Abstract

Vertical Slot Fishways (VSF) are the most efficient and least selective typology of technical fish passage, due to their ability to remain effective even when significant upstream and/or downstream water level fluctuations occur. Fishway construction costs can be reduced by increasing its bed slope, but this affects the flow field inside the pools, with higher head drops between the basins, as well as turbulence levels and flow velocities, which may affect fish passage. In light of this, a vertical slot fishway (VSF) was investigated by 3D numerical simulations to identify the possible effects of the bed slope (using values from 1.67% to 10%) on the flow field, and subsequent implications for fish passage. A particular focus was devoted to cyprinid species, but results can be extended to other species of similar swimming abilities and therefore, be applicable to multispecies rivers. Flow velocity and turbulence values like turbulent kinetic energy and Reynolds stresses were analyzed from a fish passage perspective in relation to threshold values derived from previous studies. Pool areas where turbulence values are compatible with fish ability and behavior were quantified. Maps of the location of fish friendly zones in the VSF pools were

16 produced and can constitute a reference for practical applications in fishway de-
17 sign. The flow field generated with bed slopes lower than 6.67% is more compatible
18 with fish swimming capabilities, since it exhibits a predominantly 2D behavior and
19 more suitable hydraulic conditions whereas, at higher slopes, turbulence levels in the
20 pools increase.

Keywords: bed slope, ecohydraulics, fish passage, fishway, vertical slot fishway

1. Introduction

21 The interruption of longitudinal connectivity of a natural river by anthropogenic
22 obstructions is perceived as one of the main causes in the decline of freshwater ichthy-
23 ofauna (Calles and Greenberg, 2009). With the aim of restoring to an acceptable
24 level the longitudinal connectivity of a river, the construction of fishways represents
25 the best practice where obstacle removal is not feasible.

26 The flow field and turbulence level in a fishway affect the capability of fish to
27 successfully migrate through it (Silva et al., 2011 and 2015). Shear stresses and hy-
28 drodynamic resistance generated by flowing water and turbulence on fish body make
29 migration an energetically demanding process. Therefore, the design of a fishway
30 has to take into account the biological characteristics of the migrating fish, i.e their
31 swimming capability, size and fish reaction to external stimuli like turbulence, flow
32 acceleration and velocity (Clay, 1995; Rodriguez et al., 2006; Katopodis and Gervais,
33 2016; Katopodis and Williams, 2012; DWA, 2014). In Clay (1995), Katopodis and
34 Gervais (2016), Katopodis and Williams (2012), Plaut (2012), Puertas et al. (2012),
35 Silva et al. (2011 and 2015), Tuhtan et al. (2018), Tritico and Cotel (2010), Quar-
36 anta et al. (2017) the interaction between fish and flow field in fish passes has been
37 investigated and discussed.

38 Pool-and-weir fishways are the most common type of technical fish passage device

Effects of bed slope on the flow field of vertical slot fishways

(Hatrý et al., 2016; Santos et al., 2016), consisting of a channel with a sloping bed divided into a series of pools by cross-walls at regular intervals. The most efficient and least selective typology of pool-and-weir fish passage is the Vertical slot fishway -VSF-, consisting of a sloping rectangular channel divided into a number of pools by vertical baffles. Water flows through the vertical slot between the baffles, from one pool to the downstream one. Vertical slot fishways have the advantage of allowing fish to move from one pool to the next without having to jump, being able to swim at any desired depth (Cordoba et al., 2018). Under uniform flow conditions, the water level difference Δh between two adjacent pools depends on the slope of the fishway i and on the length L of the pool, i.e. $\Delta h = iL$. VSFs remain effective even when upstream and/or downstream water level fluctuations occur (Katopodis, 1992). VSFs are recommended especially in rivers where several fish species with different swimming capabilities are present (FAO, 2002; Stuart and Berghuis, 2002; DWA, 2014).

The most seminal work on VSF design was presented in Rajaratnam et al. (1992), where eighteen different designs of VSF were physically tested. Among the investigated designs, Design 1 -D1- is the most common and represents the standard reference typically used in real applications. The geometry of D1 suggested in Rajaratnam et al. (1992) has a slot orientation $\alpha = 45^\circ$ (i.e. the angle between the width of the slot and the longitudinal direction). Taking the slot width b_0 as reference, suggested pool dimensions are $L = 10b_0$ and $B = 8b_0$, where L is the length and B is the width of the pool (Fig.1).

In addition to b_0 , B and L , another important parameter in the design of a VSF is the bed slope i . The higher the slope, the lower the costs, since fewer pools are required for a certain head difference. However, for higher bed slopes, the turbulence and flow velocities can increase to levels that impair fish passage

efficiency. Furthermore, the topology of the flow field is affected by the slope: bed slope values higher than 10% are commonly considered not fish friendly (Chorda et al., 2010). The bed slope and the pool length determine the head drop Δh between adjacent pools, which is a reference parameter for fishway design, being related to the maximum flow velocity through the slots. Different Δh values are recommended for different biocoenotic regions along the river, according to the swimming capabilities of the target species (DWA, 2014).

1.1. Range of VSF bed slopes for practical applications

In general, to ensure good ecological efficiency, the bed slope should guarantee a 2D flow pattern, because high vertical velocity components are likely to disturb fish performance (Wang et al., 2010). If a jet impacts the side-wall of a pool (that generally happens at slopes higher than 10% when the standard dimensions are used, (Rajaratnam et al., (1992)) a swirl is created with a horizontal axis that generates high-velocity vertical components. The formation of recirculation zones, that are too large and that drive the jet in the direction of the baffle, has to be avoided (Wang et al., 2010). Hence 5% slope is considered appropriate for multispecies rivers to limit species selectivity and to ensure a predominant 2D flow field (Marriner et al., 2016; Quaranta et al., 2017), while 10% is a value used to limit fishway construction costs, especially when passage of larger Salmonids or other species of similar swimming ability and behaviour, is expected.

However, there is no clear ecological assessment of VSF for different slopes in the literature. The general question is whether a given bed slope configuration can determine hydrodynamic conditions affecting fish pass efficiency. Field experiments on the ecological efficiency of VSF found in the literature (Laine et al., 1998; Romao et al., 2017; Thiem et al., 2013; Stuart and Cooper, 1999; Duarte et al., 2012; Silva et

al., 2015) show that for bed slopes lower than 5%, fish passage efficiency is generally higher than 30% and in certain cases higher than 60% (Stuart and Cooper, 1999; Duarte et al., 2012; Thiem et al., 2013; Silva et al., 2015), while it falls below 30% at higher slopes (Laine et al., 1998; Quaresma et al., 2017; Romao et al., 2017; Romao et al., 2018). Based on experiments in non uniform flow conditions, fish were found making broader use of the fishway pool in scenarios with lower water drops, which are highly correlated with regions of overall lower turbulence and velocity magnitude (Fuentez-Perez et al., 2018). However, geometric and hydraulic configurations of these field experiments significantly differ from each other, not allowing a clear assessment of fish behavior in relation to bed slope. Furthermore, each study tested only one bed slope configuration, making it difficult to generalize results.

On the other hand, experimental and numerical studies on the hydraulic of VSFs at different slopes generally involved only a few slopes, typically 5%, 10% and 15%, with no results for intermediate slopes. In addition, areas compatible with fish rest, based on threshold values available in the literature, were not highlighted (Liu et al., 2006; Tarrade et al., 2008; Chorda et al., 2010; Wang et al., 2010).

In Chorda et al. (2010), Tarrade et al. (2008) and Wang et al. (2010), bed slopes of 5%, 10% and 15% were investigated. At 5% slope, a smaller downwelling jet and a longer jet core occurred, while the turbulence in the lower part of the pool and in the main recirculation zone was less pronounced. Furthermore, at 15% slope, low velocity areas were substantially limited, thus excluding this steep setup for practical applications. Threshold values distribution inside the pool was not discussed, and 3D turbulence effects were not considered. Considering the optimal pool dimensions ($L = 10b_0$ and $B = 8b_0$ according to Rajaratnam et al., 1992), at 5% slope the flow field comprised of a well identified jet and two large recirculating areas on its sides, while at 10% slope the left eddy split into two smaller ones, as also found in Quaranta

Effects of bed slope on the flow field of vertical slot fishways

et al. (2018), and at 15% slope the jet impacted on the left wall, completely changing the flow field by making it more complex. Liu et al. (2006) confirmed such result on design 18 -D18- presented in Rajaratnam et al. (1992), showing that at 10% slope the flow field substantially changed, and the water jet impacted against the wall creating conditions not suitable for fish.

Bed slopes lower than 5%, have been investigated by Li et al. (2017), who focused on water depths and 1D water profiles, instead of the flow field which may be more important for fish. Furthermore, the benefit gained at slopes below 5% might not justify the increase in construction costs.

Therefore, with limited hydraulic results from the literature, along with fish tests on only a few slopes and geometric configurations, it is difficult to provide a clear assessment of hydrodynamic variations in relation to the bed slope. In order to improve the knowledge on the effect of bed slope on the flow field and on its potential implications on fish passage efficiency, the present study will investigate the flow field of the standard VSF design D1 (according to Rajaratnam et al. 1992) at different bed slopes, testing six bed slopes between 1.67% and 10%. Higher slopes will not be considered due to their limited passage efficiency, as highlighted in all literature results. The distribution of turbulence parameters inside the pool will be analyzed, in order to determine the pool zones considered suitable for fish passage or rest, according to threshold values derived by previous laboratory experiments (described in section 2.1). In order to provide results directly applicable to VSFs design, the pool dimensions and the tested slopes correspond to head drop values between adjacent pools ranging from 5 to 30 cm, covering the typical range of Δh used in practical applications (e.g. DWA, 2014, Larinier, 2002).

140 **2. Materials and Methods**

141 Although turbulence can be numerically resolved in its different scales using di-
142 rect numerical simulations (DNS), this approach is computationally too demanding.
143 Therefore, RANS and LES methods are the most reasonable alternatives. The ma-
144 jority of studies have implemented RANS methods as a numerical technique for the
145 3D modeling of VSF, since these have shown to be capable of providing a compromise
146 between accuracy and computational cost (Fuentes-Perez et al., 2018). Therefore,
147 in this study a Computational Fluid Dynamic (CFD) RANS model was used. The
148 CFD model was based on the commercial software Ansys Fluent, and it has been
149 validated against experimental data (head-discharge and flow field) in Quaranta et
150 al. (2017). Three momentum equations (one equation for each cartesian coordinate)
151 and the continuity equation were solved.

152 The VOF (Volume of Fluid) method was used to determine the free surface
153 position (Quaranta et al., 2017). The Reynolds shear stresses (RS) in the momentum
154 equations $\tau_{i,j}$ were modeled by means of the turbulent dynamic viscosity μ_t :

$$\tau_{i,j} = -\rho \overline{v'_i v'_j} = \mu_t \left(\frac{\partial V_i}{\partial x_j} + \frac{\partial V_j}{\partial x_i} \right) - \frac{2}{3} \rho k \delta_{ij} \quad (1)$$

155 where μ_t is the turbulent dynamic viscosity, ρ is water density, k is the turbulent
156 kinetic energy and δ_{ij} is the Kronecker delta (Ansys Manual, 2018). The fluctuating
157 component v'_i of velocity in direction x_i is the difference between the instantaneous
158 value of velocity and the average velocity V_i .

159 The $k - \epsilon$ Realizable model was used to model the turbulent viscosity since it
160 performs better than the standard $k - \epsilon$ model for recirculating flows (Ansys Fluent
161 manual, 2018). The turbulent viscosity is expressed as a function of turbulent kinetic
162 energy k and turbulent dissipation ϵ .

$$\mu_t = \rho C_\mu \frac{k^2}{\epsilon} \quad (2)$$

¹⁶³ where $C_\mu = 0.09$.

¹⁶⁴ Turbulent kinetic energy TKE is defined as $k = 1/2[u_i'^2 + u_j'^2 + u_w'^2]$. u_i' , u_j' ,
¹⁶⁵ $u_w'^i$ are the fluctuating velocities, i.e. the differences between the instantaneous flow
¹⁶⁶ velocities and the mean flow velocities along the corresponding direction i , j and w .
¹⁶⁷ In the present case, $i = x$ (longitudinal direction), $j = y$ (transversal direction) and
¹⁶⁸ $w = z$ (vertical direction).

¹⁶⁹ The pressure-velocity coupling was solved by PISO scheme. Spatial discretiza-
¹⁷⁰ tions were realized by the following schemes: PRESTO for pressure and QUICK for
¹⁷¹ momentum and turbulent kinetic energy, in alignment with Barton et al. (2008).
¹⁷² The Curvature correction was added to sensitize the model to streamline curvatures.
¹⁷³ The numerical simulations were run in stationary and uniform conditions (same wa-
¹⁷⁴ ter level in the pools).

¹⁷⁵ The geometric domain was made of five pools, plus a headrace and a tailrace 12
¹⁷⁶ m long. The geometric dimensions of each pool were the standard ones, $L = 10b_0$
¹⁷⁷ long and $B = 8b_0$ wide, where $b_0 = 0.3$ m is the slot width. The average pool water
¹⁷⁸ level was $y_0 = 2$ m under the uniform scenario, and six different bed slopes were
¹⁷⁹ investigated. The flow rate was imposed at the inlet, based on y_0 and geometry
¹⁸⁰ (Rajaratnam et al, 1992), while the water depths at the inlet and at the outlet were
¹⁸¹ set to ensure a water depth of $y_0 = 2$ m at the center of the pool. This method was
¹⁸² used and validated in Quaranta et al. (2017). As initial condition, all the volume
¹⁸³ was filled with air, and only at the inlet a water surface was imposed. Table 1 shows,
¹⁸⁴ for each slope value, the resulting head difference Δh between two adjacent pools
¹⁸⁵ and the flow rate Q for $y_0 = 2$ m.

Effects of bed slope on the flow field of vertical slot fishways

186 A tetrahedral mesh was generated, with cell dimensions ranging between 0.025 m
187 and 0.05 m, that is considered a good mesh to simulate hydraulic structures affecting
188 fish behavior. Such mesh size is comparable with mesh dimensions typically used in
189 literature (Khan, 2006; Marriner et al., 2014; Quaranta et al., 2017), and hydraulic
190 phenomena (like eddies) are of one order of magnitude larger than mesh dimensions.

191 *2.1. Examined variables and threshold values*

192 Results were discussed in relation to the central pool, which is generally used as
193 a representative reference in CFD fishways modeling (Khan, 2006; Heimerl et al.,
194 2008; Quaranta et al., 2017). The flow field was examined on a deeper plane H_b
195 (bottom plane) located at $0.33y_0$ (representing the flow field for bottom oriented fish
196 species), and on a plane H_t (top plane) located at $0.67y_0$ (flow field faced by fish
197 swimming in the upper portion of the water column). This approach was similar to
198 Silva et al. (2012), and was useful to compare results with those found in Quaranta
199 et al. (2017) for Design 16, which is the simplified version of the design investigated
200 here (D1).

201 The examined turbulent variables were the turbulent kinetic energy TKE, the
202 power dissipation D_ϵ and the Reynolds shear stresses RS (more specifically the tan-
203 gential Reynolds stress $\tau_{x,y}$). Furthermore, the flow topology at different slopes was
204 also analyzed along a vertical plane passing through the center of the slots, in order
205 to better evaluate up- and downwelling phenomena.

206 Typical threshold velocity values recommended in fish resting zones are 0.2-0.4
207 m/s; this range is recommended for Cyprinids to rest before a subsequent upstream
208 movement through higher velocity areas (Silva et al., 2012 and 2015, where fish 15-35
209 cm long were tested). Since Marriner et al. (2016) found that flow velocities must
210 be kept under 0.30 m/s in 30% to 50% of the pool's volume, in this study the upper

211 reference velocity value was taken as 0.3 m/s.

212 For TKE, a large portion of the pool should stay below $0.05 \text{ m}^2/\text{s}^2$, since higher
 213 values might affect fish passage (Marriner et al., 2016; Quaranta et al., 2017). In
 214 Romao et al. (2017), average TKE values occurring during Cyprinid passage (Iberian
 215 barbel *Luciobarbus bocagei* and Southern Iberian chub *Squalius pyrenaicus*) through
 216 a VSF ranged between $0.05 \text{ m}^2/\text{s}^2$ and $0.1 \text{ m}^2/\text{s}^2$. Therefore, preferable TKE values
 217 used in this study stay below $0.05 \text{ m}^2/\text{s}^2$, while $0.1 \text{ m}^2/\text{s}^2$ was considered a maximum
 218 acceptable limit.

219 With regards to RS, on the horizontal plane Iberian barbel occupied positions
 220 with absolute *RS* between $20 - 60 \text{ N/m}^2$ (Silva et al., 2011), so that 60 N/m^2 can
 221 be considered the upper reference threshold (in Romao et al., 2017, average RS were
 222 estimated to be about 30 N/m^2 in a regular pool). Note that the upper limit 60
 223 N/m^2 may not be enough to cause injuries or mortalities, which typically occur at
 224 much higher levels ($> 700 \text{ N/m}^2$) (Silva et al., 2011).

225 Finally, the power dissipation inside the pool, defined as $D_\epsilon = \frac{1}{V_p} \int_{V_p} \rho \epsilon dV_p$, where
 226 dV_p is the infinitesimal pool wet volume and ϵ is the dissipation of turbulence coming
 227 from the turbulent model, was evaluated. Usually, for the sake of simplicity in the
 228 design of technical fishways, the global volumetric dissipated power D_V is used as a
 229 reference parameter, calculated as $D_V = \frac{P}{V_p}$ where $P = \rho g Q \delta h$ (ρ is water density, g
 230 is gravity, Q is the flow rate and δh is the head difference). In general, $D_V > D_\epsilon$, since
 231 D_V includes all power losses and friction losses, not only the turbulent ones computed
 232 with D_ϵ . However, D_ϵ allows the determination of the dissipation distribution inside
 233 the pool, while D_V is just a global pool parameter (Chorda et al., 2010). Analyzing
 234 D_ϵ , the pool area was subdivided according to the the following threshold values: 1)
 235 $D_\epsilon = 200 \text{ W/m}^3$: highly turbulent areas not suitable for fish resting, where generally
 236 fish use burst speed to pass through slots (Liu, 2004); 2) $150-200 \text{ W/m}^3$: acceptable

237 for larger salmonids; 3) $100\text{-}150 \text{ W/m}^3$ acceptable for most cyprinids species; 4) \leq
238 100 W/m^3 conservative upper threshold for fish species with weaker swimming ability
239 (ICPDR, 2013; Larinier, 2002).

240 Flow velocity and turbulent values were discussed by considering absolute local
241 values (like maximum values), and averaged values (\bar{V} , \bar{RS} and \overline{TKE}). Velocity
242 and turbulence results were quantitatively described distinguishing between jet and
243 low-velocity areas. Finally, based on threshold values reported within the current
244 section 2.1, pool areas considered fish friendly were quantified and their topology
245 within the VSF pool is presented.

246 **3. Results and discussion**

247 Figures 2-3 show the flow field in the pool by means of flow velocity vectors on
248 the planes H_b and H_t . Along the plane H_b , a well visible jet and low-velocity areas
249 on its sides are present. It can be noticed that the left eddy is progressively shifted
250 downstream; at $i=6.67\%$, it disappears reappearing again at $i=10\%$ splitted into two
251 smaller ones, in agreement with Tarrade et al. (2008). As reported in Romao et al.,
252 (2018), turbulent flow fields with vortices of various sizes represents an additional
253 difficulty for fish passage, especially for small individuals with limited swimming
254 ability; therefore, VSFs with 10% slope are not recommended. The absence of the
255 vortex at $i=6.67\%$ and 8.33% is due to the increased vertical component of velocities,
256 i.e. upwelling and downwelling phenomena. This implies a higher level of turbulence
257 in the vertical plane. Instead, the right eddy tends to be quite stable as the bed
258 slope changes, except at $i=10\%$ where it approaches a more circular shape. Looking
259 at the plane H_t in Fig.3, the left eddy is initially circular and located upstream. At
260 $i=5\%$ it becomes elliptical and moves downstream, splitting into two smaller ones
261 at $i=6.67\text{-}8.33\%$. In all cases, average jet flow velocities are generally smaller than

the maximum theoretical ones V_m , while locally maximum effective values could be slightly higher than V_m . Furthermore, as also shown in Wang et al. (2010), there is an increase in flow velocity near the left wall of the pool and in the proximity of the main transversal baffle, due to the rotation of the big vortex on the left of the pool.

When looking at a longitudinal vertical plane passing through the center of the slot (Fig.4), it can be seen that flow velocities increase from the center of the pool towards the slot downstream; this is because, in the downstream portion of the pool, the vertical plane intersects the main jet. Instead, in the upstream portion of the pool, the resting zone on the right side of the jet is shown, where the horizontal axis eddy generates flow velocities directed upstream as confirmed by Tarrade et al. (2008). This may help the upstream movements of fish that swim near the free surface. This hydraulic configuration does not occur at $i = 1.67\%$ and $i = 5\%$, where instead upstream pointed flow velocities appear in the lower portion of the pool. Indeed, the eddy on the right is more elongated, and the vertical plane intersects it in its internal part (flow velocities pointed downstream), while at the other slopes it is intersected in its external part, where flow velocities are directed upstream. Another interesting output is related to the zone where flow velocities start pointing downstream. At $i = 1.67\%$ and $i = 5\%$ the velocity increase starts from the upper portion of the pool, while at the other slopes from the bottom portion, and this is coherent with the rotation of the horizontal axis eddy. Therefore, at each slope and corresponding head difference, vertical flow velocities occur, i.e. up- and downwelling phenomena. The higher the slope, the higher the intensity of the vertical velocities, ranging from $0.05 V_m$ to $0.25 V_m$, where V_m is the maximum flow velocity in the slot.

The water jet is responsible for the flow rate transport, and it has to be sensed readily by fish which will use their burst speed to move upstream along or through the jet length. Mean jet velocity and maximum flow velocities increase with the

slope (Tab. 2). On the bottom plane, velocity values are generally higher, because the jet is more straight between the slots and less affected by the free surface. As the bed slope increases, maximum flow velocities pass from $\simeq 1$ m/s to 2.6 m/s; this is an expected behavior, since as the slope increases also the flow rate increases, and thus the flow velocity. Instead, average jet values range between 0.71 m/s to 1.76 m/s from $i = 1.67\%$ to $i = 10\%$, which is a smaller range than that found for the maximum velocities, where the variation range of the mean velocity can be calculated as $\frac{\overline{V}_{10\%} - \overline{V}_{1.67\%}}{\overline{V}_{1.67\%}}$.

Same analogies can be found for TKE and RS, whose variation ranges are wider when considering maximum values (Tab. 2). TKE and RS at 10% slope are around 7 times compared to those at 1.67% slope when considering mean values, and approximately 10 times when considering maximum values. Furthermore, maximum and average values of turbulence and velocity change substantially from H_b to H_t (from bottom to top) as the bed slope increases, due to the highly 3D character of flow behavior and due to the flow rate increase.

In contrast, flow behavior in the low-velocity areas (Tab. 3) is more quiet, and average values change from H_b to H_t only at the highest slope, corresponding to $i=10\%$. Maximum velocities in the low-velocity areas occur in the boundaries with the jet emanating from the slot. Variation ranges for the average values of TKE and RS are again around 7, and less than 10 times when considering maximum values, because in the low velocity areas flow behavior is less turbulent, and, therefore, the slope may have a lesser influence on turbulence in the low velocity areas with respect to the jet.

Results related to the extension of low velocity areas in the pool are reported in Tab. 4, showing the area percentage where effective values of flow velocity, TKE and RS are lower than threshold values (see section 2.1). In Tab. 4 the average values of

314 velocity, TKE and RS inside the pool are also reported with reference to planes H_b
315 and H_t .

316 Area percentages below threshold values decrease with bed slope increase, due
317 to the increase in turbulence. In particular, a substantial decrease of low velocity
318 areas occurs passing from $i = 1.67\%$ to $i = 3.33\%$ (see Tab.4). No substantial
319 difference between the two planes (H_b and H_t) can be noticed. Fish friendly areas,
320 i.e. areas with values below the threshold ones, are more developed when considering
321 RS instead of TKE, showing that the threshold value of $TKE = 0.05 \text{ m}^2 \text{ s}^{-2}$ is more
322 conservative than $RS = 60 \text{ N m}^{-2}$. Nevertheless, fish friendly TKE areas are generally
323 extended by about 30% of the pool, according to recommendations suggested in
324 Marriner et al. (2016).

325 Areas with high TKE values are confined in the jet at low bed slopes (Fig.5),
326 while at higher slopes, these start appearing downstream, because the water flow
327 impacts on the downstream wall, and then spreads upstream. This is in agreement
328 with Wang et al. (2010) and Liu et al. (2006). Instead, RS values higher than
329 60 N m^{-2} are restricted only inside the main jet. Therefore, it is expected that fish
330 resting would occur in the upstream part of the pool, where turbulence is lower, as
331 confirmed in Laine et al. (1998), where it was found that fish gathered behind the
332 baffles attempting to swim through the slot.

333 With regard to the power dissipation, in Tab.4 D_V is compared with D_ϵ , as
334 suggested in Chorda et al. (2010). The maximum difference in percentage is 30% at
335 $i = 5\%$, comparable with the values found in Chorda et al. (2010). The local power
336 dissipation $\rho\epsilon$ along the plane is illustrated in Fig.7. The highest dissipation values
337 occur near the slot and along the jet. Such distribution is in agreement with the
338 RS distribution, because, in turbulent regimes, RS are those factors that generate
339 power dissipation. The distribution of D_ϵ is also in agreement with results described

340 in Chorda et al. (2010).

341 Looking at Figs.5-6, it can be seen that areas where flow velocity and turbulence
342 values are lower than the maximum threshold ones are restricted to the water jet for
343 bed slopes smaller than 5% (included). This means that low velocity areas are well
344 developed, and they are suitable for fish to rest up to the 5% slope. The bed slope
345 of 6.67% may still be considered fish friendly, although TKE values are not below
346 threshold values.

347 Several hydraulic parameters used in this study were derived from research on
348 a few Cyprinid species, especially Iberian barbel and chub (Silva et al., 2011; Ro-
349 mao et al., 2017). It is worthwhile to note that several groups of species display
350 similarity in swimming performance (Katopodis and Gervais, 2016). For example,
351 Sanz-Ronda et al. (2016), reported that two Cyprinids (barbel and nase) ascended
352 the vertical slot easily. Moreover, the meta-analysis on swimming performance by
353 Katopodis and Gervais (2016) grouped cyprinids and salmonids, indicating that fish
354 of similar body length from these large groups of species have similar fish speeds.
355 Furthermore, results from a recent field study on a vertical slot fishway, demon-
356 strated that the Iberian barbel and another Cyprinid, the northern straight-mouth
357 nase (*Pseudochondrostoma duriense*), performed similarly to a Salmonind, the brown
358 trout (*Salmo trutta*), which were of similar size (Sanz-Ronda et al., 2016). These
359 findings allow recommendations on VSF bed slope from this study to apply to a
360 greater number of species.

361 **4. Conclusions**

362 The general question addressed by this study was whether a given slope config-
363 uration may allow more fish to pass; this is a complex matter, involving hydraulics
364 and fish behavior, since the bed slope can significantly affect flow characteristics.

Effects of bed slope on the flow field of vertical slot fishways

365 The limited field experiments in the recent scientific literature make it difficult to
366 relate ecological performances of VSFs with the slope. Meanwhile, there is a lack
367 of a clear and comprehensive flow field assessment of VSFs at different slopes since
368 existing studies have only tested a maximum of three slopes.

369 Therefore, in this study the effects of bed slope on the flow field of a standard
370 VSF type were analyzed by 3D numerical simulations, testing six bed slope values
371 from 1.67% to 10%, corresponding to head drop values between pools commonly
372 used in fishway design (from 5 to 30 cm). Comparison with results from existing
373 literature indicate good agreement, validate simulated parameters and offer greater
374 generalizations. The flow field was discussed analyzing flow velocities and turbulent
375 variables as TKE, RS and power dissipation.

376 The velocity field was characterized by a main water jet with recirculating areas
377 on the sides of the pools. These areas changed with the bed slope, both in size
378 and flow behavior: indeed, at 6.67% and 8.33% the vortex on the left split into two
379 smaller ones, and due to their dimensions more comparable with fish size, they could
380 be perceived as obstacles for fish passage (Silva et al., 2012).

381 Low velocity areas in the pools, that are important for fish rest and energy recov-
382 ery, decreased with the bed slope increase. Areas where flow velocity and turbulent
383 values are higher than the maximum threshold ones are restricted to the water jet
384 for bed slopes smaller than 5% (included). With the exception of TKE, the 6.67%
385 ($\Delta H = 20$ cm) bed slope may be considered fish friendly. Higher slopes are not
386 recommended, because turbulence may form a barrier for migrating fish.

387 Therefore, the slope of 6.67% ($\Delta H = 20$ cm) can be considered the upper limit
388 in the design of fishways except for larger salmonids or species of similar swimming
389 abilities and behavior. The 6.67% slope may be reasonable only when there is a need
390 to reduce construction costs related to a 5% slope. Milder slopes would result in an

391 increase in fish passage construction costs, whilst no significant improvement in the
392 ecological efficiency would occur, and may be recommended only when passage has
393 to be provided to species with very weak swimming abilities. It is also essential to
394 guarantee a maximum flow velocity lower than the burst speed of fish.
