and cooled by dedicated CCCs. The casing is discretized in eight poloidal cuts, equally spaced on the inboard (A1-A4) and outboard (B1-B4) legs, see Fig. 2.

Fig. 1. (a) ENEA 2016 design of the TF WP with six DLs including Nb3Sn (blue) and NbTi (red) conductors. The 2D magnetic field amplitude map on the inboard equatorial cross section is reported (the plasma is on the left). (b) Cross section of the ENEA conductor concept on which 2016 WP design is based. (c) Polar distribution of the magnetic field amplitude in the central turn of DL1.1 (green) and in the last turn of DL6.1 (blue) at 180°. (For interpretation of the references to colour in this figure legend, the reader is referred to the web version of this article.)

The He inlets are located on the equatorial plane of the outboard leg, on the lateral side of the WP, while the outlets are located on the opposite side, at the same poloidal location. The CCCs inlets are located at the bottom of the coil, as in ITER [13]. Each of the two legs has 48 CCCs connected to inlet/outlet manifolds. We consider here the oneway-through circulation option [5]. The preliminary design of two cryogenic circuits for the WP and for the casing cooling of [5] is adopted, see Fig. 2, supplying ~150 g/s to the CCCs circuit and ~60 g/s to the WP (with the target pressure drop of ~1 bar and inlet pressure of ~6 bar during the transient [14]).

The distribution of the magnetic field at End of Flat top (EOF, see below) and nominal operating current (70.8 kA) is reported in Fig. 1a and c, including all contributions from the Central Solenoid (CS), the Poloidal Field (PF) coils and the plasma. The highest field within the WP is located on the central turns of DL1, the innermost layer, at the inboard equatorial plane, while on the outermost DLs the maximum magnetic field is located at the coil sides due to PF contribution, see Fig. 1a and c.

4. Simulation setup

The nominal pulsed operation (“normal” operation, case α) consists in a series of standard cycles [15], see Fig. 3, including a 7200 s

plasma burn and ~1800s dwell time, which are simulated here until periodicity is reached.

Only the nuclear heat (NH) load $P_{NH}(r) = 50 \exp(-r/140)$ [W/m³] is accounted for in both casing and WP in the current analysis, as a function of the radial distance $r$ (in mm) from the plasma facing wall [16], while more detailed NH maps based on Monte Carlo calculations are being prepared and will be implemented in future analyses. The static heat load on the casing surface and the AC/eddy current losses in the conductor/casing during CS and PF coils current ramps are not accounted for.

We then consider also the pulsed operation when the cooling capability in a subset of cooling paths is reduced ("off-normal" operation), and namely the flow is choked:

- in the relief channels of the CICCs with the lowest $\Delta T_{marg}$ (DL1.1, DL1.2 and DL6.1), corresponding e.g. to the collapse of one (case $\beta$) or both (case $\gamma$) spirals, due to the high mechanical stress during the conductor compaction
- in the most critical CICCs, corresponding to the plugging of some CICCs in proximity of the $\Delta T_{marg}$ location in DL1.1 (facing the casing all along its length, case $\delta$), near the outlet of DL2.1 ($\Delta T_{marg}$ for Nb$_3$Sn DLs, case $\zeta$) and near the outlet of DL6.1 (absolute $\Delta T_{marg}$ location, case $\eta$), see Fig. 4 - a situation that is relevant since the CICCs play an important role in the removal of the NH load, partially contributing also to the cooling of the WP [5].

5. Results

5.1. Normal operation

The periodic behavior in normal operation is reached after two cycles, as shown in Fig. 5a, reporting the evolution of both the maximum cable temperature and $\Delta T_{marg}$ in DL1.1 (the most loaded conductor). At EoF the $\Delta T_{marg}$ requirement of 1.5 K is satisfied in all the conductors, see Fig. 5b. Only in DL6.1 (NbTi) it is slightly below the threshold, ~1.43 K, but this is well within the uncertainty on the NH load used in input. In Fig. 5b it is also shown that, with respect to the initial steady state value, the NH during cyclic operation erodes the initial available $\Delta T_{marg}$ of ~0.1 ± 0.4 K, depending on the distance from the plasma. Note, however, that the adiabatic condition assumed for the casing surface is not conservative, so that any design for the casing cooling should also be addressed to the static load removal, once a good estimate of it will become available, not to affect and reduce the $\Delta T_{marg}$. 

5.2. Off-normal operation

The evolution of the $\Delta T_{marg}$ at EoF during the standard plasma burn for both cases $\Delta T_{marg}$ are reported in Fig. 5a, where it is compared with the nominal case $\alpha$, showing that a maximum $\Delta T_{marg}$ reduction <0.1 K is computed, see also Table 2, in the worst case ($\gamma$), despite a reduction of the mass flow rate >50%. The decrease of the active cooling of the WP is indeed compensated by an increase of the heat transfer to the casing in case of DL1.1, see Fig. 6, and/or to the neighboring layers.

The effect of CICCs plug on the $\Delta T_{marg}$ in the different cases is also always <0.1 K, as summarized in Table 2.

</table>
The DL1.1 is, as expected, the most affected by the cooling reduction caused by the CCCs plugging, since it is in contact with the casing all along its length: Fig. 6 shows the negative heat transfer from the WP to the casing (i.e., the WP is heated by the casing) in correspondence of the plugged CCCs, close to turn #12, for case $\delta$. This is however a conservative situation, as the detachment of the WP from the plasma side of the casing during burn is not taken into account.

6. Conclusions and perspective

The 4C model of an EU DEMO TF coil has been applied to assess the coil performance during standard pulsed operation. The computed $\Delta T_{\text{marg}}$ is in line with the design value of 1.5 K assuming the static heat load on the casing surface is negligible. As soon as a good estimate of it will become available, we plan to include it in the analysis and the design of the casing cooling should then be targeted to remove it, not to decrease the WP temperature margin.

Off-normal operating conditions, including the reduction of the available cooling due to collapse of relief channels in the WP and plugging of selected CCCs at critical locations, have also been analyzed, showing that the corresponding erosion of the $\Delta T_{\text{marg}}$ remains in all cases marginal (<0.1 K).
