Magnetic field effects on a nanowire with inhomogeneous Rashba spin-orbit coupling: Spin properties at equilibrium

Fabrizio Dolcini^{*} and Fausto Rossi

Dipartimento di Scienza Applicata e Tecnologia del Politecnico di Torino, I-10129 Torino, Italy

(Received 20 December 2017; published 31 July 2018)

By modeling a Rashba nanowire contacted to leads via an inhomogeneous spin-orbit coupling profile, we investigate the equilibrium properties of the spin sector when a uniform magnetic field is applied along the nanowire axis. We find that the interplay between magnetic field and Rashba coupling generates a spin current, polarized perpendicularly to the applied field and flowing through the nanowire even at equilibrium. In the nanowire bulk, such effect persists far beyond the regime where the nanowire mimics the helical states of a quantum spin Hall system, while in the leads, the spin current is suppressed. Furthermore, despite the nanowire not being proximized by superconductors, at the interfaces with the leads we predict the appearance of localized spin torques and spin polarizations, orthogonal to the magnetic field and partially penetrating into the leads. This feature, due to the inhomogeneity of the Rashba coupling, suggests to use caution in interpreting spin polarization as signatures of Majorana fermions. When the magnetic field has a component also along the Rashba field, its collinearity with the spin polarization and orthogonality to the spin current are violated in the nanowire bulk too. We analyze these quantities in terms of the magnetic field and chemical potential for both long and short nanowires in experimentally realistic regimes.

I. INTRODUCTION

Rashba nanowires, i.e., semiconductor nanowires characterized by a strong Rashba spin-orbit coupling (RSOC), such as InSb or InAs, are currently on the spotlight of a broad and growing scientific community, as they turn out to play a relevant role in various fields. In spintronics, for instance, RSOC enables one to act electrically on the electron spin degree of freedom, with the fascinating perspective to encode and manipulate information [1]. Furthermore, it has been realized that, for sufficiently strong RSOC, a nanowire exposed to a magnetic field can effectively mimic the helical edge states of a quantum spin Hall (QSH) system [2–4] and that, when a superconducting film is further deposited on it, the proximized nanowire can realize a topological superconductor [5,6]. In view of all these applications, a remarkable effort has been devoted in recent theoretical and experimental studies to improve the tunability of the RSOC, reaching unprecedented high values of such coupling constant [7–11]. Not only the bulk properties of nanowires are interesting. The recent discovery that, under suitable conditions, Majorana fermions can be localized at the interfaces between a nanowire and a superconductor [5,6] has been confirmed in a number of experiments [12–18] and has provided a major boost to the investigation of Rashba nanowires.

Despite the huge interest that nanowires are receiving nowadays, various questions still remain mostly unexplored, so that a gap of understanding still exists in comparison to the analogous two-dimensional (2D) systems with RSOC. In the first instance, most theoretical works related to hybrid

structures involving nanowires assume a uniform RSOC throughout the system. Since the origin of RSOC is the strong electric field caused by structural inversion asymmetry (SIA), metallic or superconducting films deposited on top of a nanowire locally alter the RSOC [19]. In fact, top or lateral gates are precisely exploited to this purpose. Similarly, the nanowire is contacted to ordinary metallic electrodes, where RSOC typically vanishes. The effects of the inhomogeneities of the RSOC are thus crucial and may affect the behavior of a nanowire-based setup, possibly even in terms of its topological properties. However, while inhomogeneous RSOC has been discussed in 2D systems like semiconductor quantum wells and graphene [20–24], only a few groups have addressed it in one-dimensional (1D) systems [25–30].

Secondly, as far as equilibrium properties are concerned, nanowires have been much less analyzed than 2D electron gases (2DEGs) with RSOC. In 2D, for instance, RSOC can lead to a background spin current flow even at equilibrium [31], a surprising effect that opened up an interesting conceptual debate about its observability, with various proposals by several groups [32–45]. In 1D systems, however, such effect is absent [46], and this has probably contributed to convey the impression that the equilibrium properties of Rashba nanowires are trivial. In fact, most works on nanowires have focused on out of equilibrium properties, concerning either the charge sector, such as the behavior of the linear conductance as a function of the gate voltage or magnetic field [25,26,48–51], or the spin sector, such as the spin current under time-dependent perturbations [28,46,52,53]. Notably, in many of these works, the presence of an external magnetic field is crucial.

This paper is devoted to show that in a nanowire+leads setup, the interplay between a uniformly applied magnetic field and the inhomogeneous RSOC leads to interesting effects in the

^{*}fabrizio.dolcini@polito.it

spin sector, even at equilibrium and at low temperatures. First, while a mere RSOC or a magnetic field, separately, cannot cause any equilibrium spin current, the latter does arise in the nanowire bulk when both are present and the magnetic field is applied along the nanowire axis. Such equilibrium spin current is polarized along the Rashba field direction, i.e., orthogonally to the direction of the applied magnetic field. Notably, while the spin current decays in the leads, it persists in the bulk far beyond the regime where the nanowire mimics the helical states of the QSH effect, and can be tuned by the magnetic field and the chemical potential. Secondly, at the nanowire/lead interfaces, we predict the appearance of localized spin torque and spin polarization orthogonal to the magnetic field, whose penetration into the leads is discussed in various regimes of chemical potential. Notably, this effect is qualitatively similar to the orthogonal spin polarization of the Majorana states localized at the boundaries of a proximized nanowire in the topological phase [54], despite that in our case there is no superconducting coupling and the nanowire is in the topologically trivial phase. This result, purely due to the inhomogeneity of the RSOC, suggests that caution should be taken in interpreting a localized and orthogonal spin polarization as a signature of Majorana fermions. Furthermore, our analysis also shows that, in the inhomogeneous nanowire+leads system, the leads effectively act as magnetic barriers, and the interface spin torques as sources and sinks of the equilibrium spin current carried by spin bound states in the nanowire, similarly to the charge current carried by the Andreev bound states in a superconductor/normal/superconductor junction. Finally, we address the effects of a magnetic field component parallel to the Rashba spin direction, showing that it leads to a spin polarization not collinear with the magnetic field and to a spin-orbit torque also in the nanowire bulk.

The paper is organized as follows. In Sec. II, we introduce the model and the quantities we shall analyze. Then, in Sec. III, we discuss the bulk properties of the nanowire by taking the limit of homogeneous RSOC. Specifically, we examine in details the origin of the emerging equilibrium spin current and analyze its behavior as a function of the applied magnetic field and chemical potential. In Sec. IV, we account for the presence of the leads by an inhomogeneous profile smoothly varying at the interfaces, and discuss the appearance of the spin torque and the orthogonal spin polarization at the interfaces, as well as their penetration into the leads. Section V is devoted to analyze the effects of a magnetic field component parallel to the Rashba field direction. Finally, in Sec. VI, after summarizing our main results, we conclude with a discussion of some possible experimental realizations and an outlook of future developments of this work.

II. MODEL AND SPIN EQUATION OF MOTION

A. System Hamiltonian

We consider a nanowire deposited on a substrate and assume that one single electronic channel is active in the nanowire. The SIA emerging at the interface with the substrate gives rise to an effective Rashba spin-orbit “magnetic” field \mathbf{h}^{SO} orthogonal to the nanowire axis, in the substrate plane. We also consider the presence of an actual external magnetic field, applied along an

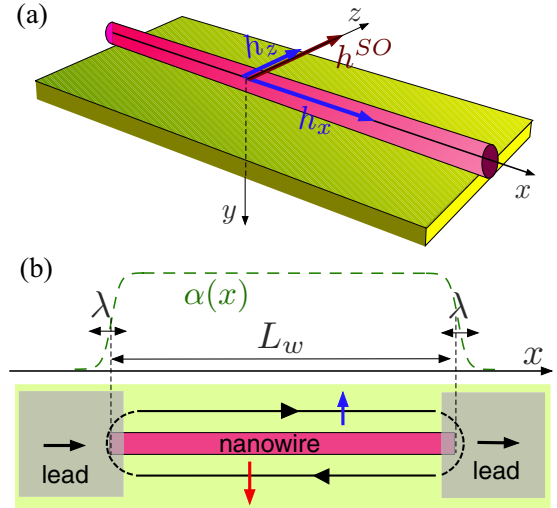

FIG. 1. (a) A Rashba nanowire deposited on a substrate: the Rashba effective magnetic field \mathbf{h}^{SO} is directed along z , whereas an actual magnetic field, externally applied in the substrate plane, has components h_x (along the nanowire axis) and h_z (along the Rashba effective magnetic field). (b) Top view of the Rashba nanowire contacted to leads: the setup can be modelled by an inhomogeneous Rashba coupling $\alpha(x)$ (dashed green curve) that varies from a finite value in the bulk of the nanowire to zero in the leads, over a smoothing length λ . Due to the inhomogeneous Rashba coupling, the leads act as magnetic barriers: spin flip processes caused by the spin torque at the interfaces (red areas), form spin bound states carrying a spin current in the nanowire.

arbitrary direction in the substrate plane. For definiteness, we shall denote the longitudinal direction of the nanowire by x , the direction perpendicular to the substrate plane and pointing downwards by y , while the direction of the Rashba field by z [see Fig. 1(a)].

Denoting by $\hat{\Psi}(x) = (\psi_{\uparrow}(x), \psi_{\downarrow}(x))^T$ the electron spinor field, where \uparrow, \downarrow correspond to spin projections along positive and negative Rashba field direction z , respectively, the Hamiltonian for a Rashba nanowire reads

$$\hat{\mathcal{H}} = \int \hat{\Psi}^\dagger(x) H(x) \hat{\Psi}(x) dx, \quad (1)$$

where

$$H(x) = \frac{p_x^2}{2m^*} \sigma_0 - \frac{\{\alpha(x), p_x\}}{2\hbar} \sigma_z - \mathbf{h} \cdot \boldsymbol{\sigma}, \quad (2)$$

$p_x = -i\hbar\partial_x$ is the momentum operator, σ_0 the 2×2 identity matrix, and $\boldsymbol{\sigma} = (\sigma_x, \sigma_y, \sigma_z)$ are the Pauli matrices. Furthermore, $\alpha(x)$ denotes the RSOC profile, in general inhomogeneous along the nanowire, so that the anticommutator with p_x is necessary in Eq. (2). Finally, $\mathbf{h} = g\mu_B \mathbf{B}/2$ is the Zeeman energy vector induced by the external magnetic field $\mathbf{B} = (B_x, 0, B_z)$, with μ_B denoting the Bohr magneton and g the Landé factor. It is useful to decompose the Zeeman energy vector as $\mathbf{h} = h_x \mathbf{i}_x + h_z \mathbf{i}_z$, where h_x and h_z denote the components parallel and perpendicular to the nanowire axis x , i.e., perpendicular and parallel to the Rashba spin-orbit field direction z , respectively [see Fig. 1(a)].

Before focusing on the behavior of quantities in the spin sector, it is worth recalling an aspect related to the charge sector

in systems with RSOC: while the charge density has the usual expression

$$\hat{n} = e \hat{\Psi}^\dagger(x) \hat{\Psi}(x), \quad (3)$$

where e denotes the electron charge, the charge current density

$$\begin{aligned} \hat{j}^c = & -\frac{ie\hbar}{2m^*}(\hat{\Psi}^\dagger(x) \partial_x \hat{\Psi}(x) - \partial_x \hat{\Psi}^\dagger(x) \hat{\Psi}(x)) \\ & - e \frac{\alpha(x)}{\hbar} \sigma_z \hat{\Psi}^\dagger(x) \hat{\Psi}(x) \end{aligned} \quad (4)$$

includes a term [second line of Eq. (4)] associated to the Rashba coupling α in the Hamiltonian (2). Such term originates from the fact that, in the presence of RSOC, the (charge) velocity operator becomes spin-dependent,

$$v \doteq \frac{[x, H(x)]}{i\hbar} = \frac{p_x}{m^*} - \frac{\alpha}{\hbar} \sigma_z, \quad (5)$$

and is essential to ensure the fulfillment of the charge continuity equation,

$$\partial_t \hat{n} + \partial_x \hat{j}^c = 0. \quad (6)$$

In the following, we shall show that an analogous term plays a crucial role in the spin sector.

B. Spin density, spin current, torques, and spin equation of motion

Let us now focus on the spin sector. We define the spin density and spin current density operators in the standard way as [31,42]

$$\hat{\mathbf{S}} = \frac{\hbar}{2} \hat{\Psi}^\dagger(x) \boldsymbol{\sigma} \hat{\Psi}(x), \quad (7)$$

$$\begin{aligned} \hat{\mathbf{J}}^s = & \frac{1}{2} (\hat{\Psi}^\dagger(x) \hat{\mathbf{S}} v \hat{\Psi}(x) + \text{H.c.}) \\ = & \frac{\hbar}{2} \left(-\frac{i\hbar}{2m^*} (\hat{\Psi}^\dagger(x) \boldsymbol{\sigma} \partial_x \hat{\Psi}(x) - \partial_x \hat{\Psi}^\dagger(x) \boldsymbol{\sigma} \hat{\Psi}(x)) \right. \\ & \left. - \frac{\alpha(x)}{\hbar} \hat{\Psi}^\dagger(x) \frac{\{\boldsymbol{\sigma}, \sigma_z\}}{2} \hat{\Psi}(x) \right), \end{aligned} \quad (8)$$

respectively. Formally, Eqs. (7) and (8) can be obtained from the related charge operators (3) and (4) by replacing $e \rightarrow \hbar/2$ and by inserting the set $\boldsymbol{\sigma}$ of Pauli matrices between $\hat{\Psi}^\dagger$ and $\hat{\Psi}$, implying that electrons with opposite spins contribute with opposite sign to spin density and current, as compared to the related charge quantities. Note that, similarly to the second line of Eq. (4), the last term of Eq. (8) stems from Rashba coupling, which modifies the spin velocity by an extra term along the z direction of the Rashba field \mathbf{h}^{SO} ,

$$\mathbf{v}^s \doteq \frac{\{\boldsymbol{\sigma}, v\}}{2} = \left(\frac{p_x}{m^*} \sigma_x, \frac{p_x}{m^*} \sigma_y, \frac{p_x}{m^*} \sigma_z - \frac{\alpha}{\hbar} \right). \quad (9)$$

Differently from charge, however, spin does not obey in general a continuity equation. For the Rashba nanowire, one can prove that

$$\partial_t \hat{\mathbf{S}} + \partial_x \hat{\mathbf{J}}^s = \hat{\mathbf{T}}^h + \hat{\mathbf{T}}^{\text{SO}}, \quad (10)$$

where torque operators appear on the right-hand side [see Eq. (6) for comparison]. In particular, $\hat{\mathbf{T}}^h$ denotes the custom-

ary spin torque due to the magnetic field \mathbf{h} ,

$$\hat{\mathbf{T}}^h \doteq \hat{\Psi}^\dagger(\boldsymbol{\sigma} \times \mathbf{h}) \hat{\Psi}, \quad (11)$$

while $\hat{\mathbf{T}}^{\text{SO}}$ is an additional spin-orbit torque appearing in systems with RSOC, which can be given two equivalent expressions:

$$\hat{\mathbf{T}}^{\text{SO}} \doteq \frac{\alpha(x)}{4} (\hat{\Psi}^\dagger[\boldsymbol{\sigma}, \sigma_z] \partial_x \hat{\Psi} - \partial_x \hat{\Psi}^\dagger[\boldsymbol{\sigma}, \sigma_z] \hat{\Psi}) \quad (12)$$

$$= \frac{1}{2} (\hat{\Psi}^\dagger(\boldsymbol{\sigma} \times \mathbf{h}^{\text{SO}}) \hat{\Psi} + \text{H.c.}), \quad (13)$$

with

$$\mathbf{h}^{\text{SO}}(x, t) = \frac{\{\alpha(x), p_x\}}{2\hbar} (0, 0, 1) \quad (14)$$

denoting the spin-orbit field operator (it actually has the dimension of an energy density). Note that, by definition, the spin-orbit torque $\hat{\mathbf{T}}_{\text{SO}}$ has components only in the plane (x, y) orthogonal to the Rashba direction z . The proof of the equation of motion (10) is provided in Appendix.

C. Equilibrium expectation values

The equilibrium properties of the system are obtained as

$$\begin{aligned} n(x) &= \langle \hat{n} \rangle_0, \\ J^c(x) &= \langle \hat{j}^c \rangle_0, \\ \mathbf{S}(x) &= \langle \hat{\mathbf{S}} \rangle_0, \\ \mathbf{J}^s(x) &= \langle \hat{\mathbf{J}}^s \rangle_0, \\ \mathbf{T}^{h/\text{SO}}(x) &= \langle \hat{\mathbf{T}}^{h/\text{SO}} \rangle_0, \end{aligned} \quad (15)$$

where $\langle \dots \rangle_0$ denotes the quantum and statistical expectation value over the equilibrium state. Note that, at equilibrium, these expectation values are time-independent. However, they can be space-dependent in the case of inhomogeneous RSOC, as we shall see below.

Besides the above quantities, it is also useful to introduce the particle density

$$\rho(x) \doteq \frac{n(x)}{e} \quad (16)$$

and the spin polarization,

$$\mathbf{P}(x) \doteq \frac{\langle \hat{\Psi}^\dagger \boldsymbol{\sigma} \hat{\Psi} \rangle_0}{\langle \hat{\Psi}^\dagger \hat{\Psi} \rangle_0} = \frac{2}{\hbar} \frac{\mathbf{S}(x)}{\rho(x)} \quad |\mathbf{P}| \leq 1. \quad (17)$$

The dimensionless quantity \mathbf{P} identifies, up to a universal constant, the spin density \mathbf{S} per electron, and is more straightforwardly interpreted and customarily probed in experiments.

III. THE LIMIT OF HOMOGENEOUS RASHBA COUPLING: NANOWIRE BULK

We start by analyzing the bulk properties of the nanowire [55], which can be addressed in the limit of very long nanowire length $L_w \rightarrow \infty$ [see Fig. 1(b)], i.e., assuming a homogeneous Rashba coupling $\alpha(x) \equiv \alpha$. The Hamiltonian (2) of the

nanowire then commutes with p_x . By expressing the electron spinor field in terms of its Fourier components

$$\hat{\Psi}(x) = \frac{1}{\sqrt{L_w}} \sum_k e^{ikx} \hat{C}_k, \quad (18)$$

with $\hat{C}_k = (\hat{c}_{k\uparrow}, \hat{c}_{k\downarrow})^T$ denoting the Fourier mode operators, the Hamiltonian is block-diagonal in k -space, $\hat{\mathcal{H}} = \sum_k \hat{C}_k^\dagger H_k \hat{C}_k$, where H_k can be compactly written as

$$\begin{aligned} H_k &= \varepsilon_k^0 \sigma_0 - (\alpha k + h_z) \sigma_z - h_x \sigma_x \\ &= \varepsilon_k^0 \sigma_0 - \sqrt{(\alpha k + h_z)^2 + h_x^2} \mathbf{n} \cdot \boldsymbol{\sigma}. \end{aligned} \quad (19)$$

Here, $\varepsilon_k^0 = \hbar^2 k^2 / 2m^*$, while the unit vector

$$\mathbf{n}(k) \doteq (\sin \theta_k, 0, \cos \theta_k) \quad (20)$$

identifies the k -state spin-orientation in the x - z plane. Here the angle $\theta_k \in [-\pi; \pi]$ is defined through

$$\begin{cases} \cos \theta_k &= \frac{\alpha k + h_z}{\sqrt{(\alpha k + h_z)^2 + h_x^2}} \\ \sin \theta_k &= \frac{h_x}{\sqrt{(\alpha k + h_z)^2 + h_x^2}} \end{cases} \quad (21)$$

and depends on both the magnetic field and k , due to the RSOC α . From the expression (19), one straightforwardly obtains the two spectrum bands

$$E_{\pm}(k) = \varepsilon_k^0 \pm \sqrt{h_x^2 + (\alpha k + h_z)^2} \quad (22)$$

as well as the related eigenvectors

$$w_{k-} = \begin{pmatrix} \cos \frac{\theta_k}{2} \\ \sin \frac{\theta_k}{2} \end{pmatrix} \quad w_{k+} = \begin{pmatrix} -\sin \frac{\theta_k}{2} \\ \cos \frac{\theta_k}{2} \end{pmatrix}. \quad (23)$$

Thus, by performing a rotation $U_k = \exp[-i\theta_k \sigma_2 / 2]$ by the angle θ_k , the Fourier mode operators \hat{C}_k can be re-expressed in terms of new fermionic operators $\hat{\Gamma}_k = (\hat{\gamma}_{k-}, \hat{\gamma}_{k+})^T$ related to the eigenvectors (23),

$$\hat{C}_k = U_k \hat{\Gamma}_k = w_{k-} \hat{\gamma}_{k-} + w_{k+} \hat{\gamma}_{k+}, \quad (24)$$

and the Hamiltonian straightforwardly acquires a diagonal form

$$\hat{\mathcal{H}} = \sum_k (E_-(k) \hat{\gamma}_{k-}^\dagger \hat{\gamma}_{k-} + E_+(k) \hat{\gamma}_{k+}^\dagger \hat{\gamma}_{k+}). \quad (25)$$

Notably, in the presence of a perpendicular component $h_x \neq 0$ of the Zeeman field (i.e., $\theta_k \neq 0, \pi$), the eigenstates $\Psi_{k\pm}(x) = w_{k\pm} e^{ikx}$ diagonalizing the Hamiltonian are *not* eigenstates of the (charge) velocity operator v , due to the Rashba spin-orbit term appearing in Eq. (5). This aspect will be important in interpreting the spin current, as we shall discuss below. Yet, the quantum expectation value of v on each eigenstate corresponds of course to the group velocity associated to the slope of the spectrum,

$$v_{\pm}(k) \doteq \langle \Psi_{k\pm} | v | \Psi_{k\pm} \rangle = \frac{\hbar k}{m^*} \pm \frac{\alpha}{\hbar} \cos \theta_k = \frac{1}{\hbar} \frac{\partial E_{\pm}}{\partial k}, \quad (26)$$

where E_{\pm} is given in Eq. (22).

Using Eqs. (18) and (24) to re-express the operators Eqs. (3), (4), (7), (8), (11), and (12) in terms of the diagonalizing operators $\hat{\gamma}_{k\pm}$'s, and exploiting the fact that, at equilibrium

$$\langle \hat{\gamma}_{kb}^\dagger \hat{\gamma}_{k'b'} \rangle_0 = \delta_{k,k'} \delta_{b,b'} f^\circ(E_b(k)) \quad b, b' = \pm, \quad (27)$$

where $f^\circ(E) = \{1 + \exp[(E - \mu)/k_B T]\}^{-1}$ is the Fermi distribution at temperature T and chemical potential μ , the equilibrium expectation values (15) are straightforwardly obtained. In particular, in the bulk limit, $L_w \rightarrow \infty$, one can pass to the continuum. For the charge sector, one obtains

$$n = e \int \frac{dk}{2\pi} [f^\circ(E_-(k)) + f^\circ(E_+(k))], \quad (28)$$

$$J^c = e \sum_{b=\pm} \int \frac{dk}{2\pi} \left(\frac{\hbar k}{m^*} + b \frac{\alpha}{\hbar} \cos \theta_k \right) f^\circ(E_b(k)), \quad (29)$$

and by combining Eqs. (22) and (29) one straightforwardly sees that $J^c = e(2\pi\hbar)^{-1} \sum_b \int dk \partial_k E_b f^\circ(E_b(k)) = 0$, i.e., the charge current vanishes, as expected at equilibrium. In contrast, for the spin sector one finds

$$S_x = \frac{\hbar}{2} \int \frac{dk}{2\pi} \sin \theta_k [f^\circ(E_-(k)) - f^\circ(E_+(k))], \quad (30)$$

$$S_y = 0, \quad (31)$$

$$S_z = \frac{\hbar}{2} \int \frac{dk}{2\pi} \cos \theta_k [f^\circ(E_-(k)) - f^\circ(E_+(k))], \quad (32)$$

$$J_x^s = \frac{\hbar}{2} \int \frac{dk}{2\pi} \frac{\hbar k}{m^*} \sin \theta_k [f^\circ(E_-(k)) - f^\circ(E_+(k))], \quad (33)$$

$$J_y^s = 0, \quad (34)$$

$$J_z^s = -\frac{\hbar}{2} \sum_{b=\pm} b \int \frac{dk}{2\pi} \left(\frac{\hbar k}{m^*} \cos \theta_k + b \frac{\alpha}{\hbar} \right) f^\circ(E_b(k)), \quad (35)$$

$$T_x^h = 0, \quad (36)$$

$$T_y^h = \sum_{b=\pm} b \int \frac{dk}{2\pi} (h_z \sin \theta_k - h_x \cos \theta_k) f^\circ(E_b(k)), \quad (37)$$

$$T_z^h = 0, \quad (38)$$

$$T_x^{\text{SO}} = 0, \quad (39)$$

$$T_y^{\text{SO}} = - \int \frac{dk}{2\pi} \alpha k \sin \theta_k [f^\circ(E_-(k)) - f^\circ(E_+(k))], \quad (40)$$

$$T_z^{\text{SO}} = 0. \quad (41)$$

Note that, since we are considering at the moment the *homogeneous* bulk of the nanowire, all above equilibrium quantities are independent of the space coordinate x , besides being independent of time. Then, the expectation values of the torque operators appearing on the left-hand side of Eq. (10)

vanish,

$$\mathbf{T}^h + \mathbf{T}^{\text{SO}} = 0, \quad (42)$$

and the spin continuity equation is fulfilled. This can also be directly deduced by summing up Eqs. (37) and (40) and by using Eq. (21). Here below we shall analyze the above quantities as a function of the magnetic field and chemical potential, focusing on the spin sector.

A. Vanishing magnetic field

Let us first briefly recall the effects of a purely Rashba coupling α on the spin sector. For vanishing magnetic field, $h_x = h_z = 0$, the Hamiltonian (19) commutes with σ_z , so that the spin quantization axis is z for all electronic states of the nanowire, i.e., $\theta_k = 0$ or π in Eq. (21). The Rashba coupling thus leads to the well known spectrum displayed by the solid curves of Fig. 2(a): the spin- \uparrow and spin- \downarrow states are horizontally displaced in opposite directions by the Rashba wave vector

$$k_{\text{SO}} = \frac{m^*|\alpha|}{\hbar^2}, \quad (43)$$

and the minima of the parabolic spectrum are lowered to $E_{\text{min}} = -E_{\text{SO}}$, where

$$E_{\text{SO}} = \frac{m^*\alpha^2}{2\hbar^2} = \frac{\hbar^2 k_{\text{SO}}^2}{2m^*} \quad (44)$$

is the Rashba spin-orbit energy. Inserting $\sin \theta_k = 0$ and $\cos \theta_k = \text{sgn}(\alpha k)$ in the general expressions (30)–(38) one can show that

$$\mathbf{P} = \mathbf{J}^s = \mathbf{T}^h = \mathbf{T}^{\text{SO}} = 0. \quad (45)$$

The absence of a net spin polarization is due to the fact that the spin- \uparrow and \downarrow bands, despite being displaced, lead to perfectly opposite contributions at each energy E . The absence of spin current can be understood from Fig. 2(a) as follows: at any energy E , each pair of time-reversed states ($k \uparrow, -k \downarrow$) is characterized by opposite group velocities and opposite spin orientations (filled circles), thereby carrying a spin current. However, at the same energy E , another time-reversed pair ($k' \downarrow, -k' \uparrow$) exists, with the same group velocities but reversed spin orientations (empty circles), whose spin current cancels the one of the former pair. Finally, since the spin torque \mathbf{T}^h is trivially absent for vanishing magnetic field, Eq. (42) implies that the spin-orbit torque \mathbf{T}^{SO} vanishes too. As summarized in Eq. (45), the mere presence of a RSOC has no effect on the nanowire spin sector at equilibrium.

B. Effects of a perpendicular magnetic field: appearance of an equilibrium spin current

When a magnetic field h_x is applied along the nanowire axis x , i.e., perpendicularly to the spin-orbit direction z , the scenario changes significantly. The spin orientation, Eq. (20), of each electron state becomes k -dependent [see Eq. (21)]. Furthermore, the two bands do not intersect anymore, and at $k = 0$ they are separated by a gap $2\Delta_Z$ in the spectrum (22), with

$$\Delta_Z = |h_x| = \left| \frac{g \mu_B}{2} B_x \right|. \quad (46)$$

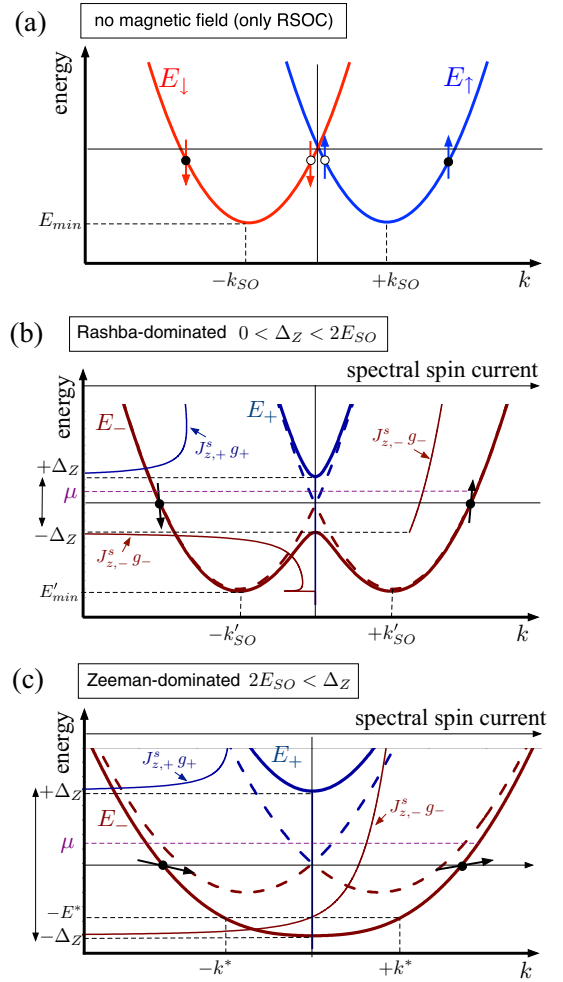

FIG. 2. The bulk spectrum of the Rashba nanowire (homogeneous RSOC). (a) In the absence of magnetic field, spin is a good quantum number and the spectrum consists of two bands E_+ and E_- . Vertical arrows describe the spin orientation for the case $\alpha > 0$. (b) Effects of a weak magnetic field h_x : the Rashba-dominated regime. Thick solid curves denote the electronic spectrum (left axis) in the presence of a magnetic field h_x applied along the nanowire axis, i.e., perpendicularly to the Rashba spin-orbit direction z . Arrows denote the spin orientation when $\alpha > 0$. Thick dashed curves denote the spectrum for $h_x = 0$ and are a guide to the eye. Thin solid curves describe the spectral weight $J_{z,\pm}^s(E) g_{\pm}(E)$ of the two bands [the reader should refer to the left vertical axis (energy) and to the upper horizontal axis (spectral spin current)]. (c) Effects of a strong magnetic field: in the Zeeman-dominated regime, the minimum of the bands is at $k = 0$. The meaning of the curves is the same as in (b).

Two regimes can be identified, as illustrated in Fig. 2. For a weak applied field, namely in the Rashba-dominated regime $\Delta_Z < 2E_{\text{SO}}$ [see Fig. 2(b)], the effect of the magnetic field is (i) to decrease to the value

$$k'_{\text{SO}} \doteq k_{\text{SO}} \sqrt{1 - \frac{\Delta_Z^2}{4E_{\text{SO}}^2}}, \quad (47)$$

the magnitude of the wave vectors $k = \pm k'_{\text{SO}}$ corresponding to the minima of the lower band E_- , and (ii) to correspondingly

lower the value of such minima,

$$E'_{\min} = -E_{SO} \left(1 + \frac{\Delta_Z^2}{4E_{SO}^2} \right). \quad (48)$$

In contrast, for stronger fields, i.e., in the Zeeman-dominated regime $\Delta_Z > 2E_{SO}$ [see Fig. 2(c)], the lower band has only one minimum at $k = 0$, with energy

$$E'_{\min} = -\Delta_Z. \quad (49)$$

These essentially different features with respect to the case of vanishing magnetic field entail deviations from the trivial situation of the spin sector Eq. (45), and give rise to two effects. The first one is the expected emergence of a spin polarization along the direction of the applied magnetic field h_x ,

$$\mathbf{P} = (P_x, 0, 0) \quad (50)$$

with

$$P_x = \frac{1}{\rho} \int \frac{dk}{2\pi} \frac{h_x [f^\circ(E_-(k)) - f^\circ(E_+(k))]}{\sqrt{(\alpha k)^2 + h_x^2}}, \quad (51)$$

as can be deduced from Eqs. (30), (32), and (17). An inspection of Eq. (51) shows that this effect is essentially due to the magnetic field, since it exists also without RSOC, i.e., for $\alpha = 0$. However, the RSOC $\alpha \neq 0$ does affect the dependence of P_x on h_x . Indeed, for each k state, the spin lies in the x - z plane and forms an angle θ_k with the z axis [see Eq. (20)]. Thus, although the spin z component of states with opposite k 's mutually cancel out and leave a net spin polarization directed along x , the latter is only a fraction $\sin \theta_k$ of the available polarization [see Eq. (21)].

The second effect is not trivial, and is one of our main results. It consists in the appearance of an equilibrium spin current flowing through the nanowire and polarized *along* the Rashba direction z , i.e., *perpendicularly* to direction x of the applied magnetic field h_x . Explicitly, from Eqs. (33)–(35), one finds

$$\mathbf{J}^s = (0, 0, J_z^s) \quad (52)$$

with

$$J_z^s = - \sum_{b=\pm} \int \frac{dk}{2\pi} \left(\frac{\alpha}{2} + b \frac{\hbar^2 k}{2m^*} \frac{\alpha k}{\sqrt{(\alpha k)^2 + h_x^2}} \right) f^\circ(E_b(k)), \quad (53)$$

where $E_\pm(k)$ is given in Eq. (22). The behavior of J_z^s is illustrated in Fig. 3 as a function of the ratio Δ_Z/E_{SO} of the Zeeman gap energy to the Rashba spin-orbit energy, for various values of the chemical potential μ , in the case $\alpha > 0$. As one can see, while for $\mu \leq 0$, its magnitude monotonously increases with the magnetic field, for $\mu > 0$, the behavior is nonmonotonous. Furthermore, cusps arise for any $\mu \neq 0$. The physical origin of the spin current and its behavior deserve a detailed analysis, which will be carried out in the next subsection. Here we just mention that, although for simplicity of presentation we have assumed here a magnetic field applied along the nanowire axis x , the result (53) for the equilibrium spin current holds for any magnetic field $\mathbf{h}_\perp = (h_x, h_y, 0)$ lying in the (x, y) plane orthogonal to the Rashba direction z , upon the replacement $|h_x| \rightarrow |\mathbf{h}_\perp|$. Instead, the case of a

FIG. 3. The zero-temperature behavior of the equilibrium spin current J_z^s , induced by the interplay between the applied magnetic field and the RSOC, is shown as a function of the ratio Δ_Z/E_{SO} of the Zeeman gap energy (46) to the Rashba spin-orbit energy Eq. (44), for various values of the chemical potential μ .

magnetic field with a component along the Rashba direction z will be analyzed in Sec. V.

We conclude this subsection by a comment related to the torques. In the present case, where the magnetic field $\mathbf{h} = (h_x, 0, 0)$ is applied along the nanowire axis x , the equilibrium spin density vector \mathbf{S} and the polarization \mathbf{P} are both collinear with \mathbf{h} [see Eq. (50)]. One can thus deduce from Eqs. (7) and (11) that the spin torque \mathbf{T}^h vanishes. Then, the spin-orbit torque \mathbf{T}^{SO} must vanish as well, because of Eq. (42). In conclusion, for a magnetic field applied along the nanowire axis, both torques separately vanish:

$$\mathbf{T}^h = \mathbf{T}^{SO} = 0. \quad (54)$$

This can also be deduced from Eqs. (40) and (37) by noticing that, for $h_z = 0$, $\sin \theta_k$ and $\cos \theta_k$ are even and odd in k , respectively [see Eqs. (21)], and all integrals therein vanish by antisymmetry.

C. Origin and meaning of the bulk equilibrium spin current

Let us now discuss the physical origin and the behavior of the equilibrium spin current found in Eq. (53) and shown in Fig. 3. We start by specifying the conditions for its appearance, which can be done analyzing some special limits of Eq. (53). On the one hand, when $\alpha = 0$ the spin current vanishes. On the other hand, when $h_x = 0$ the band spectrum reduces to the case of the purely Rashba coupling [see Fig. 2(a)] where the net spin current also vanishes, as observed in Sec. III A. Thus, differently from the spin polarization (51), the equilibrium spin current needs the presence of *both* the Rashba coupling $\alpha \neq 0$ and the perpendicular magnetic field $h_x \neq 0$. We thus emphasize the difference with respect to the case of 2D systems with RSOC, where an equilibrium spin current has been predicted to arise already without magnetic field, i.e., when time-reversal symmetry is preserved [31]. For nanowires the presence of the magnetic field is crucial.

Secondly, we observe that the direction of flow of the spin current is determined by the sign of the RSOC α , and *not* by the direction of the magnetic field along the nanowire

axis. Indeed from Eqs. (22) and (53), one can rewrite $J_z^s = (2\pi)^{-1} \int dk \sum_{b=\pm} J_{z,b}^s(k) f^\circ(E_b(k))$, where each spin current contribution

$$J_{z,b}^s(k) = -\frac{\hbar^2}{2m^*} \frac{\partial \mathcal{E}_b(k)}{\partial \alpha}, \quad (55)$$

can be regarded to as the response to the RSOC α of the energy $\mathcal{E}_b(k) = E_b(k) + E_{\text{SO}}$ measured from the band bottom $-E_{\text{SO}}$. In particular, J_z^s is an *odd* function of the Rashba coupling α and an *even* function of the magnetic field h_x , i.e., it depends only on the gap energy Δ_Z [see Eq. (46)]. Notice the striking contrast with the spin polarization in Eq. (50): \mathbf{P} is pointing along x , i.e., orthogonally to the equilibrium spin current polarization Eq. (52), it exists also for vanishing RSOC, is an odd function of the magnetic field h_x and an even function of α [see Eq. (51)]. Indeed each contribution to the spin polarization \mathbf{P} can be expressed as the response of the energy $\mathcal{E}_b(k)$ to the applied magnetic field \mathbf{h} ,

$$\mathbf{P}_b(k) = -\rho^{-1} \nabla_{\mathbf{h}} \mathcal{E}_b(k), \quad (56)$$

as straightforwardly obtained from Eqs. (22) and (30)–(32). The quantities J_z^s and \mathbf{P} are thus related only indirectly. In particular, the spin polarization component P_z parallel to the spin current polarization vanishes [compare Eqs. (50) and (52)], implying that J_z^s is not due to an unbalance of the number of spin- \uparrow carriers with respect to spin- \downarrow carriers.

In order to understand the origin of the spin current induced by the magnetic field at equilibrium, we recall its physical meaning, which can be straightforwardly read off from its definition [see first line of Eq. (8)]: the spin current consists, up to the symmetrization of the noncommuting operators $\hat{\mathbf{S}}$ and v , in a nonvanishing expectation value $\langle \hat{\mathbf{S}}v \rangle$. Such expectation value can always be rewritten as the sum of two terms [42]. The first one is related to the product $\langle \hat{\mathbf{S}} \rangle \langle v \rangle$, and describes the fact that a charge current transfers spin, when a spin unbalance occurs along some orientation. The second one encodes the correlation between between velocity v and spin $\hat{\mathbf{S}}$. When the average velocity $\langle v \rangle$ vanishes, the latter term is the only surviving contribution, and is also referred to as the *pure* spin current [42]. This is precisely what we find in the Rashba nanowire at equilibrium when the magnetic field is applied. As the effect survives down to zero temperature, the spin current (53) describes the *nontrivial* quantum correlation between the propagation direction v and the spin orientation $\hat{\mathbf{S}}$. The ground state is thus characterized by electrons with opposite spins propagating in opposite directions, corresponding to a pure transport of spin, without net charge current.

As far as 1D systems are concerned, this phenomenon is known to occur in Rashba nanorings [32,36,41], where the circular geometry induces a spin texture of the RSOC, leading to a spin Berry phase [56–58]: electrons with opposite spin polarizations circulate clockwise and counter-clockwise along the ring, carrying a persistent spin current without an accompanying charge current. An equilibrium spin current also arises in the 1D helical edge states of a QSH system, where right-moving electrons are characterized by (say) spin- \uparrow and left-moving electrons by spin- \downarrow . At equilibrium, there is an equal number of right- and left-movers, so that there is no net velocity in the system ($\rightarrow \langle v \rangle = 0$), no net spin polarization ($\rightarrow \langle \hat{S}_z \rangle = 0$), but a spin current ($\rightarrow \langle \hat{S}_z v \rangle \neq$

0), corresponding to a spin flow from left to right without charge flow. This effect is a straightforward consequence of the velocity-spin locking characterizing the helical QSH edge states [59].

In single-channel Rashba nanowires, where the RSOC has no spin texture, there is no bulk equilibrium spin current without magnetic field [46,47]. However, as shown above, it does appear when a uniform magnetic field h_x is added. Notably, for weak magnetic fields (Rashba-dominated regime) the states inside the magnetic gap of the nanowire are known to effectively behave like QSH edge states [5,6,12–18,60], where the equilibrium spin current is known to flow [59]. One is thus tempted to argue that this analogy with QSH edge states also explains why the equilibrium spin current arises. We anticipate that this argument is not sufficient to account for the features of the equilibrium spin current shown in Fig. 3, which can only be explained when the contribution of states outside the magnetic gap is also considered. Nevertheless, such analogy does give an intuitive argument to qualitatively justify the origin of the equilibrium spin current. We shall thus briefly recall it here below.

1. The analogy with QSH edge states and the role of the states inside the gap

To illustrate the analogy with the QSH helical states, let us consider a weak applied magnetic field, $\Delta_Z \ll 2E_{\text{SO}}$, and compare Fig. 2(b) with the spectrum in the absence of magnetic field depicted in Fig. 2(a). One observes that, while any energy $|E| \geq \Delta_Z$ outside the magnetic gap always identifies two pairs of states like in Fig. 2(a), for energies $|E| < \Delta_Z$ inside the gap only one pair of “time-reversed states” is left [filled circles of Figs. 2(a) and 2(b)]. It thus seems at first plausible that the spin current is mainly due to the only pair remaining inside the gap, whose contribution at any energy $|E| < \Delta_Z$ is left unbalanced. Notably, such pair surviving inside the gap consists of counterpropagating states with equal and opposite velocities, so that it carries no net current. Furthermore, as the magnetic field is weak, their spin directions of are essentially determined by the Rashba coupling, and are (almost) opposite to each other, similarly to the helical states of a quantum spin Hall (QSH) system. Explicitly, for $\alpha > 0$, right-moving states have (almost) spin- \uparrow , while left-moving states have (almost) spin- \downarrow , whereas the opposite occurs for $\alpha < 0$. This analogy explains why the states inside the gap carry an equilibrium spin current, and why its flow is determined by the sign of α , and not by the sign of h_x .

Although intuitive and appealing, the above analogy with the QSH edge states is not sufficient to account for the behavior of the nanowire equilibrium spin current shown in Fig. 3. This is straightforwardly seen by focusing on the case of chemical potential lying in the middle of the magnetic gap ($\mu = 0$), described by thick solid black curve of Fig. 3. It reveals two key features. The first one is the sign of the spin current: the analogy with QSH would predict that at weak fields the spin current has the same sign $\text{sgn}(\alpha)$ as the RSOC, whereas the actual sign is quite the opposite, as described by the following asymptotic expression at weak fields,

$$J_z^s|_{\mu=0} \simeq -\frac{\text{sgn}(\alpha)}{8\pi} \frac{\Delta_Z^2}{E_{\text{SO}}} \left[\ln \left(\frac{8E_{\text{SO}}}{\Delta_Z} \right) - 1 \right] \quad \Delta_Z \ll E_{\text{SO}}, \quad (57)$$

and illustrated in the case $\alpha > 0$ by the *negative* thick solid black curve. The second feature is the behavior at strong magnetic field: When the Zeeman-dominated regime $\Delta_Z > 2E_{\text{SO}}$ is entered [see Fig. 2(c)], the magnetic field tends to align parallelly along x the spins of the two states at the Fermi level, and the analogy with the QSH helical pair is lost. One would thus expect the spin current to decrease with Δ_Z , whereas the solid black curve of Fig. 3 shows that the magnitude of J_z^s is *increasing*, as confirmed by the strong field asymptotic behavior

$$J_z^s|_{\mu=0} \simeq -\frac{\text{sgn}(\alpha)}{\pi} \left(\frac{\sqrt{\Delta_Z E_{\text{SO}}}}{3} - \frac{E_{\text{SO}}^{3/2}}{5\sqrt{\Delta_Z}} \right) \quad \Delta_Z \gg E_{\text{SO}}. \quad (58)$$

This proves that the equilibrium spin current arising in the nanowire persists far beyond the Rashba-dominated regime, and that the analogy with QSH edge states is not sufficient to account for the behavior displayed in Fig. 3, not even qualitatively.

2. The role of the states outside the gap

In order to go beyond the argument of the analogy with the QSH edge states and explain the behavior of the equilibrium spin current in Fig. 3, two aspects must be taken into account. First, while the charge current is essentially due to the states near the Fermi level, the *equilibrium* spin current takes contribution from *all* states up to the Fermi level μ . Second, the states with energy $|E| \geq \Delta_Z$ outside the gap turn out to provide a significant contribution to the spin current. This seems counter-intuitive at first, since a comparison of the electron spectra without magnetic field [Fig. 2(a)] and with magnetic field [Fig. 2(b)] would suggest that the difference causing the spin current stems from the states inside the gap only. However, when both RSOC and magnetic field are present in the nanowire, spin and velocity are not factorizable, $\langle \hat{S}_z v \rangle \neq \langle \hat{S}_z \rangle \langle v \rangle$, implying that the spin current contribution of a state cannot be simply deduced by separately inspecting its spin direction (spin arrows in the spectrum) and its group velocity (slope of the spectrum). This is why, even in the Rashba-dominated regime, the scenario for the nanowire is more complicated and richer than in QSH edge state case. More specifically, for each eigenstate $\Psi_{k\pm}(x) = w_{k\pm} e^{ikx}$ with wave vector k in the band $b = \pm$, the following inequality holds:

$$\langle \hat{S}_z v \rangle_{k\pm} - \langle \hat{S}_z \rangle_{k\pm} \langle v \rangle_{k\pm} = -\frac{\alpha}{2} \frac{h_x^2}{(\alpha k)^2 + h_x^2} \neq 0, \quad (59)$$

where $\langle \dots \rangle_{k\pm} = \langle \Psi_{k\pm} | \dots | \Psi_{k\pm} \rangle$. In particular, for states with a large wave vector $|k| \sim k_{\text{SO}}$, the right-hand side of Eq. (59) is small in the limit $h_x \ll E_{\text{SO}}$, so that spin and velocity effectively factorize, similarly to the QSH edge states. In contrast, for states with small wave vector $|k| \ll k_{\text{SO}}$, the lack of factorization becomes important, and spin current gets a nontrivial contribution. This is particularly striking for the two states at $k = 0$: While their group velocity vanishes for any arbitrarily small magnetic field as they become the extremal points of the two bands at the gap edges [$\langle v \rangle_{0,\pm} = 0 \ \forall h_x \neq 0$, see Fig. 2(b)], their spin current contribution is insensitive to h_x and remains equal to $-\alpha/4\pi$, i.e., the value in the absence

of magnetic field [see Eq. (53)]. At the same time, because the density of states (DOS) $g_{\pm}(E)$ of the 1D nanowire diverges at the gap edges $E = \pm\Delta_Z$ where the group velocity vanishes, the contribution of the $k = 0$ states to the total spin current turns out to be dramatically enhanced by the presence of the magnetic field. Note that this is quite different from the behavior of the charge current, where the DOS divergence is compensated by the vanishing of the velocity v .

This consequence of the inequality (59)—a spin current carried by states with vanishing velocity—deserves a comment. It is worth noting that Eq. (59) originates from the fact that, when both RSOC and magnetic field are present, the nanowire eigenstates are *not* eigenstates of the velocity operator (5). Rather, they are linear combinations $|k\pm\rangle = w_{k\pm,\uparrow}|k\uparrow\rangle + w_{k\pm,\downarrow}|k\downarrow\rangle$ of states with opposite spins and propagating in opposite directions [see dashed curves of Fig. 2(b)]. In particular, at $k = 0^+$ and $k = 0^-$, the linear combinations involve states with exactly opposite velocities, opposite spins, and the same spin current. This is why the $k = 0$ states carry a finite spin current despite a vanishing net velocity. For this reason, already at the band edges $E = \pm\Delta_Z$ the dominating contribution to the spin current counterintuitively arises from the states at $k = 0$, and not from the other pair of states at the same energy and with finite wave vector. More in general, each energy $|E| \geq \Delta_Z$ outside the gap identifies *two* pairs of counterpropagating states, one characterized by a large and one by a small wave vector, carrying spin currents of opposite signs. While for vanishing magnetic field a perfect cancellation occurs, in the presence of the magnetic field the spin current contribution of the pair with small wave vector prevails.

3. Spectral decomposition of the equilibrium spin current

It is useful to introduce its spectral decomposition of the equilibrium spin current Eq. (53) through

$$J_z^s = \int dE \left(\sum_{b=\pm} J_{z,b}^s(E) g_b(E) \right) f^{\circ}(E), \quad (60)$$

where $g_{\pm}(E) = (2\pi)^{-1} \int dk \delta(E - E_{\pm}(k))$ denotes the DOS, and

$$J_{z,\pm}^s(E) g_{\pm}(E) = \int \frac{dk}{2\pi} \delta(E - E_{\pm}(k)) J_{z,\pm}^s(k), \quad (61)$$

are the spectral weights related to the two bands $b = \pm$, illustrated by the two thin solid curves in Figs. 2(b) and 2(c), in the case $\alpha > 0$ [the reader should refer to the left vertical axis (energy) and to the upper horizontal axis (spectral weight of spin current)]. Let us focus in particular on the *sign* of the spectral weights of the two bands. As one can see, independently of whether the nanowire is in the Rashba-dominated or in the Zeeman-dominated regime [see Figs. 2(b) and 2(c)], all states of the upper band E_+ carry a spectral weight $J_{z,+}^s(E) g_+(E)$ with a sign $-\text{sgn}(\alpha)$ (i.e., negative in the case $\alpha > 0$ shown in Fig. 2), with a van Hove divergence appearing in correspondence of the upper band edge $E = \Delta_Z$. In contrast, the lower band E_- exhibits states both with positive and negative spectral weight, whose energy behavior depends on the specific regime. In the Rashba-dominated regime, the spectral weight $J_{z,-}^s(E) g_-(E)$ consists of two branches; the states with energy $E > -\Delta_Z$ [including the “helical states” at

$E = 0$] carry a spectral weight that has a sign $+\text{sgn}(\alpha)$ and is weakly dependent on energy, whereas the states below the band edge $-E'_{\min} \leq E \leq -\Delta_Z$ carry a spectral weight that has a sign $-\text{sgn}(\alpha)$ and is strongly energy dependent. In particular, a van Hove singularity arises as $E \rightarrow -\Delta_Z$, due to the states with small wave vector $|k| \ll k'_{\text{SO}}$. Notice that a third van Hove singularity is present at the local minima (48) in Fig. 2(b). This unbalance in the sign of the spectral weight shows that low-energy states play a major role in determining the sign and magnitude of the equilibrium spin current, which cannot be deduced just from the states near $E \simeq 0$.

D. Dependence of the equilibrium spin current on the magnetic field and chemical potential

With the help of the spectral decomposition introduced above, we can now understand the behavior of the spin current shown in Fig. 3. Indeed, as can be seen from Eq. (60), the zero-temperature spin current is obtained by integrating the spectral weight up to the chemical potential μ , which thus determines which branches—and therefore which sign—of the spectral weight are active.

In particular, at $\mu = 0$ only the lower band E_- is involved (see Fig. 2). The branch of the spectral weight $J_{z,-}^s(E)g_-(E)$ that has sign $-\text{sgn}(\alpha)$ (i.e., negative in Fig. 2) and contains the van Hove singularities dominates over the branch with sign $+\text{sgn}(\alpha)$. This explains why the spin current at $\mu = 0$, described in the case $\alpha > 0$ by the solid black curve of Fig. 3, is negative, oppositely to what one would naively conclude from the analogy with QSH edge states. The inequality (59) also justifies why the spin current increases in magnitude with the magnetic field. Indeed, despite a strong field $h_x > 2E_{\text{SO}}$ [see Fig. 2(c)] tends to align spins along the direction x , so that $\langle \hat{S}_z \rangle_{k\pm} \rightarrow 0$, the first term on the left-hand side (l.h.s.) of (59) remains finite. In fact, the range of states Ψ_{k-} of the lower band contributing to the spin current $\langle \hat{S}_z v \rangle_{k\pm}$ with a sign $-\text{sgn}(\alpha)$ increases with h_x . Explicitly, such range is identified by $|k| < k^*$, where

$$k^* = k_{\text{SO}} \sqrt{\frac{1 + \sqrt{1 + h_x^2/E_{\text{SO}}^2}}{2}}, \quad (62)$$

or equivalently by the energy window $E'_{\min} < E < -E^*$, with $E^* \doteq -E_-(k^*) \equiv \hbar^2 k^{*2}/2m^*$. In particular, in the Zeeman-dominated regime [see Fig. 2(c)], where E'_{\min} is given by Eq. (49), such range increases with h_x , and so does the magnitude of the spin current.

In the case $\mu < 0$, the spin current is described by dashed red curve of Fig. 3. Although only the lower band E_- contributes to J_z^s at zero temperature, two situations can be identified in this case. For weak fields $\Delta_Z < |\mu|$, only the branch with sign $-\text{sgn}(\alpha)$ of the spectral weight $J_{z,-}^s(E)g_-(E)$ is filled [see thin solid curves of Fig. 2(b)]. At $\Delta_Z = |\mu|$, the van Hove singularity of the spectral weight at $E = -\Delta_Z$ is encountered, whereas for higher field values the branch $J_{z,-}^s(E)g_-(E)$ with sign $+\text{sgn}(\alpha)$ starts to contribute. This explains why the dashed red curve of Fig. 3 displays a cusp at $\Delta_Z = |\mu|$ and increases in magnitude with a lower rate for $\Delta_Z > |\mu|$. At high fields, the behavior is qualitatively similar to the case of $\mu = 0$.

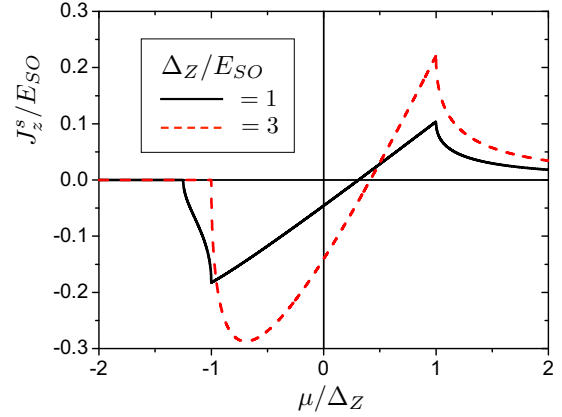

FIG. 4. The zero-temperature behavior of the equilibrium spin current J_z^s as a function of the chemical potential μ of the nanowire, for two values of the Zeeman gap energy Δ_Z related to the magnetic field applied along the nanowire axis. The solid black curve refers to the Rashba-dominated regime $\Delta_Z/E_{\text{SO}} = 1$ [see Fig. 2(b)], while the dashed red curve to the Zeeman-dominated regime $\Delta_Z/E_{\text{SO}} = 3$ [see Fig. 2(c)]. Singularities correspond to the gap edges $\mu = \pm\Delta_Z$.

For $\mu > 0$, the spin current is given by the thin blue solid and green dash-dotted curves in Fig. 3. For weak fields $\Delta_Z < \mu$, both bands E_- and E_+ contribute to J_z^s . However, as h_x is ramped up, part of the spectral weight $J_{z,+}^s(E)g_+(E)$, which carries a sign $-\text{sgn}(\alpha)$, is cut off. The spin current for $\mu > 0$ at low fields thus increases with Δ_Z . However, when $\Delta_Z = \mu$, the van Hove singularity of the upper band edge is encountered, the upper band is pushed above the Fermi level and does not contribute anymore. This is why a cusp occurs at $\Delta_Z = \mu$ in Fig. 3. For higher fields, the states of the spectral weight $J_{z,-}^s(E)g_-(E)$ carrying a sign $-\text{sgn}(\alpha)$ dominate and the spin current becomes negative.

Importantly, these results also show that the equilibrium spin current can be tuned by the chemical potential μ of the nanowire, which can be varied, e.g., with an applied gate. This is shown in Fig. 4, which displays J_z^s as a function of μ , for two different values of magnetic field. The solid curve refers to the Rashba-dominated regime $\Delta_Z < 2E_{\text{SO}}$ [see Fig. 2(b)], and the spin current increases (in magnitude) as μ varies from the minimal energy of the band E'_{\min} [see Eq. (48)] to the value $\mu = -\Delta_Z$ corresponding to the first gap edge, where J_z^s exhibits a cusp and starts to decrease in magnitude. Then, inside the magnetic gap, $|\mu| < \Delta_Z$, J_z^s grows essentially linearly with μ . Interestingly, the change of sign occurring with varying μ shows that the polarization of the spin current can be controlled through the chemical potential. A second cusp then arises at the other gap edge $\mu = +\Delta_Z$ where the states of the upper band E_+ start to provide an opposite contribution to the spin current. Eventually, for $\mu \gg \Delta_Z$, J_z^s decreases since at such high energies the effect of the magnetic field becomes negligible. In contrast, in the case of the Zeeman-dominated regime $\Delta_Z > 2E_{\text{SO}}$, illustrated by the dashed curve of Fig. 4, the first cusp reverses its curvature and occurs at the lower edge $\mu = -\Delta_Z$, corresponding to the minimum of the lower band at $k = 0$ [see Fig. 2(c)].

IV. INHOMOGENEOUS RASHBA PROFILE: NANOWIRE CONTACTED TO THE LEADS

As observed in Introduction, in realistic setups the nanowire has a finite length L_w and is typically contacted to metallic electrodes, where the Rashba spin-orbit coupling is negligible, as sketched in Fig. 1(b). We shall thus now investigate the equilibrium spin properties for the system nanowire+leads. Inspired by the model used in Ref. [26] to analyze transport properties, we shall adopt in Eq. (2) an inhomogeneous Rashba coupling, which takes a finite value in a central region (the nanowire), and vanishing value in the external regions (the leads). However, instead of the abrupt piecewise constant profile used in Ref. [26], here we take into account a smooth crossover between the leads and the nanowire. Explicitly, we shall adopt

$$\alpha(x) = \frac{\alpha_0}{2} \left[\text{Erf} \left(\frac{x + L_w/2}{\sqrt{2}\lambda} \right) + \text{Erf} \left(\frac{L_w/2 - x}{\sqrt{2}\lambda} \right) \right], \quad (63)$$

where α_0 denotes the value of the Rashba coupling in the “bulk” of the nanowire, L_w the nanowire length and λ the crossover lengthscale. The magnetic field is assumed to be uniform over the whole system (nanowire + leads), for which we can adopt periodic boundary conditions over a total length L of the system nanowire+leads, without loss of generality.

A crucial difference with respect to the homogeneous case analyzed in Sec. III is that the inhomogeneous profile (63) makes the Hamiltonian (2) not commute with p_x . Nevertheless, the states $\Psi_{k\uparrow,\downarrow}(x) = e^{ikx} \chi_{\uparrow,\downarrow}$, obtained by the product of plane waves and the eigenvectors $\chi_{\uparrow} = (1, 0)^T$ and $\chi_{\downarrow} = (0, 1)^T$ of the Rashba spin direction σ_z , form a complete set for the Hilbert space. Exploiting Eq. (18), the Hamiltonian (1) in such basis reads

$$\hat{H} = \sum_{k_1, k_2} \hat{C}_{k_1}^\dagger \left((\varepsilon_{k_1}^0 \sigma_0 - \mathbf{h} \cdot \boldsymbol{\sigma}) \delta_{k_1, k_2} - \alpha_{k_1 - k_2} \frac{k_1 + k_2}{2} \sigma_3 \right) \hat{C}_{k_2}, \quad (64)$$

where $\alpha_q = L^{-1} \int \alpha(x) e^{-iqx} dx$ denotes the Fourier component of the inhomogeneous RSOC. The homogeneous case is recovered by $\alpha_{k_1 - k_2} = \alpha \delta_{k_1, k_2}$, while for the profile (63), one has

$$\alpha_q = \frac{2\alpha_0}{qL_w} \sin \left(\frac{qL_w}{2} \right) e^{-(q\lambda)^2/2}. \quad (65)$$

We have thus numerically diagonalized the Hamiltonian matrix Eq. (64), thereby obtaining diagonalizing operators \hat{c}_ξ 's. Then, by expressing the operators (3), (4), (7), (8), (11), and (12) in terms of the \hat{c}_ξ 's, the equilibrium expectation values (15) are evaluated by using $\langle \hat{c}_\xi^\dagger \hat{c}_\xi \rangle_0 = f^\circ(E_\xi)$. Differently from the bulk limit of Sec. III, in this case, the inhomogeneity of the RSOC makes the equilibrium expectation values space-dependent, as we shall discuss here below.

A. Orthogonal spin polarization and spin torque pinned at the interfaces

The results for the spin sector of the nanowire contacted to leads are shown in Figs. 5 and 6, and refer to the cases of a long ($L_w = 2 \mu\text{m}$), and a short ($L_w = 200 \text{ nm}$) nanowire, respectively. The parameters correspond to experimentally

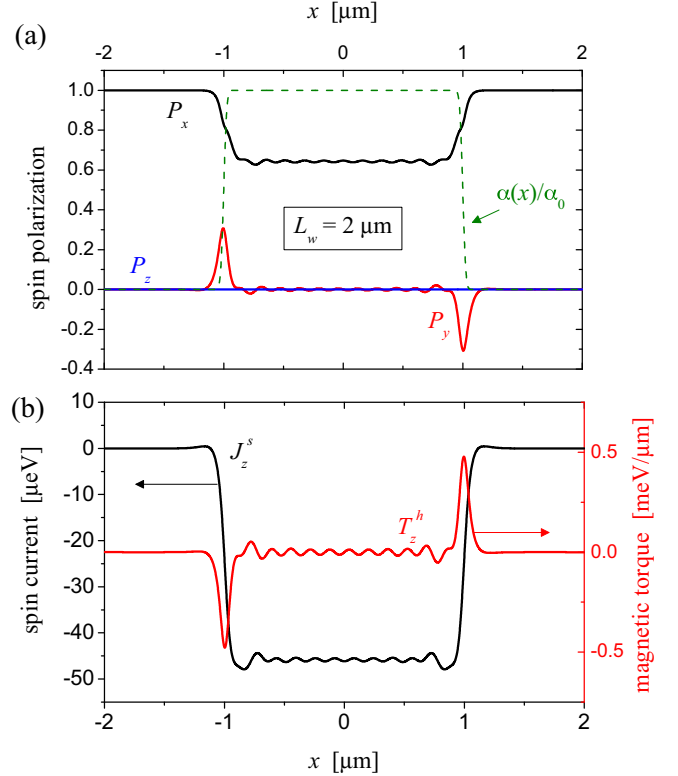

FIG. 5. Equilibrium spin properties of a long nanowire ($L_w = 2 \mu\text{m}$) contacted to leads, with $\Delta_z = 0.4 \text{ meV}$, $\mu = -0.2 \text{ meV}$, at the temperature $T = 50 \text{ mK}$. In the inhomogeneous RSOC profile Eq. (63), the smoothing length is $\lambda = 20 \text{ nm}$, while the value of α_0 corresponds to a Rashba energy $E_{\text{SO}} = 0.3 \text{ meV}$ in the nanowire bulk, through Eq. (44) with an effective mass $m^* = 0.015m_e$. (a) The solid curves describe the space profile of the three components of the spin polarization (17), while the dashed curve depicts the inhomogeneous RSOC profile. At the interfaces with the leads, a spin polarization P_y orthogonal to the substrate plane appears. (b) The solid black curve describes the space profile of the spin current (to be read on the left vertical axis), while the solid red curve describes the spin torque (to be read on the right vertical axis).

realistic values for Rashba nanowires, with a smoothing length $\lambda = 20 \text{ nm}$ of the Rashba profile (63).

Let us focus first on the long nanowire. Figure 5(a) displays the profile of inhomogeneous RSOC (dashed green curve) and the behavior of the three components of the spin polarization \mathbf{P} as a function of the space coordinate x along the nanowire, while Fig. 5(b) shows the spin current J_z^s and the spin torque T_z^h along the Rashba direction z (the other spin current components $J_{x,y}^s$ and the spin-orbit torque \mathbf{T}^{SO} vanish). In the bulk of the nanowire ($|x| < 1 \mu\text{m}$), one observes a weakly oscillatory behavior of the spin polarization component P_x , collinear with the applied magnetic field h_x [black curve of Fig. 5(a)] and of the spin current component J_z^s polarized along the Rashba field direction z [black curve of Fig. 5(b)]. These oscillations, which describe deviations from the bulk values of P_x and J_z^s obtained from the analysis of the infinitely long wire (in Sec. III), are a quantum interference effect due to the finite size of the nanowire, which leads the states of the nanowire bulk to be reflected at the interfaces, for each energy E . The

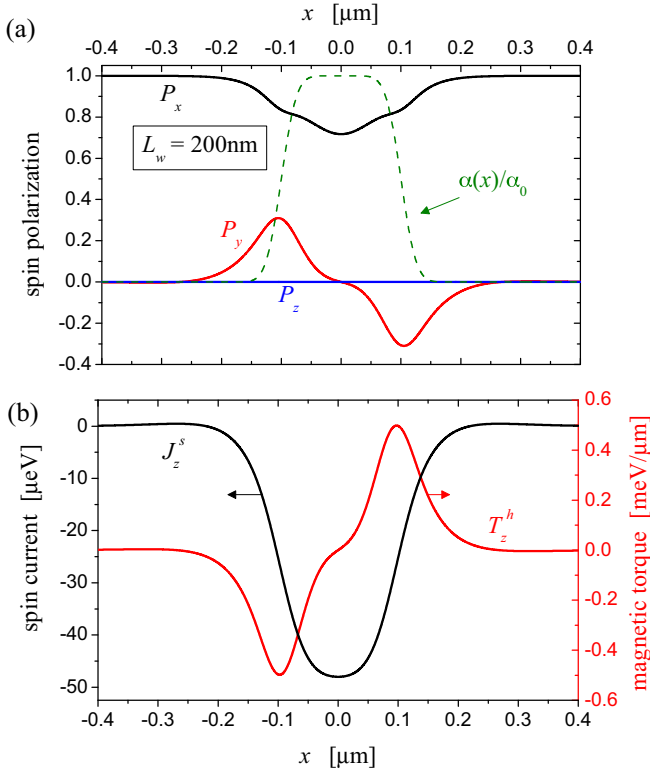

FIG. 6. Equilibrium spin properties of a short nanowire ($L_w = 200$ nm) contacted to leads. All other parameter values and the meaning of the curves are the same as in Fig. 5.

wavelength of these interferences can be estimated as

$$\lambda_{\text{osc}} \simeq \frac{\pi \hbar}{\sqrt{2m^*}} (\mu + 2E_{\text{SO}} + \sqrt{4\mu E_{\text{SO}} + 4E_{\text{SO}}^2 + \Delta_Z^2})^{-1/2} \quad (66)$$

and depends on the Rashba spin-orbit energy, chemical potential and magnetic gap energy. For the specific values of Fig. 5 it takes a value of about 165 nm.

Furthermore, the space dependence of the polarization P_x collinear to the magnetic field [black curve of Fig. 5(a)] displays a crossover from the “nanowire value” (due to the magnetic field but also affected by the Rashba coupling) to a “lead value” (bigger in magnitude and purely due to the magnetic field). Importantly, at the nanowire/lead interfaces, one observes the appearance of a spin polarization P_y orthogonal to both the direction x of the applied magnetic field $\mathbf{h} = (0, 0, h_x)$ and the Rashba direction z . Note that P_y takes opposite signs at the two interfaces, as shown by the red curve of Fig. 5(a). This behavior can be understood as follows. At each energy E , the wave function inside the nanowire is a superposition of states whose spin is lying in the x - z plane, as a result of the combined effect of the magnetic field (pointing along x) and the effective Rashba field (pointing along z). In contrast, in the bulk of the leads, where no RSOC is present, the spin is simply oriented like the magnetic field along x . At the interfaces, the wave-function matching between these two regions can occur only if an orthogonal spin component $\langle S_y \rangle$ arises. This is causes the behavior of the spin polarization P_y in Fig. 5(a).

In turn, precisely because such interface polarization is orthogonal to the magnetic field \mathbf{h} , it generates a spin torque $\mathbf{T}^h = \rho(\mathbf{P} \times \mathbf{h}) = (0, 0, T_z^h)$, as can be straightforwardly deduced from Eqs. (7), (11), and (17). Thus the spin torque component

$$T_z^h = -P_y \rho h_x \quad (67)$$

is also pinned at the interfaces, as shown in the red curve of Fig. 5(b).

At the same time, across the interface we also observe a suppression of the equilibrium spin current J_z^s [black curves of Fig. 5(b)], which eventually vanishes in the bulk of the leads, consistently with the result shown in Sec. III that \mathbf{J}^s vanishes when the RSOC is absent. The space profile of the J_z^s is closely related to the interface spin torque T_z^h , according to the equation

$$\partial_x \mathbf{J}^s = \mathbf{T}^h, \quad (68)$$

showing that any space variation of the spin-current $\mathbf{J}^s = (0, 0, J_z^s)$ is associated with the presence of a spin torque $\mathbf{T}^h = (0, 0, T_z^h)$. This can be seen by taking the expectation values (15) of the equation of motion (10), and by noting that at equilibrium \mathbf{S} is time-independent and $\mathbf{T}^{\text{SO}} = 0$ for symmetry reasons.

For a shorter nanowire, $L_w = 200$ nm, the behavior of these quantities is shown in Fig. 6. Notice that in this case, where the Rashba profile (green dashed curve) is relatively smooth, the length scale (66) of the oscillations becomes comparable with the length L_w of the nanowire, so that P_x and J_z^s [black curves in Figs. 6(a) and 6(b), respectively] do not exhibit the oscillations observable in the long nanowire case of Fig. 5, and the only residual track of the bulk value of P_x and J_z^s is the minimum located at the center of the nanowire. Furthermore, the orthogonal spin polarization component P_y and the spin torque T_z^h [red curves in Figs. 6(a) and 6(b), respectively] exhibit a node in the middle of the nanowire and one sign change across the two interfaces.

B. Equilibrium spin current from spin bound states

The results obtained for the inhomogeneous RSOC also provide an alternative way to interpret the equilibrium spin current of the nanowire from purely a spin polarization argument. To illustrate it, let us focus for simplicity on the helical-like states inside the magnetic gap. In the nanowire, the spin direction is mainly determined by the RSOC and is pointing along z , whereas in the leads it is dictated only by the magnetic field applied along x . Thus, in a scattering formalism picture, an electron with (almost) spin- \uparrow traveling rightwards from the nanowire bulk cannot freely propagate into the right lead, which instead acts as a magnetic “barrier,” backscattering the electron at the interface into a left-moving electron with (almost) spin- \downarrow . The appearance of the interface spin torque T_z^h [red curves of Figs. 5(b) and 6(b)] is the hallmark of such spin-flip process. A similar process occurs at the left interface, where left-moving electrons with (almost) spin- \downarrow are backscattered into right-moving electrons with (almost) spin- \uparrow . Sandwiched between the two magnetic “barriers,” i.e., the leads, the nanowire hosts *spin bound states*, characterized by electrons with opposite spins traveling in opposite directions,

which are converted into each other by the spin torques present at the interfaces. These bound states, sketched in Fig. 1(b), carry the equilibrium spin current inside the wire. Notice that the presence of the magnetic field inside the nanowire is crucial in creating the gap and removing the other pair of counterpropagating states with opposite spin orientations: that would otherwise give rise to a spin torque opposite to the previous one, at each interface, and to another bound state inside the nanowire canceling the above spin current. For energies outside the gap, the reasoning follows the same lines, the bound states being formed out of two inequivalent pairs of states, though.

These spin bound states are reminiscent of the Andreev bound states (ABS) of a superconductor-normal-superconductor hybrid junction, where electrons (holes) are back-reflected as holes (electrons) at each interface, carrying a net charge current. However, differently from charge current, which is conserved across the interface transforming from a ABS current in the normal region into a superfluid current in the superconducting leads, the spin current is not conserved and it vanishes in the leads, where carriers with opposite velocities have the same spin. The spin torques, which have opposite signs at the two interfaces, thus act as a “source” and “sink” of spin current, as described by Eq. (68).

C. Orthogonal spin penetration length inside the leads

Figures 5 and 6 show that the orthogonal spin polarization P_y and the related spin torque T_z^h in Eq. (67) localized at the interface, penetrate inside the leads, even into regions where the RSOC is vanishing. The origin of this effect is the wave-function matching at the nanowire/lead interfaces mentioned in Sec. IV A, which we now want to discuss in more detail from the lead side. There, only the magnetic field component h_x is present, and at each energy E the eigenfunction Ψ of the leads consists of a superposition of waves (propagating or evanescent), whose spinorial parts w are eigenstates $w_{\pm} = (1, \pm 1)^T / \sqrt{2}$ of σ_x , related to the different eigenvalues ± 1 . For each of such eigenstates the expectation value of σ_y is vanishing. However, in order for the wave function in the lead to match the one in the nanowire, whose spin also has a component along z , both eigenstates w_{\pm} must be present in Ψ in the leads. It is their interference term $\langle w_+ \sigma_y w_- \rangle$ that yields a finite expectation value of the orthogonal spin polarization $P_y = \langle \Psi^\dagger \sigma_y \Psi \rangle / \langle \Psi^\dagger \Psi \rangle$ in the leads. This effect is reminiscent of the anomalous expectation value induced by a superconductor into a normal lead, where both particle and hole states must be combined in the latter to match the wave function in the former. For this reason, the penetration of P_y in the leads represents a sort of “spin proximity effect.” There is, however, an important difference. Here, the expectation value of the orthogonal polarization P_y is vanishing in both the nanowire bulk and in the lead bulk. The penetration is thus purely due to the interface, i.e., to the inhomogeneity of the RSOC, and each interface side can be considered as “proximizing” the other.

To determine the penetration length into the leads, let us focus on an interface between a nanowire in the Rashba-dominated regime [see Fig. 2(b)] and a lead. The latter is by definition always in the Zeeman-dominated regime [see

Fig. 2(c)], since $\alpha = 0$. For definiteness, we shall consider here below the case of a short nanowire $L_w = 200$ nm, with spin-orbit energy $E_{SO} = 0.3$ meV in its bulk and a Zeeman gap energy $\Delta_Z = 0.1$ meV. Then, depending on the value of the common equilibrium chemical potential μ , there can be three possible cases, illustrated on the left hand side of Fig. 7.

(a) $E'_{\min} < \mu < -\Delta_Z$. In this case, the chemical potential lies above the band bottom Eq. (48) of the nanowire, but below the band bottom of the lead [see Fig. 7(a)], so that the eigenfunction in the lead at the energy E is a superposition of two evanescent waves $w_+ e^{-q_{E+}x}$ and $w_- e^{-q_{E-}x}$, where $q_{E\pm} = \sqrt{2m^*(-E \mp \Delta_Z)}/\hbar$. The penetration length for P_y , originating from the interference between these two wave components, can be estimated by the minimal values for $q_{E\pm}$, and reads

$$\lambda_{\text{pen}} \simeq \frac{\pi \hbar}{\sqrt{2m^*(-\mu + \Delta_Z)} - \sqrt{2m^*(-\mu - \Delta_Z)}}. \quad (69)$$

For the value $\mu = -0.2$ meV, the estimate of (69) yields $\lambda_{\text{pen}} \sim 680$ nm, and is in agreement with the behavior of P_y shown by the solid red curve of Fig. 7(d). The green dashed curve again describes the inhomogeneous RSOC profile near the interface. Notice that in this regime of chemical potential the electron density ρ decays exponentially into the lead. Because ρ appears in the denominator of the polarization (17), the profile of the spin polarization P_y exhibits an exponential enhancement of its penetration length as compared to the spin density S_y appearing in the numerator. Indeed, S_y decays over a length scale of about 180 nm [61].

(b) $|\mu| < \Delta_Z$. In this case, the chemical potential lies inside the magnetic gap [see Fig. 7(b)], and the lead eigenfunction is a superposition of a propagating wave $w_+ e^{\pm i q_{E\pm} x}$ and an evanescent wave $w_- e^{-q_{E-} x}$. Their interference thus leads to a damped oscillatory behavior for P_y , as can be seen in Fig. 7(e). In this case, the electron density in the lead does not decay, and the penetration depth for both the spin polarization P_y and the spin density S_y is given by

$$\lambda_{\text{pen}} \simeq \frac{\pi \hbar}{\sqrt{2m^*(-\mu + \Delta_Z)}}. \quad (70)$$

For $\mu = 0$, Eq. (70) yields a value of about 500 nm, in agreement with the solid red curve of Fig. 7(e). Notice that, as compared to case (a), the length scale (70) is shorter than the penetration length (69) of the polarization P_y , but longer than the penetration length of S_y in that case [61].

(c) $\mu > \Delta_Z$. In this case, the chemical potential lies above the magnetic gap, so that also in the lead there are only propagating waves $w_+ e^{\pm i q_{E\pm} x}$ and $w_- e^{\pm i k_{E-} x}$. Their interference is thus a long range oscillatory behavior, as described by the solid red curve of Fig. 7(f). Notice that the x axis has been widely extended purposely as compared to Figs. 7(d) and 7(e).

It should be mentioned that the orthogonal spin penetration is of course ultimately cut off by the spin diffusion length in the leads, which depends on the specific material and the spin relaxation rate of the lead [62]. In the low-temperature regime considered here and for narrow leads, the penetration effect may still be observable [63]. We conclude by noticing that, for a nanowire in the Zeeman-dominated regime [see Fig. 2(c)],

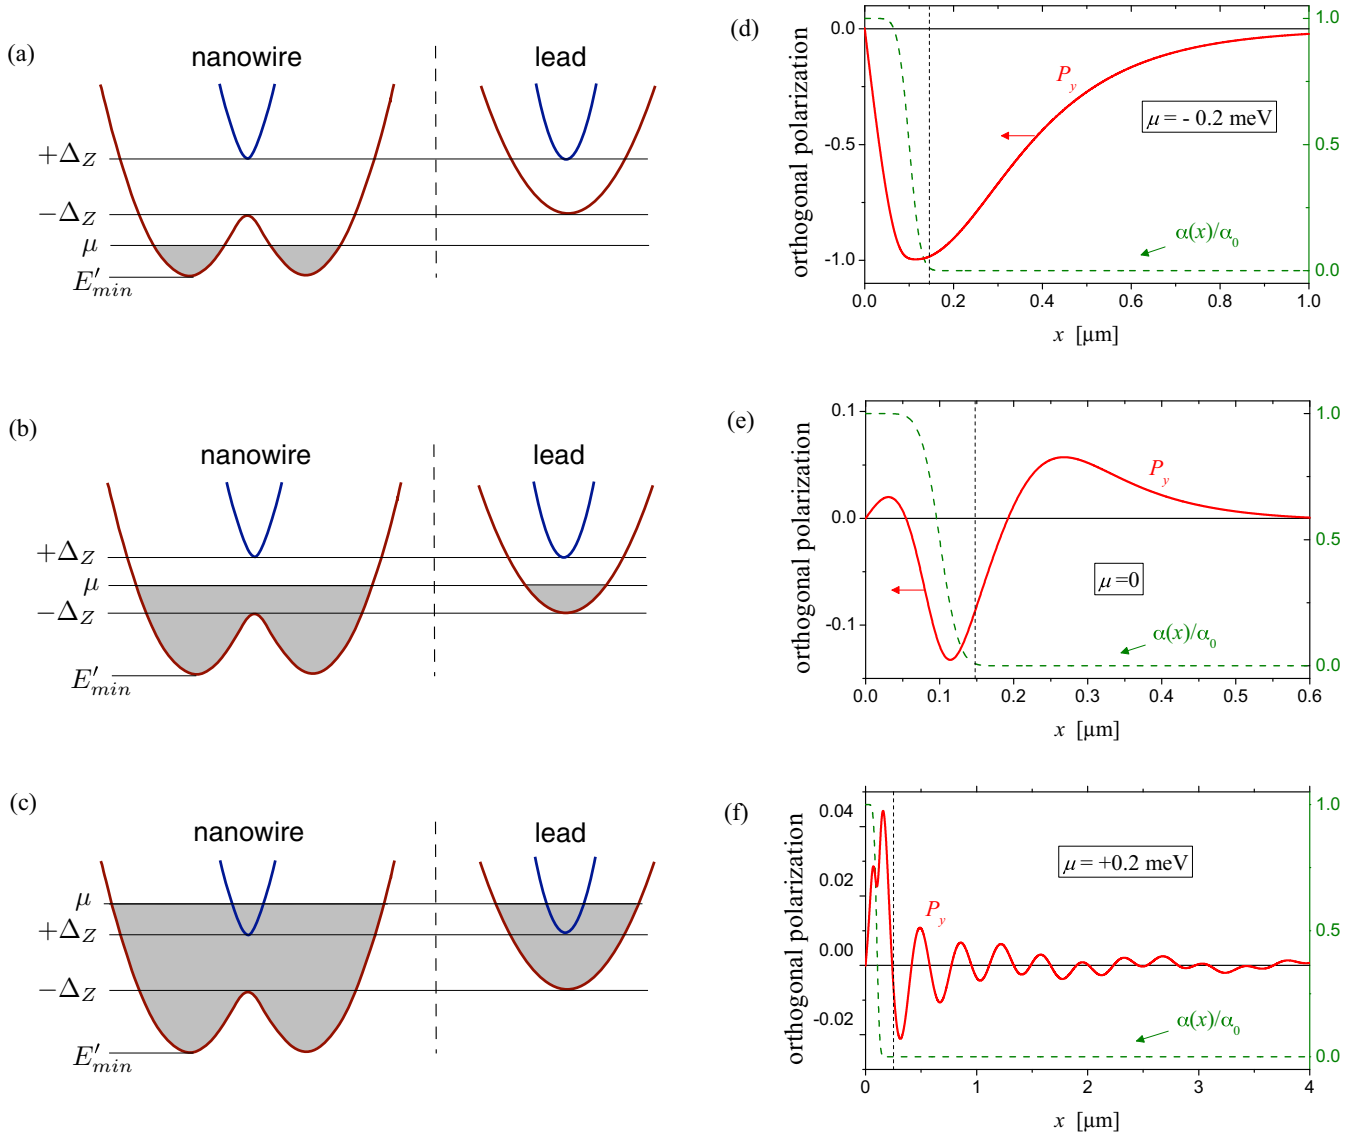

FIG. 7. The penetration of the orthogonal spin polarization P_y into a lead, caused by the inhomogeneous RSOC. (a)–(c) sketch the “band” spectrum of the bulk of the nanowire and the bulk of the lead, describing the three possible cases of the nanowire/lead interface in terms of the common chemical potential μ . Correspondingly, the solid curve in (d)–(f) describe the space profile of P_y , while the dashed curve corresponds to the inhomogeneous Rashba profile (63) describing a short nanowire ($L_w = 200 \text{ nm}$) contacted to leads. The value of the Zeeman gap energy is $\Delta_Z = 0.1 \text{ meV}$, while in the inhomogeneous RSOC profile Eq. (63) the smoothing length is $\lambda = 20 \text{ nm}$, and the value taken for α_0 corresponds to a Rashba energy $E_{SO} = 0.3 \text{ meV}$ in the nanowire bulk.

the nanowire band bottom (49) coincides with the lead band bottom, and only the first two cases (b) and (c) are possible.

V. EFFECTS OF A MAGNETIC FIELD PARALLEL TO THE RASHBA FIELD

So far, we have considered a magnetic field h_x perpendicular to the direction z of the Rashba field. Here we wish to discuss the effects of a magnetic field component h_z parallel to such direction. Again, we first analyze the effects in the bulk, and then consider the whole system nanowire+leads with a finite nanowire length.

A. Effects of h_z in the nanowire bulk

1. Magnetic field parallel to the spin-orbit field

When the magnetic field is applied *only* along the Rashba field direction z ($h_z \neq 0$, $h_x = 0$), the spin quantization axis remains z for all electronic states, similarly to the case of a purely Rashba coupling. In this case, however, the spin- \uparrow and spin- \downarrow bands are further shifted vertically in opposite directions by the parallel Zeeman energy h_z [see dashed curves in Fig. 8(a)]. Since the spectrum is no longer symmetric in k , there is an energy range where only electron states with a spin direction exist, giving rise to a net spin polarization along the

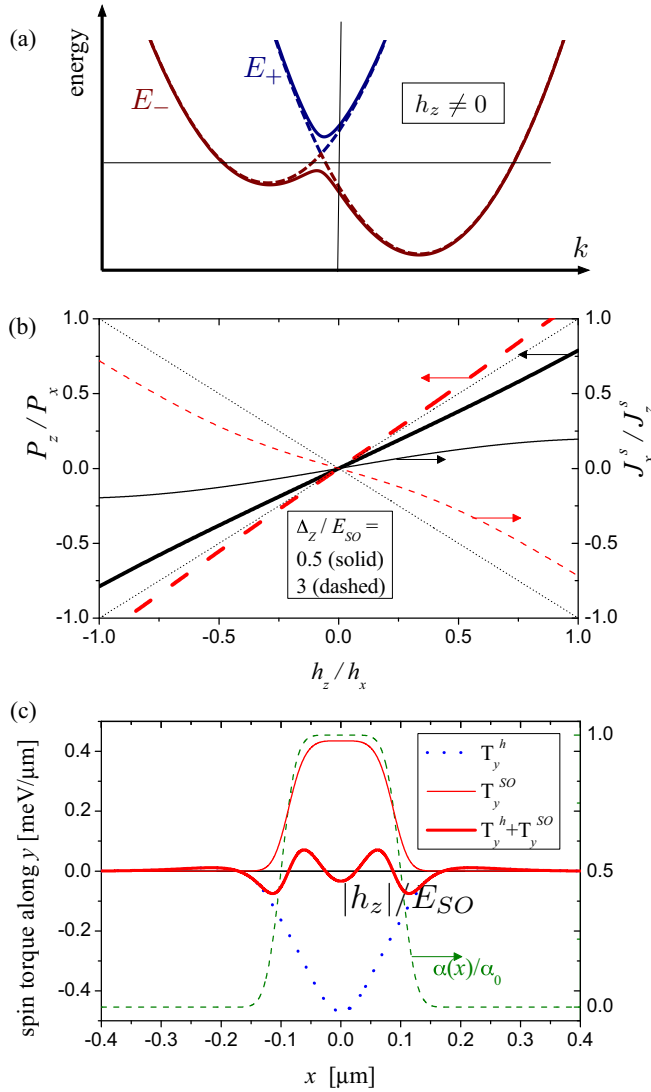

FIG. 8. The effect of an additional field component h_z parallel to the Rashba direction z . (a) The spectrum of the nanowire bulk is no longer symmetric in k (see Fig. 2 for comparison). (b) The thick curves describe the zero-temperature behavior of the bulk ratio P_z/P_x as a function of h_z/h_x , for $\Delta_Z/E_{SO} = 0.5$ (thick black solid) and $\Delta_Z/E_{SO} = 3$ (thick red dashed), and show that the spin polarization \mathbf{P} is not collinear to the magnetic field \mathbf{h} . The reader should refer to the left vertical axis. The thin curves describe the bulk ratio J_z^s/J_x^s as a function of h_z/h_x , for $\Delta_Z/E_{SO} = 0.5$ (thin black solid) and $\Delta_Z/E_{SO} = 3$ (thin red dashed), and show that the polarization of the equilibrium spin current is not perpendicular to the applied magnetic field \mathbf{h} . The reader should refer to the right vertical axis. The thin dotted curves are the separatrices and serve as guides to the eye. (c) The space profile of the orthogonal components T_y^h of the spin torque (dotted curve), T_y^{SO} of the spin-orbit torque (thin solid curve), and $T_y^h + T_y^{SO}$ the total torque (thick solid curve) in the case of a short nanowire $L_w = 200$ nm contacted to leads, with $E_{SO} = 0.3$ meV, $\Delta_Z = 0.4$ meV, $h_z = 0.2$ meV, $\mu = -0.2$ meV, and $T = 50$ mK.

direction z of the magnetic field,

$$\mathbf{P} = (0, 0, P_z) \neq 0, \quad (71)$$

where $P_z = (\rho_\uparrow - \rho_\downarrow)/(\rho_\uparrow + \rho_\downarrow)$ and $\rho_{\uparrow,\downarrow} = (2\pi)^{-1} \int dk f^\circ(E_{\uparrow,\downarrow}(k))$ is the equilibrium spin-resolved particle density. In particular, at zero temperature, one obtains

$$\rho_{\uparrow,\downarrow} = \frac{1}{\pi} \sqrt{\frac{2m^*(\mu + E_{SO} \pm h_z)}{\hbar^2}} \theta(\mu + E_{SO} \pm h_z), \quad (72)$$

where θ is the Heaviside function, implying that $P_z \simeq h_z/(4(\mu + E_{SO}))$ for weak fields $|h_z| \ll \mu + E_{SO}$, while $P_z = \text{sgn}(h_z)$ for large fields $|h_z| \geq \mu + E_{SO}$.

The spin current \mathbf{J}^s instead vanishes. Indeed, despite the presence of a spin polarization, at any energy E , each state with a definite spin orientation and group velocity has a partner state with the same spin orientation and opposite group velocity. In each spin channel $\sigma = \uparrow, \downarrow$ the current J_σ vanishes, and so do the equilibrium charge current and spin current, as a straightforward evaluation of Eqs. (33) and (35) shows. Furthermore, substituting $\sin \theta_k = 0$ and $h_x = 0$ into Eqs. (40) and (37), the torques are also vanishing, and one has

$$\mathbf{J}^s = \mathbf{T}^h = \mathbf{T}^{SO} = 0. \quad (73)$$

As a consequence, a magnetic field h_z parallel to the Rashba spin-orbit direction cannot give rise, alone, to any equilibrium spin current or torques.

2. Magnetic field with components parallel and perpendicular to the spin-orbit field

When the field component h_z parallel to the Rashba direction is *added* to a component h_x perpendicular to the Rashba spin-orbit field, the spectrum depicted by the dashed curves of Fig. 8(a) modifies into the one described by the solid curves, where the asymmetry in k appears as the essential difference from Fig. 2(b). As compared to the case of purely perpendicular field h_x discussed in Sec. IIIB, the additional component h_z has mainly three effects on the spin sector.

The first one is quite expected, and is the appearance of an additional spin polarization component along z ,

$$\mathbf{P} = (P_x, 0, P_z) \quad (74)$$

with P_z being obtained from Eqs. (17), (32), and (3). Notably, because of the interplay between h_z and the RSOC, the spin polarization \mathbf{P} is *not collinear* to the magnetic field \mathbf{h} , as can be seen by the two thick curves in Fig. 8(b), which describe the behavior of $P_z/P_x = S_z/S_x$ as a function of the ratio h_z/h_x (the thin dotted separatrix lines are meant as guides to the eye). Explicitly, the thick black solid curve refers to $\Delta_Z/E_{SO} = 0.5$, while the thick red dashed curve to $\Delta_Z/E_{SO} = 3$. The reader should refer to the left vertical axis.

Secondly, h_z thereby modifies the polarization of the equilibrium spin current \mathbf{J}^s , since a component J_x^s polarized along the nanowire axis adds up to the component J_z^s along the Rashba field caused by h_x ,

$$\mathbf{J}^s = (J_x^s, 0, J_z^s). \quad (75)$$

In particular, when $h_z \neq 0$, the bulk polarization of \mathbf{J}^s is no longer perpendicular to the applied magnetic field \mathbf{h} , as shown by the thin curves in Fig. 8(b) that display the ratio J_z^s/J_x^s as a function of h_z/h_x . The thin black solid curve refers to $\Delta_Z/E_{SO} = 0.5$, while the thin red dashed curve to

$\Delta_Z/E_{SO} = 3$. The reader should refer to the right vertical axis, with the thin dotted lines indicating the separatrix lines.

The third effect caused by the component h_z is the emergence of torques also in the bulk of the nanowire. Indeed, since \mathbf{S} is not collinear to the magnetic field \mathbf{h} , the spin torque \mathbf{T}^h is no longer vanishing [see Eq. (11)], and exhibits a component T_y^h perpendicular to the substrate plane, where \mathbf{S} and \mathbf{h} lie. Then, a spin-orbit torque $\mathbf{T}^{SO} = (0, T_y^{SO}, 0)$ must cancel such contribution, as dictated by Eq. (42), i.e.,

$$(0, T_y^h, 0) = \mathbf{T}^h = -\mathbf{T}^{SO} \neq 0. \quad (76)$$

This is thus qualitatively different from the case (54) of a field along the nanowire axis.

B. Effects of h_z in the nanowire contacted to leads

By adopting again the inhomogeneous RSOC profile (63), one can analyze the effects of h_z for a nanowire contacted to the leads. In this case the effects of the finite length L_w are particularly visible for a short nanowire, $L_w = 200$ nm, as shown by Fig. 8(c), which shows the space profile of the torque y component, orthogonal to substrate plane. Explicitly, the dotted curve describes the behavior of the spin torque T_y^h , the thin solid curve the spin-orbit torque T_y^{SO} , while the thick solid curve the total torque $T_y^h + T_y^{SO}$. As one can see, T_y^h and T_y^{SO} take relatively large values with opposite sign near the middle of the nanowire. However, differently from an infinitely long nanowire (homogeneous RSOC) where their contributions perfectly cancel [see Eq. (76)], a finite total torque appears because of the finite length of the nanowire.

VI. CONCLUSIONS

In conclusion, in this paper we have analyzed a Rashba nanowire contacted to leads by using an inhomogeneous RSOC (see Fig. 1), and we have determined the equilibrium properties of the spin sector (spin density and polarization, spin current and torques) when a uniform magnetic field is applied to the nanowire. Differently from a 2DEG with RSOC, in a nanowire the mere presence of a RSOC yields a trivial behavior of the spin sector, with all spin quantities vanishing [see Eq. (45)]. In contrast, here we have found that the interplay between the inhomogeneous RSOC and a uniformly applied magnetic field leads to interesting effects already at equilibrium.

Focussing first on the bulk of the nanowire we have shown that, when the magnetic field is applied along the nanowire axis, i.e., perpendicularly to the Rashba field direction, a spin current polarised along the Rashba field direction flows even at equilibrium. Differently from the equilibrium spin current found in nanorings with magnetic field texture [56,57], this is a bulk effect that does not disappear in the limit of infinitely long wire. It exists only if *both* RSOC and magnetic field are present, since under these conditions a nontrivial quantum correlation between the velocity direction and the spin orientation appears, so that in the system ground state electrons with opposite spin counter-propagate. Remarkably, the analogy between the nanowire states inside the magnetic gap and the helical states of a QSH system, which is useful to intuitively understand why such states give rise to an equilibrium spin current [see Fig. 2(b)], is not sufficient to explain the actual behavior of

the equilibrium spin current (see Fig. 3), which persists far beyond the Rashba-dominated regime where such analogy holds. Indeed we have shown that also the states outside the magnetic gap provide an unexpectedly significant contribution to the equilibrium spin current, due to the lack of factorization between velocity and spin [see Eq. (59)] that characterize the Rashba nanowire eigenstates under a magnetic field. Such equilibrium spin current is tunable by both the applied magnetic field (see Fig. 3) and the chemical potential (see Fig. 4).

Then, considering the whole system nanowire+lead with the inhomogeneous RSOC profile, we find that inside the nanowire the equilibrium spin current exhibits weak oscillations around the finite bulk value, characterized by a wavelength (66), while \mathbf{J}^s dies out in the bulk of the leads, where RSOC eventually vanishes. Interesting effects emerge at the nanowire/lead interfaces, namely the appearance of a spin polarization component P_y orthogonal to both the magnetic field and the RSOC field, and a localized spin torque T_z^h related to it (see Fig. 5 for a long nanowire and Fig. 6 for a short nanowire). These interface spin torques act as sources and sinks of the spin current, which is carried in the nanowire by spin bound states sketched in Fig. 1(b), while the leads play the role of magnetic barriers. The inhomogeneity of the RSOC thus leads to effectively spin-active interfaces, even under a uniform magnetic field and in the absence of magnetic material. The appearance of this orthogonal spin polarization at the nanowire edges also impacts in the interpretation of results concerning proximized nanowires where Majorana fermions should be observable, as we shall discuss below. Notably, the orthogonal spin polarization and the spin torque partially penetrate into the leads for a length scale λ_{pen} that depends on the three possible configurations of chemical potential (see Fig. 7).

Finally, we have analyzed the effect of a magnetic field not collinear with the nanowire axis. A magnetic field h_z directed along the Rashba field leads to essentially trivial results, as the only nonvanishing quantity is a spin polarization component P_z [see Eq. (73)]. However, when h_z is added to a component h_x , different effects emerge in the nanowire bulk: the spin polarization \mathbf{P} becomes not collinear with the magnetic field, the polarization of the equilibrium spin current \mathbf{J}^s is no longer orthogonal to the magnetic field [see Fig. 8(b)], and both a spin torque and a spin-orbit torque appear. While the contributions of the two torques perfectly cancel for a homogeneous infinitely long nanowire, for a realistic nanowire with finite length a residual of torque survives [see Fig. 8(c)].

A. Experimental realizations

The setup of Fig. 1 is currently realized with, e.g., InSb nanowires or InAs nanowires, and realistic values for the involved parameters have been used here for the plots. In the case of InSb, for instance, the effective mass and the g factor are $m^* \simeq 0.015m_e$ and $g \simeq 50$, respectively, while the value of the RSOC depends on the specific implementation and experimental conditions and can be widely tunable, e.g., $\alpha \sim (0.03-1)$ eV Å [8,12,15,64,65]. In the case of InAs nanowires, $m^* \simeq 0.022m_e$, $g \simeq 20$ and $\alpha \sim (0.05-0.3)$ eV Å [7,14,66,67]. The spin-orbit energy E_{SO} resulting from these values [see Eq. (44)] and used in the plots is some fractions of

meV. We have taken similar values for the Zeeman gap energy Δ_Z , which corresponds to a magnetic field of some hundreds of millitesla, while the temperature of 50 mK is taken from recent low temperature experiments [12,14].

As far as the measurements of the predicted spin polarization is concerned, spatially resolved detection of spin orientation with nanometer scale resolution can be performed with various methods such as magnetic resonance force microscopy [68,69], spin-polarized scanning electron microscopy [70,71], by exploiting quantum dots as probes [72,73], or also electrically by potentiometric measurements using ferromagnetic detector contacts [74,75].

Concerning spin currents, they are customarily measured by exploiting the Kerr effect [76,77], the inverse spin Hall effect [78], or the charge imbalance voltage appearing on the normal lead [79]. Also, pure spin current can be indirectly revealed via or by optical detection exploiting a polarized light beam [80]. However, for the detection of spin current at equilibrium, these methods are not straightforwardly applicable, and various alternative principles have been proposed. Equilibrium spin current can for instance be detected by measuring the thereby generated spin torque [81]. Another proposal is based on detection of the mechanical deformations that the equilibrium spin current induces onto the substrate underneath the Rashba spin-orbit material: a mechanical cantilever magnetometer with an integrated 2D electron system can be used to this purpose [35]. Other works suggested that an equilibrium spin current can be measured through the electric field it produces, similarly to the case of a charge current that generates a magnetic field [37,82]. These methods can in principle apply to the nanowire as well. In particular, as emphasized in Sec. IV B, the spin torque generated at the interfaces [see Figs. 5(b) and 6(b)] is precisely the hallmark of the equilibrium spin current present in the nanowire bulk. It is thus plausible that the predicted spin properties are at experimental reach.

B. Future developments

We conclude by outlining some possible future developments of the present work. We first notice that, although we have focused here on an inhomogeneous RSOC profile that vanishes in the leads, it is straightforward to generalize our results to more complex hybrid structures, such as interfaces between regions where RSOC takes different signs, which may possibly be obtained by coupling the nanowire with different finger gates.

Secondly, the present analysis of the equilibrium properties represents the first necessary step for any out of equilibrium analysis, such as the effects of a time-dependent RSOC induced by ac voltages applied to the gates. In particular, in order to correctly determine the impact of the external drive on the spin current, the equilibrium contribution found here must be subtracted, for otherwise one could mistakenly interpret a nonvanishing spin current as entirely due to the out of equilibrium conditions [31]. In particular, the value of the equilibrium spin current also identifies the limit of sensitivity for the out of equilibrium spin current contribution.

Finally, a promising future development of this work would be the inclusion of superconducting (SC) leads. For a nanowire with homogeneous RSOC, it is well known that, in

appropriate parameter ranges, the interplay between an *s*-wave superconducting coupling and RSOC leads the proximized nanowire to effectively behave as a *p*-wave topological superconductor, hosting Majorana fermions at the boundaries with normal regions. In this respect, there are two aspects that we would like to comment about. The first one is related to the spin polarization. For a proximized nanowire with homogeneous RSOC, the behavior of spin polarization has been shown to provide useful insights about the topological transition, and it has been recently suggested that the spin polarization of Majorana fermions could be exploited to distinguish them from ordinary fermion states of the nanowire [54,83–85]. Let us compare this case to the spin polarization shown in Fig. 5(a) that we find for a normal nanowire without proximity effect and with inhomogeneous RSOC. In both cases, a spin polarization orthogonal to the nanowire axis arises at the ends of the nanowire, where it takes opposite values. However, while in the former case the spin polarization is an effect of the topological phase, in the latter case, the nanowire is purely due to inhomogeneity of the RSOC. Such comparison shows that a caution should thus be taken in interpreting experimental analysis of orthogonal spin polarization at the boundaries as a signature of Majorana fermions. The second aspect that we would like to point out is the interplay between the inhomogeneous RSOC and the superconducting coupling. Although so far most works have focused on the effect of inhomogeneities of either the scalar potential or the superconducting parameter [86–92], we expect that inhomogeneities of the RSOC can impact as well, in a twofold way. In the first instance, the very presence of a superconducting film deposited on top of a nanowire portion can produce a structural inversion asymmetry, altering locally the magnitude of the RSOC. Such inhomogeneity can thus affect the stability of the topological phase, as the topological gap crucially depends on the value of α in the proximized nanowire portion [60]. Furthermore, when the RSOC profile changes sign, either because of the very presence of the SC film or because of locally applied finger gate voltages, fermionic localized states form at the sign change region. It has been recently shown [30] that, under suitable conditions, these states have zero energy and can lead to an hybridization of the otherwise spatially separated Majorana fermions. This effect would split the Majorana off from zero energy and disguise, or even jeopardize, their observability. For these reasons, a detailed investigation of a proximized nanowire with inhomogeneous RSOC seems a promising research topic. Work is in progress along these lines.

ACKNOWLEDGMENTS

Fruitful and inspiring discussions with Ch. Fleckenstein, C. Gorini, B. Trauzettel, and N. Traverso are greatly acknowledged.

APPENDIX: SPIN EQUATION OF MOTION AND TORQUES

Here we provide the proof of the spin equation of motion (10). From the Heisenberg equation for the electron field spinor

$$\partial_t \hat{\Psi} = \frac{1}{i\hbar} \left[-\frac{\hbar^2}{2m^*} \partial_x^2 \hat{\Psi} - \frac{\sigma_z}{2\hbar} \{ \alpha(x), \hat{p}_x \} \hat{\Psi} - \mathbf{h} \cdot \boldsymbol{\sigma} \hat{\Psi} \right] \quad (\text{A1})$$

and the one for its adjoint $\hat{\Psi}^\dagger$, the evolution of the spin density is given by

$$\begin{aligned} \partial_t \hat{\mathbf{S}} = & \frac{\hbar}{2} \left[-\frac{i\hbar}{2m^*} (\partial_x^2 \hat{\Psi}^\dagger \boldsymbol{\sigma} \hat{\Psi} - \hat{\Psi}^\dagger \boldsymbol{\sigma} \partial_x^2 \hat{\Psi}) \right. \\ & + \frac{i}{2\hbar^2} \hat{\Psi}^\dagger \boldsymbol{\sigma} \sigma_z \{\alpha(x), \hat{p}_x\} \hat{\Psi} \\ & + \frac{i}{2\hbar^2} \{\alpha(x), \hat{p}_x\} \hat{\Psi}^\dagger \sigma_z \boldsymbol{\sigma} \hat{\Psi} \\ & \left. + \frac{i}{\hbar} \hat{\Psi}^\dagger [\boldsymbol{\sigma}, \mathbf{h} \cdot \boldsymbol{\sigma}] \hat{\Psi} \right]. \end{aligned} \quad (\text{A2})$$

Rewriting $\boldsymbol{\sigma} \sigma_z = (\{\boldsymbol{\sigma}, \sigma_z\} + [\boldsymbol{\sigma}, \sigma_z])/2$ and $\sigma_z \boldsymbol{\sigma} = (\{\boldsymbol{\sigma}, \sigma_z\} - [\boldsymbol{\sigma}, \sigma_z])/2$, one obtains

$$\begin{aligned} \partial_t \hat{\mathbf{S}} = & \frac{\hbar}{2} \left[\frac{i\hbar}{2m^*} \partial_x (\hat{\Psi}^\dagger \boldsymbol{\sigma} \partial_x \hat{\Psi} - \partial_x \hat{\Psi}^\dagger \boldsymbol{\sigma} \hat{\Psi}) \right. \\ & + \frac{i}{2\hbar^2} \hat{\Psi}^\dagger \frac{\{\boldsymbol{\sigma}, \sigma_z\}}{2} \{\alpha(x), \hat{p}_x\} \hat{\Psi} + \text{H.c.} \\ & + \frac{i}{2\hbar^2} \hat{\Psi}^\dagger \frac{[\boldsymbol{\sigma}, \sigma_z]}{2} \{\alpha(x), \hat{p}_x\} \hat{\Psi} + \text{H.c.} \\ & \left. + \frac{i}{\hbar} \hat{\Psi}^\dagger [\boldsymbol{\sigma}, \mathbf{h} \cdot \boldsymbol{\sigma}] \hat{\Psi} \right]. \end{aligned} \quad (\text{A3})$$

A straightforward calculation leads to show that the second line in Eq. (A3) can be rewritten as

$$\begin{aligned} & \frac{i}{2\hbar^2} \hat{\Psi}^\dagger \frac{\{\boldsymbol{\sigma}, \sigma_z\}}{2} \{\alpha(x), \hat{p}_x\} \hat{\Psi} + \text{H.c.} \\ & = \partial_x \left(\frac{\alpha(x)}{\hbar} \hat{\Psi}^\dagger \frac{\{\boldsymbol{\sigma}, \sigma_z\}}{2} \hat{\Psi} \right), \end{aligned} \quad (\text{A4})$$

while the third line in (A3) can be rewritten as

$$\begin{aligned} & \frac{i}{2\hbar^2} \hat{\Psi}^\dagger \frac{[\boldsymbol{\sigma}, \sigma_z]}{2} \{\alpha(x), \hat{p}_x\} \hat{\Psi} + \text{H.c.} \\ & = \frac{\alpha(x)}{2\hbar} (\hat{\Psi}^\dagger [\boldsymbol{\sigma}, \sigma_z] \partial_x \hat{\Psi} - \partial_x \hat{\Psi}^\dagger [\boldsymbol{\sigma}, \sigma_z] \hat{\Psi}) \\ & = \frac{i}{\hbar} \hat{\Psi}^\dagger \frac{[\boldsymbol{\sigma}, \boldsymbol{\sigma} \cdot \mathbf{h}^{\text{SO}}]}{2} \hat{\Psi} + \text{H.c.}, \end{aligned} \quad (\text{A5})$$

where we have used the definition (14) of the Rashba field operator. Inserting Eqs. (A4) and (A5) into Eq. (A3), exploiting the properties of Pauli matrices $[\boldsymbol{\sigma}, \mathbf{a} \cdot \boldsymbol{\sigma}] = -2i \boldsymbol{\sigma} \times \mathbf{a}$, and recalling the definitions of spin current density (8), spin torque (11), and spin-orbit torque (12), one obtains Eq. (10).
