ABSTRACT: We derive a 2+1 dimensional model with unconventional supersymmetry at the boundary of an AdS₄ \mathcal{N} -extended supergravity, generalizing previous results. The (unconventional) extended supersymmetry of the boundary model is instrumental in describing, within a top-down approach, the electronic properties of graphene-like 2D materials at the two Dirac points, \mathbf{K} and \mathbf{K}' . The two valleys correspond to the two independent sectors of the $\text{OSp}(p|2) \times \text{OSp}(q|2)$ boundary model in the $p = q$ case, which are related by a parity transformation. The Semenoff and Haldane-type masses entering the corresponding Dirac equations are identified with the torsion parameters of the substrate in the model.

1 Introduction

Chern-Simons theories including gravity and matter in three dimensions developed three decades ago by Achúcarro and Townsend [1], have been shown to exhibit interesting features [2, 3], particularly in connection with the holographic correspondence [4–6]. Our interest here focuses on the Achúcarro-Townsend (AT) theory, following the Ansatz proposed in [7, 8] (referred to as the AVZ model in the sequel). The AVZ model consists of a Chern-Simons system in $2 + 1$ dimensions for the supergroup $\text{OSp}(2|2)$. It is an effective theory for a massive spin-1/2 fermion, generically defined on a curved geometry and minimally coupled to the background gravity and a $U(1)$ gauge field. This system exhibits an unconventional form of supersymmetry based on a graded Lie algebra that extends the local invariance of the tangent of the spacetime manifold, with the addition of the internal gauge generators necessary to close the superalgebra. All the fields are contained in the

gauge connection for the adjoint representation of the supergroup, namely¹

$$\mathbb{A} = \frac{1}{2} \omega^{ij} \mathbb{J}_{ij} + A \cdot \mathbb{T} + \bar{\psi}_A \mathbb{Q}^A + \bar{\mathbb{Q}}_A \psi^A + \dots, \quad (1.1)$$

where ω^{ij} , A and ψ^A are one-forms, while \mathbb{J} , \mathbb{T} and \mathbb{Q} are the generators of Lorentz, internal gauge and supersymmetry transformations, respectively. What makes this model unconventional is that it assumes a peculiar Ansatz for the fermionic gauge fields ψ_μ^A , expressing them as composite fields of the vielbein e^i and spin-1/2 fields χ_A ,

$$\psi^A = i \gamma_i e^i \chi^A. \quad (1.2)$$

In three dimensions, the simplest Lagrangian for the connection (1.1) is a Chern-Simons form and the resulting AVZ model is particularly suited for describing graphene near the Dirac points in a generic spatial lattice with nonvanishing curvature and torsion [9].

In 3 + 1 dimensions, on the other hand, the simplest action for a superconnection of the form (1.1) is a Yang-Mills theory for the smallest superalgebra that extends the AdS₄ symmetry and yields a spin-1/2 field minimally coupled to Einstein gravity and the Maxwell field [10]. This four-dimensional unconventional SUSY model was in turn shown to correspond to the boundary theory of a Chern-Simons theory for a super connection in five-dimensions [11].

In what follows, we consider a three dimensional model of unconventional supersymmetry at the boundary of an AdS₄ supergravity vacuum, extending the analysis in [12], where it was shown that the three-dimensional AVZ model could be holographically realized as the boundary theory of an $\mathcal{N} = 2$ four-dimensional supergravity of the AdS₄ spacetime. The model in [12] was constructed by embedding the OSp(2|2)-Chern-Simons theory of the AVZ model in an $\mathcal{N} = 2$, $D = 3$ AdS₃ supergravity described by an AT theory with gauge group OSp(2|2)₊ × SO(1, 2)₋. This theory was in turn obtained as an effective model at the boundary of an AdS₄ space on which an $\mathcal{N} = 2$ supergravity is defined. This results from a suitable choice of boundary conditions for the four-dimensional fields. Imposing then the AVZ Ansatz (1.2) for the $D = 3$ fermions identifies the resulting spin-1/2 fields χ_A as the radial component of the four-dimensional gravitini whose mass is related to the AdS₃ radius. Applying the resulting model to the effective description of the electronic properties of graphene and other graphene-like 2D materials² provides a top-down approach to the understanding of the origin of supersymmetric phenomenology of this physical system [13–15]. The quantum BRST formulation of the same $D = 3$ model was discussed in [16].

The aim of the present paper is to generalize the construction of [12] to an \mathcal{N} -extended supergravity, with maximally supersymmetric AdS₄ vacuum related to an OSp(p |2)₊ × OSp(q |2)₋, $p + q = \mathcal{N}$, Chern-Simons theory at the boundary.

¹Here we assume \mathbb{Q} and ψ to have dimensions (length)^{- $\frac{1}{2}$} and (length) ^{$\frac{1}{2}$} , respectively, as it is common in the supergravity literature. The one-form gauge fields A and ω on the other hand, are assumed to be dimensionless.

²By *graphene-like* materials we mean two-dimensional materials featuring a honeycomb lattice and an emergent behaviour as Dirac fermions for the pseudo-particle wavefunction.

It is achieved by generalizing the boundary conditions for the $D = 4$ fields used in [12]. Applying the AVZ Ansatz for $\psi_{A\mu}$ ($A = 1, \dots, \mathcal{N}$) an effective model for the massive spin-1/2 fields χ_A on a curved background in the presence of a larger amount of supersymmetry and a larger internal symmetry group $\text{SO}(p) \times \text{SO}(q)$ is obtained. This allows to introduce extra internal degrees of freedom which can provide an application of the model to the description of graphene. The supersymmetry of the boundary model is defined by the partition (p, q) of \mathcal{N} and depends on the signature of a real symmetric matrix η_{AB} entering the boundary conditions for the gravitini.

Besides discussing the relation to the four-dimensional supergravity, the effective theory for the χ_A fields is explicitly constructed and its symmetries illustrated. The fermionic fields χ_A naturally split into two sets, χ_{a_1} and χ_{a_2} , with $a_1 = 1, \dots, p$ and $a_2 = 1, \dots, q$, which correspond to the representations $(\frac{1}{2}, \mathbf{0})$ and $(\mathbf{0}, \frac{1}{2})$ of the AdS_3 isometry group $\text{SL}(2, \mathbb{R})_+ \times \text{SL}(2, \mathbb{R})_-$. In the special case $p = q$, a manifest *reflection symmetry* emerges in the model, under which the fermions in the two sets are interchanged. In light of this we argue that, in this particular case, the Dirac fermions χ_{a_1}, χ_{a_2} may possibly describe the wave functions of the π -electrons in graphene-like systems at the two inequivalent Dirac points \mathbf{K}, \mathbf{K}' . Both fermions have masses which, as in the original AVZ model, depend on the torsion of the three-dimensional spacetime. We briefly elaborate on a microscopic (i.e. at scales comparable with the honeycomb lattice spacing) description of graphene-like materials which can account for the massive Dirac equations that we find at the two Dirac points.

We emphasize that our construction follows a top-down approach, in that the effective $D = 3$ theory that we derive at the boundary of AdS_4 originates from a well defined supersymmetric effective supergravity in the bulk. Nevertheless it bears similarities with the $D = 3$ models considered in [17], whose formulation also features an underlying AdS_3 symmetry. We shall elaborate on this at the end of section 4.

The paper is organized as follows:

In section 2 we discuss the emergence of an \mathcal{N} -extended Achúcarro-Twonsend model in $D = 3$ at the boundary of an AdS_4 supergravity by choosing appropriate boundary conditions on the supergravity fields. We also discuss the effect of a reflection transformation on the boundary model, showing that in the $p = q$ case it becomes a symmetry.

In section 3 we implement the AVZ Ansatz (1.2) in the \mathcal{N} -extended AT theory of section 2 and discuss the properties of the resulting model and its symmetries in the presence of a general world-volume torsion. In particular, we write the Dirac equations for the spin-1/2 fields χ_{\pm} in the two sectors acted on by each simple factor of the supergroup, and relate the corresponding masses to the torsion parameters.

In section 4 we apply our model as an effective long wave-length description of the electronic properties of graphene-like Dirac materials. We show that in the particular case $p = q$ the spin-1/2 fields χ_{\pm} can be consistently related to the electron wave-functions in two \mathbf{K} and \mathbf{K}' Dirac points. This allows us to identify the parity-even and odd components of the corresponding masses with Semenoff and Haldane-type mass contributions, respectively. These quantities, in light of the discussion in section 3, are then consistently expressed in terms of the torsion parameters of the model. In the last subsection we consider a different

model within our general construction, defined by $p = 4$ and $q = 0$, which allows us to make contact with the analysis in [17].

We end with a general discussion of our results and possible generalizations thereof. The appendices contain our notations and conventions and a brief account of some facts about graphene-like systems which are relevant to our analysis.

2 Achúcarro-Townsend $D = 3$ theory from AdS_4 supergravity

The starting point of our analysis is an AdS_4 vacuum of an \mathcal{N} -extended pure supergravity theory preserving all \mathcal{N} supersymmetries. The vacuum symmetry is described by the supergroup $\text{OSp}(\mathcal{N}|4)$ group.³ We consider fluctuations on this background which exhibit the full vacuum symmetry at radial infinity. We require, in particular, all scalar and spin-1/2 fields at the conformal boundary to be frozen at their vacuum values, and that the remaining fields obey the $\mathfrak{osp}(\mathcal{N}|4)$ Maurer-Cartan equations. This condition is satisfied, for instance, by the four dimensional vacuum configuration. We therefore do not consider here boundary terms depending on the scalar fields of the \mathcal{N} -extended AdS_4 -supergravity. For pure $\mathcal{N} = 2$, where scalar fields are not present, this choice of asymptotic symmetry is consistent with the analysis of [18], applied in [12].

The dual description of the $\mathfrak{osp}(\mathcal{N}|4)$ algebra is given in terms of the connection

$$\mathbb{A} = \theta^i \otimes E_i = \frac{1}{2} \omega^{AB} L_{AB} + \frac{1}{2} A^{CD} T_{CD} + \bar{\Psi}_\alpha^A Q_A^\alpha, \quad (2.1)$$

where L_{AB} ($A, B = 0, \dots, 4$) and T_{AB} ($A, B = 1, \dots, \mathcal{N}$) are the $\text{SO}(2, 3)$ and $\text{SO}(\mathcal{N})$ generators respectively, whereas Q_A^α ($\alpha = 1, \dots, 4$) are the Majorana supersymmetry generators (see appendix A). The structure of the algebra is encoded in the Maurer-Cartan equations $d\mathbb{A} + \mathbb{A} \wedge \mathbb{A} = 0$, which can be conveniently written in a manifestly covariant form with respect to the $D = 4$ Lorentz group $\text{SO}(1, 3)$ by splitting $\mathcal{A} = (a, 4)$, with $a = 0, 1, 2, 3$ and defining $L_{a4} := \ell P_a$, $\omega^{a4} := \ell^{-1} V^a$, where V^a is the four-dimensional vielbein:

$$\begin{aligned} d\omega^{ab} + \omega^a_c \wedge \omega^{cb} - \ell^{-2} V^a \wedge V^b - \frac{1}{2\ell} \left(\bar{\Psi}^A \wedge \Gamma^{ab} \Psi_A \right) &= 0, \\ dV^a + \omega^a_b \wedge V^b - \frac{i}{2} \left(\bar{\Psi}^A \wedge \Gamma^a \Psi_A \right) &= 0, \\ dA^{CD} + A^C_B \wedge A^{BD} + \ell^{-1} \left(\bar{\Psi}^C \wedge \Psi^D \right) &= 0, \\ d\Psi^A + \frac{1}{4} \omega^{ab} \wedge \Gamma_{ab} \Psi^A + \frac{i}{2\ell} V^a \wedge \Gamma_a \Psi^A + A^{AB} \wedge \Psi^B &= 0. \end{aligned} \quad (2.2)$$

As mentioned above, we shall restrict to $D = 4$ asymptotically anti-de Sitter backgrounds in which the above algebra *only* holds at the UV boundary located at radial infinity.

To proceed, it is convenient to rewrite the Maurer-Cartan equations in a form which is covariant with respect to the Lorentz group at the spatial boundary, $\text{SO}(1, 2)$. This is

³We work with the “mostly minus” convention for the metric and refer to a parametrization of AdS_4 given by $ds^2 = \frac{r^2}{\ell^2} ds_{(3)}^2 - \ell^2 \frac{dr^2}{r^2}$, where $ds_{(3)}^2$ is a locally AdS_3 metric of the conformal UV boundary at $r \rightarrow \infty$.

achieved by further splitting the rigid index a into $a = (i, 3)$, where $i = 0, 1, 2$ labels the boundary dreibein and $a = 3$ labels the vierbein along the radial direction. This allows to decompose the AdS_4 superalgebra in terms of $\text{SO}(1, 1) \times \text{SO}(1, 2) \subset \text{SO}(2, 3)$ where L_{34} and L_{ij} are the $\text{SO}(1, 1)$ and $\text{SO}(1, 2)$ generators, respectively. We then write the asymptotic algebra in a way in which the $\text{SO}(1, 1)$ -grading of the fields is manifest. This is achieved by defining

$$E_{\pm}^i := \pm \frac{1}{2} (V^i \mp \ell \omega^{3i}), \quad (2.3)$$

$$\omega^{i3} = \frac{1}{\ell} (E_+^i + E_-^i), \quad (2.4)$$

$$V^i = E_+^i - E_-^i, \quad (2.5)$$

and decomposing the gravitini in their chiral components with respect to the same $\text{SO}(1, 1)$, represented on the spinors by the matrix Γ^3 ,

$$\Psi^{A\alpha} = \Psi_+^A + \Psi_-^A, \quad \Gamma^3 \Psi_{\pm}^A = \pm i \Psi_{\pm}^A. \quad (2.6)$$

With these definitions, the previously obtained asymptotic relations become⁴

$$\begin{aligned} d\omega^{ij} + \omega^i_k \wedge \omega^{kj} + \frac{4}{\ell^2} E_+^i \wedge E_-^j - \frac{1}{\ell} \left(\bar{\Psi}_+^A \wedge \Gamma^{ij} \Psi_{A-} \right) \Big|_{\partial\mathcal{M}} &= 0, \\ dE_{\pm}^i + \omega^i_j \wedge E_{\pm}^j \mp \frac{1}{\ell} E_{\pm}^i \wedge V^3 \mp \frac{i}{2} \left(\bar{\Psi}_{\pm}^A \wedge \Gamma^i \Psi_{A\pm} \right) \Big|_{\partial\mathcal{M}} &= 0, \\ dV^3 - \frac{1}{\ell} (E_+^i + E_-^i) \wedge V_i + \bar{\Psi}_-^A \wedge \Psi_{A+} \Big|_{\partial\mathcal{M}} &= 0, \\ dA^{CD} + A^C_M \wedge A^{MD} + \frac{2}{\ell} \left(\bar{\Psi}_+^{[C} \wedge \Psi_-^{D]} \right) \Big|_{\partial\mathcal{M}} &= 0, \\ d\Psi_{\pm}^{M\beta} + \frac{1}{4} \omega^{ij} \wedge (\Gamma_{ij} \Psi_{\pm}^M)^{\beta} \pm \frac{i}{\ell} E_{\pm}^i \wedge (\Gamma_i \Psi_{\mp}^M)^{\beta} \pm \frac{1}{2\ell} V^3 \wedge \Psi_{\pm}^{M\beta} + \delta^M_{[C} \delta_{D]B} A^{CD} \wedge \Psi_{\pm}^{B\beta} \Big|_{\partial\mathcal{M}} &= 0. \end{aligned} \quad (2.7)$$

2.1 Boundary limit

We are now interested into the AdS_4 boundary, which is reached in the limit $r \rightarrow \infty$. In order to perform the limit, we define the vielbein at the boundary as⁵

$$E_+^i(r, x) = \frac{1}{2} \left(\frac{r}{\ell} \right) E^i(x) + O\left(\frac{\ell^2}{r^2} \right), \quad E_-^i(r, x) = -\frac{1}{2} \left(\frac{\ell}{r} \right) E^i(x) + O\left(\frac{\ell^2}{r^2} \right), \quad (2.8)$$

⁴We use $\bar{\Psi}_{\pm} \Gamma^{ij} \Psi_{\pm} = \bar{\Psi}_{\pm} \Gamma^3 \Psi_{\pm} = \bar{\Psi}_{\pm} \Psi_{\pm} = 0$.

⁵Note the more symmetric choice of the numerical factors entering the boundary conditions in the “+” and “-” sectors with respect to [12]. This is achieved by a rescaling $r \rightarrow r/2$, which does not alter the asymptotic limit.

where $x = (x^\mu)$, $\mu = 0, 1, 2$, are the boundary coordinates. As for the spinors we require

$$\Psi_{+\mu}^A(r, x) dx^\mu = \sqrt{\frac{r}{2\ell}} \begin{pmatrix} [c]\psi^A(x) \\ \mathbf{0} \end{pmatrix} + O\left(\frac{\ell}{r}\right), \quad (2.9)$$

$$\Psi_{-\mu}^A(r, x) dx^\mu = \sqrt{\frac{\ell}{2r}} \begin{pmatrix} [c]\mathbf{0} \\ \eta^{AB}\psi_B(x) \end{pmatrix} + O\left(\frac{\ell}{r}\right), \quad (2.10)$$

where η_{AB} is a symmetric metric such that $\eta_{AC}\eta_{CB} = \delta_{AB}$.⁶ As far as the spin and the gauge connection, we require

$$\omega^{ij}(r, x) = \omega_\mu^{ij}(x) dx^\mu + \dots, \quad A^{AB}(r, x) = A_\mu^{AB}(x) dx^\mu + \dots, \quad (2.11)$$

where the ellipses denote subleading terms in ℓ/r . When writing the equations at the boundary we shall simply denote by ω^{ij} and A^{AB} the boundary values of the corresponding quantities in the bulk, as defined by the leading terms above.

Consistency of the boundary conditions requires that both V^3 and dV^3 vanish at the boundary. This is indeed the case since, at the boundary, $\omega^3_i \wedge E^i = 0$ (by virtue of the general properties of the extrinsic curvature of the boundary) and $(\overline{\Psi}_\mp)\Psi_\pm \propto \eta_{AB}(\psi^A)^T \sigma^2 \psi^B = 0$, the latter being a consequence of the antisymmetry of σ^2 and the symmetry of η_{AB} .

With these boundary conditions, one can verify that the boundary equations (2.7) involve only boundary fields⁷

$$\begin{aligned} d\omega^{ij} + \omega^i_k \wedge \omega^{kj} - \frac{1}{\ell^2} E^i \wedge E^j - \frac{1}{2\ell} \left(\overline{\psi}^A \wedge \gamma^{ij} \eta_{AB} \psi^B \right) &= 0, \\ dE^i + \omega^i_j \wedge E^j - \frac{i}{2} \left(\overline{\psi}^A \wedge \gamma^i \psi_A \right) &= 0, \\ dA^{CD} + A_M^C \wedge A^{MD} + \frac{1}{\ell} \overline{\psi}^{[C} \wedge \eta^{D]B} \psi_B &= 0, \\ d\psi^A + \frac{1}{4} \omega^{ij} \wedge \gamma_{ij} \psi^A + \frac{i}{2\ell} E^i \wedge \gamma_i \eta^{AB} \psi_B + A^{AB} \wedge \psi^B &= 0. \end{aligned} \quad (2.12)$$

We now examine the role of the η_{AB} in the breaking of the $D = 4$ R-symmetry group: $O(\mathcal{N}) \rightarrow O(p) \times O(q)$, $p+q = \mathcal{N}$, where the integers p, q , define the signature of η . Indeed, through an $O(\mathcal{N})$ rotation η can be brought to the diagonal form

$$\eta_{AB} = \begin{pmatrix} \mathbf{1}_{p \times p} & \mathbf{0}_{p \times q} \\ \mathbf{0}_{q \times p} & -\mathbf{1}_{q \times q} \end{pmatrix}. \quad (2.13)$$

The index $A = 1, \dots, \mathcal{N}$ then naturally splits into $A = (a_1, a_2)$, where $a_1 = 1 \dots, p$ and $a_2 = p+1 \dots, \mathcal{N}$, and similarly $B = (b_1, b_2)$. Inserting expression (2.13) into (2.12) one can verify that, in the Maurer-Cartan equations for the gauge fields A^{BC} , the fermion

⁶Being A, B indices in the fundamental \mathcal{N} -dimensional representation of the R-symmetry group $SO(\mathcal{N})$, we do not distinguish between their upper and lower positions.

⁷More specifically, it is straightforward to verify that the right-hand-side of equations (2.7) are proportional, through powers of ℓ/r , to the right hand side of equations (2.12).

bilinear is projected on the adjoint of the algebra generating the subgroup $O(p) \times O(q)$ of $O(\mathcal{N})$, so that the equation for the gauge fields $A^{a_1 b_2}$, associated with the generators in the coset $O(\mathcal{N})/(O(p) \times O(q))$, reads

$$dA^{a_1 b_2} + A^{a_1}_{c_1} \wedge A^{c_1 b_2} + A^{a_1}_{c_2} \wedge A^{c_2 b_2} = 0, \quad (2.14)$$

and therefore these fields can be consistently set to zero: $A^{a_1 b_2} = 0$. This condition, however, is not optional, implicit in the requirement that the fields at the boundary (and in particular the gravitini fields) satisfy consistent equations. The remaining equations describe the superalgebra of $OSp(p|2)_+ \times OSp(q|2)_-$ (note that the subscripts “ \pm ”, from now on, no longer refer to the eigenvalues of $-i\Gamma^3$, but to the two factors in the $D = 3$ supergroup). To see this we define

$$\begin{aligned} \Omega^i_{(\pm)} &:= \omega^i \pm \frac{E^i}{\ell}, \quad \psi_+ := (\psi^{a_1}), \quad \psi_- := (\psi^{a_2}), \quad A_+ := (A^{a_1 b_1}), \quad A_- := (A^{a_2 b_2}), \\ \mathcal{D}[\Omega_+, A_+] \psi_+ &:= \left(d\psi^{a_1} + \frac{i}{2} \Omega_+^i \wedge \gamma_i \psi^{a_1} + A^{a_1 b_1} \wedge \psi_{b_1}^\beta \right), \\ \mathcal{D}[\Omega_-, A_-] \psi_- &:= \left(d\psi^{a_2} + \frac{i}{2} \Omega_-^i \wedge \gamma_i \psi^{a_2} + A^{a_2 b_2} \wedge \psi_{b_2} \right), \end{aligned} \quad (2.15)$$

where $\omega^i := \frac{1}{2} \epsilon^{ijk} \omega_{jk}$. Equations (2.12) can then be cast into the following compact form

$$R_\pm^i := d\Omega_\pm^i - \frac{1}{2} \epsilon^{ijk} \Omega_{\pm j} \wedge \Omega_{\pm k} = \pm \frac{i}{\ell} (\bar{\psi}_\pm \wedge \gamma^i \psi_\pm), \quad (2.16a)$$

$$\mathcal{D}[\Omega_\pm, A_\pm] \psi_\pm = 0, \quad (2.16b)$$

$$\mathcal{F}^{a_1 b_1} := dA^{a_1 b_1} + A^{a_1}_{c_1} \wedge A^{c_1 b_1} = -\frac{1}{\ell} (\bar{\psi}^{a_1} \wedge \psi^{b_1}), \quad (2.16c)$$

$$\mathcal{F}^{a_2 b_2} := dA^{a_2 b_2} + A^{a_2}_{c_2} \wedge A^{c_2 b_2} = \frac{1}{\ell} (\bar{\psi}^{a_2} \wedge \psi^{b_2}), \quad (2.16d)$$

which reflects the structure of the $\mathfrak{osp}(p|2)_+ \oplus \mathfrak{osp}(q|2)_-$ superalgebra,⁸ where the two parts are described by the 1-forms Ω_+^i, ψ_+, A_+ and Ω_-^i, ψ_-, A_- , respectively.⁹

The Maurer-Cartan equations (2.16) can be derived from the Lagrangian 3-form [1]

$$\begin{aligned} \mathcal{L} &= \mathcal{L}_{(+)} - \mathcal{L}_{(-)} - \frac{1}{2} d(\Omega_{+k} \wedge \Omega_-^k), \\ \mathcal{L}_{(\pm)} &:= \frac{1}{2} \left(\Omega_{\pm i} d\Omega_\pm^i - \frac{1}{3} \epsilon_{ijk} \Omega_\pm^i \wedge \Omega_\pm^j \wedge \Omega_\pm^k \right) + \text{Tr} \left(A_\pm \wedge dA_\pm + \frac{2}{3} A_\pm \wedge A_\pm \wedge A_\pm \right) \pm \\ &\quad \pm \frac{2}{\ell} \bar{\psi}_\pm \wedge \mathcal{D}[\Omega_\pm, A_\pm] \psi_\pm, \end{aligned} \quad (2.17)$$

⁸Note that, in our conventions, the structure constants of an $\mathfrak{sl}(2, \mathbb{R})$ algebra are chosen to be $f_{ijk} = -\epsilon_{ijk}$.

⁹These curvatures are exactly those obtained by Achúcarro and Townsend in [1] in three dimensions starting from a Chern-Simons action, if we call $\psi^{i,i'} \rightarrow \sqrt{2} \psi^{a_1, a_2}$, $\bar{\psi}^{i,i'} \rightarrow i \sqrt{2} \bar{\psi}^{a_1, a_2}$, $m = \frac{1}{2\ell}$.

where the total derivative $-\frac{\ell}{2}d(\Omega_{+k} \wedge \Omega_{-k}) = d(\omega_i \wedge E^i)$ is a Gibbons-Hawking term which originates from writing the Einstein-Hilbert Lagrangian as the difference of two Chern-Simons forms. Note that one could have chosen a singular matrix η_{AB} , with p positive, q negative and r vanishing eigenvalues ($\mathcal{N} = p + q + r$). In that case, $\eta^2 = \mathbb{P}_{p+q} = (\mathbf{1} - \mathbb{P}_r)$, where \mathbb{P}_r is the projector on the 0-eigenspace of η_{AB} . Imposing $\mathbb{P}_r^A{}_B A^{BC} = 0$, $\mathbb{P}_r^A{}_B \psi^B = 0$ and $A^{a_1 b_2} = 0$ at the boundary, the resulting boundary fields are connections in the algebra $\mathfrak{osp}(p|2)_+ \oplus \mathfrak{osp}(q|2)_-$, corresponding to the smaller supersymmetry $\mathcal{N}' = p + q = \mathcal{N} - r$. This more general choice of η_{AB} therefore allows a reduced amount of supersymmetry at the boundary.

2.2 Reflection transformations and the symmetric case $p = q$

In this subsection we discuss the effect of a parity transformation on the AT model. This transformation can be characterized as a spatial reflection in the Y-axis tangent to the 2+1 dimensional boundary ($t \rightarrow t, x \rightarrow -x, y \rightarrow y$), and implemented on three-dimensional vectors by the matrix $\mathcal{O}_Y = \text{diag}(+1, -1, +1)$. Recalling that E^i are vectors and ω^i pseudo-vectors, the transformation properties under this parity of the E^i and ω^i fields are:

$$E^i \rightarrow \tilde{E}^i = \mathcal{O}_Y^i{}_j E^j, \quad \omega^i \rightarrow \tilde{\omega}^i = -\mathcal{O}_Y^i{}_j \omega^j, \quad (2.18)$$

which in turn implies: $\Omega_{\pm}^i \rightarrow \tilde{\Omega}_{\pm}^i = -\mathcal{O}_Y^i{}_j \Omega_{\mp}^j$. The action on the full supersymmetric model is not in general an invariance, since the $\text{OSp}(p|2)_+ \times \text{OSp}(q|2)_-$ model is mapped into the $\text{OSp}(q|2)_+ \times \text{OSp}(p|2)_-$ one, i.e. the + and - sectors are interchanged.

In the special case $p = q$ this discrete transformation is an invariance of the theory. To make the parity symmetry manifest in the supersymmetric case we extend its action to the fermionic¹⁰ and gauge sectors as follows:

$$\psi_{\pm} \rightarrow \tilde{\psi}_{\pm} = \sigma^1 \psi_{\mp}, \quad A_{\pm} \rightarrow \tilde{A}_{\pm} = A_{\mp}. \quad (2.19)$$

The reader can easily verify, given our spinor conventions, that:

$$\begin{aligned} \bar{\psi}_{\pm} \wedge \gamma^i \psi_{\pm} &\rightarrow \mathcal{O}_Y^i{}_j \bar{\psi}_{\mp} \wedge \gamma^j \psi_{\mp}, \\ \Omega_{\pm} \gamma^i \psi_{\pm} &\rightarrow \Omega_{\mp} \sigma^1 \gamma^i \psi_{\mp}, \\ \bar{\psi}_{\pm} \mathcal{D}[\Omega_{\pm}, A_{\pm}] \psi_{\pm} &\rightarrow -\bar{\psi}_{\mp} \mathcal{D}[\Omega_{\mp}, A_{\mp}] \psi_{\mp}. \end{aligned} \quad (2.20)$$

and that the Maurer-Cartan equations (2.16) are invariant for $p = q$. The reader can show that $\tilde{\mathcal{L}}_{(\pm)} = \mathcal{L}_{(\mp)}$, so that the Lagrangian density \mathcal{L} is odd: $\tilde{\mathcal{L}} = -\mathcal{L}$. When making contact with the effective description of certain 2D materials, in the next sections, we will, in the $p = q$ case, interpret the + and - sectors as related to the Dirac points \mathbf{K}, \mathbf{K}' .

As pointed out above, in the general $p \neq q$ case, the discrete reflection symmetry exchanges the + and the - sector so that a (p, q) model is mapped into the (q, p) one.

By the same token one can show that the inversion in the X-axis, tangent to the 2 + 1 dimensional world volume, is also a symmetry of the model for $p = q$. Its action on three-dimensional vectors is implemented by the matrix $\mathcal{O}_X = \text{diag}(+1, +1, -1)$, while on the gravitini it involves multiplication by the Pauli matrix σ^3 : $\psi_{\pm} \rightarrow \tilde{\psi}_{\pm} = \sigma^3 \psi_{\mp}$.

¹⁰The Clifford algebra representation that we use is given in appendix A.

3 Generalized AVZ model

The Chern-Simons theory discussed in [7] and [12] is naturally defined on a principal fiber bundle $[\mathcal{M}_3, \text{OSp}(2|2)]$, under the assumption that the bosonic subgroup $\text{SO}(1, 2) \subset \text{OSp}(2|2)$ of the fiber gauge group is identified with the Lorentz group on the tangent space of the three-dimensional world-volume space time \mathcal{M}_3 . This identification is implicit, in particular, in the Ansatz (1.2), where the γ -matrices act both on the odd generator Q_A^α of the $\text{OSp}(2|2)$ gauge group and on the world-volume spinor χ^α . A more general point of view was adopted in [16], where such identification is not imposed a priori. This allows in particular the construction of the quantum world-volume field theory, in the spirit of the holographic AdS/CFT correspondence [2, 3].

In this paper we are going to analyze some applications to graphene-like systems of the geometrical features of the classical model of [7, 12] in the more general case of a gauge group $\text{OSp}(p|2)_+ \times \text{OSp}(q|2)_-$. However we prefer to maintain the conceptual distinction between target space and world volume. From this point of view, $\Omega_\pm, \psi_\pm, A_\pm$ are world-volume gauge fields with values in the $\mathfrak{osp}(p|2)_+ \oplus \mathfrak{osp}(q|2)_-$ superalgebra (target space). We assume the three-dimensional world-volume to have a tangent bundle with local AdS_3 symmetry of radius ℓ' , and a local frame bundle defined by the dreibein e^i . Supersymmetry is just the odd part of the gauge supergroup and is not assumed to act on the world volume at the classical level.

According to this more general point of view, the isometry group $\text{SL}(2, \mathbb{R})'_+ \times \text{SL}(2, \mathbb{R})'_-$ of the tangent space to the world-volume geometry and the bosonic subgroup $\text{SL}(2, \mathbb{R})_+ \times \text{SL}(2, \mathbb{R})_-$ of the gauge group are in principle unrelated, and we shall use primed and unprimed symbols to emphasize this distinction. In particular, the connections $\Omega'_\pm{}^i$ of $\text{SL}(2, \mathbb{R})'_\pm$, can be written in terms of the *torsion-free* Lorentzian connection ω'^i on the world volume as $\Omega'_\pm{}^i = \omega'^i \pm e^i/\ell'$. However, in line with [7] and [12], we shall eventually identify $\Omega'_\pm{}^i$ with $\Omega_\pm{}^i$ modulo additional torsion terms (which corresponds to identifying the corresponding $\text{SL}(2, \mathbb{R})$ groups). Also, as explained in [12], the theory obtained at the boundary of the (target space) AdS_4 supergravity can be related to the model discussed in [7] by considering an Ansatz, as in (1.2), in which the gravitini are expressed in terms of the local frame and spinor fields $\chi_A = (\chi_{a_1}, \chi_{a_2})$. These are world-volume spinors in the $(\frac{1}{2}, \mathbf{0}) \oplus (\mathbf{0}, \frac{1}{2})$ representation of $\text{SL}(2, \mathbb{R})'_+ \times \text{SL}(2, \mathbb{R})'_-$.¹¹ For the sake of notational simplicity, we use for the two sets of spinor bases χ_{a_1}, χ_{a_2} on which the generators of the corresponding $\text{SL}(2, \mathbb{R})'$ groups act, to be represented by the same matrices, $i\gamma^i/2$. Eventually, along the lines of the discussion in subsection 2.2, we shall relax this condition in order to study the parity symmetry of the theory when $p = q$.

3.1 NYW scale invariance

As shown in [7, 12], the above construction leads to the description of a propagating charged fermion satisfying a Dirac equation. Implicit in the Ansatz (1.2) is the local scale invariance

¹¹In line with the previous discussion, the γ_i matrices in (1.2) should be thought of as intertwining matrices between target space spinor indices and world-volume spinor indices. This makes sense in light of the identification between $\text{SL}(2, \mathbb{R})_\pm$ and $\text{SL}(2, \mathbb{R})'_\pm$ mentioned above.

under the so-called Nieh-Yan-Weyl (NYW) symmetry [19–22]

$$e^i \rightarrow \lambda(x) e^i, \quad \chi_A \rightarrow \frac{1}{\lambda(x)} \chi_A, \quad \lambda \neq 0, \quad (3.1)$$

which leaves the gravitino, and the whole theory, invariant. It is precisely the breaking of this conformal invariance that, in the framework of [8, 12], turns an originally topological Chern-Simons theory into a system with a propagating spin-1/2 field.

The identification of $SL(2, \mathbb{R})_{\pm}$ with $SL(2, \mathbb{R})'_{\pm}$ can be established by identifying the index i of e^i with the same index of E^i and defines the action of the covariant derivatives $\mathcal{D}[\Omega_{\pm}]$ on e^i as well. In particular, one can write the following general expressions for the torsion with respect to Ω_{\pm} as

$$T_{\pm}^i = \mathcal{D}[\Omega_{\pm}]e^i = \beta_{\pm}e^i + \tau_{\pm}\epsilon^{ijk}e_j \wedge e_k, \quad (3.2)$$

where β_{\pm} and τ_{\pm} are 1- and 0-forms, respectively. Under the NYW symmetry transformation (3.1), the above expressions retain their form provided β_{\pm} and τ_{\pm} change according to

$$\beta_{\pm} \rightarrow \beta_{\pm} + \frac{d\lambda}{\lambda}, \quad \tau_{\pm} \rightarrow \frac{1}{\lambda} \tau_{\pm}, \quad (3.3)$$

that is, β_{\pm} transform as a connection under local scale transformations.

Implementing the Ansatz (1.2) in the $OSp(p|2)_+ \times OSp(q|2)_-$ structure equations (2.16) for the bosonic curvatures, yields

$$\begin{aligned} R_{\pm}^i &= \pm \frac{1}{\ell} \bar{\chi}_{\pm} \chi_{\pm} \epsilon^{ijk} e_j \wedge e_k, \\ \mathcal{D}[\Omega_{\pm}]E^i &= \mp \frac{1}{\ell} \epsilon^{ijk} E_j \wedge E_k + \frac{1}{2} (\bar{\chi}_+ \chi_+ + \bar{\chi}_- \chi_-) \epsilon^{ijk} e_j \wedge e_k, \\ \mathcal{F}^{a_1 b_1} &= -\frac{i}{\ell} (\bar{\chi}^{a_1} \gamma^i \chi^{b_1}) \epsilon_{ijk} e^j \wedge e^k, \quad \mathcal{F}^{a_2 b_2} = \frac{i}{\ell} (\bar{\chi}^{a_2} \gamma^i \chi^{b_2}) \epsilon_{ijk} e^j \wedge e^k, \end{aligned} \quad (3.4)$$

where $\chi_+ := (\chi_{a_1})$, $\chi_- := (\chi_{a_2})$. Covariantly differentiating (3.2) yields

$$\mathcal{D}[\Omega_{\pm}]^2 e^i = -\epsilon^{ijk} R_{\pm j} e_k = 0, \quad (3.5)$$

where last equality follows from the first of eqs. (3.4). This in turn requires $d\beta_{\pm} = 0$ and, for non vanishing τ_{\pm} ,

$$\beta_{\pm} = -\frac{d\tau_{\pm}}{\tau_{\pm}} = -d\ln(|\tau_{\pm}|). \quad (3.6)$$

This last relation means that β_{\pm} can be viewed as produced by the scale transformation $e^i \rightarrow (\tau_{\pm})^{-1} e^i$. Consequently, in the absence of global obstructions, either β_+ or β_- can be gauged away to zero, and correspondingly either τ_+ or τ_- can be set equal to a constant, by an appropriate NYW transformation.

Next we express E^i in the basis of e^i . Consistently with our assumptions we can write the following proportionality relation

$$E^i = f e^i, \quad (3.7)$$

where f is some indeterminate function.¹² Since we have defined $\Omega_{\pm}^i = \omega^i \pm E^i/\ell$, assuming (3.7), the covariant derivatives of e^i can be written as

$$\mathcal{D}[\Omega_{\pm}] e^i = \mathcal{D}[\omega] e^i \mp (f/\ell) \epsilon^{ijk} e_j \wedge e_k, \quad (3.8)$$

from which one obtains

$$(\beta_+ - \beta_-) e^i + (\tau_+ - \tau_- + 2f/\ell) \epsilon^{ijk} e_j \wedge e_k = 0. \quad (3.9)$$

One can also compute the covariant derivative of e^i with respect to ω^i , which has the following general form

$$\mathcal{D}[\omega] e^i = \beta \wedge e^i + \tau \epsilon^{ijk} e_j \wedge e_k. \quad (3.10)$$

Comparing equation (3.10) with (3.9), one can find

$$\beta_+ = \beta_- = \beta, \quad \tau_+ + \frac{f}{\ell} = \tau_- - \frac{f}{\ell} = \tau. \quad (3.11)$$

Note that in the absence of global obstructions the 1-form β can be disposed of through a NYW transformation (3.3) [7].¹³ This would leave the theory only invariant under global (rigid) NYW transformations, which can in turn be used to fix the value of either τ_+ or τ_- at will since, for $\beta = 0$, τ_{\pm} are constants.

In order to find $f(x)$, we use (3.7) in the second expression of (3.4). Comparing this with (3.2) leads to the following conditions for $f(x)$:

$$df + \beta f = 0, \quad (3.12)$$

$$f \tau = \frac{1}{2} (\bar{\chi}_+ \chi_+ + \bar{\chi}_- \chi_-), \quad (3.13)$$

where τ was introduced in (3.10).

For $\beta = 0$, eq. (3.12) is satisfied by $f = \alpha_{\pm} \tau_{\pm}$, where α_{\pm} are dimensionful constants. An additional constraint comes from the Bianchi identities for R_{\pm}^i , obtained from the first of eqs. (3.4),

$$\mathcal{D}[\Omega_{\pm}] R_{\pm}^i = 0 \quad \Rightarrow \quad d(\bar{\chi}_{\pm} \chi_{\pm}) = -2 \beta \bar{\chi}_{\pm} \chi_{\pm}. \quad (3.14)$$

Under a NYW transformation, one can always set $\beta = 0$ locally. Then, the second expression in (3.14) implies that, in a local patch, $\bar{\chi}_{\pm} \chi_{\pm}$ are constants, consistently with the results of [12]. In general, for non-vanishing β , the last of eqs. (3.14) implies that:

$$\bar{\chi}_+ \chi_+ = k \bar{\chi}_- \chi_-, \quad (3.15)$$

with $k = \text{constant}$.

¹²In general, the 1-form E^i may not be parallel to e^i . We briefly touch on this more general case in section 5.

¹³Clearly, in the presence of global obstructions, this can only be done locally in an open neighborhood of every spacetime point.

Let us now turn to the discussion of the fermionic sector of the model. In general, we can keep the local NYW symmetry of the theory manifest by including its connection β in the definition of the covariant derivative and defining

$$\hat{\mathcal{D}} = \mathcal{D} + w\beta, \quad (3.16)$$

where w is the NYW weight of the field (-1 for e^i and $+1$ for χ_{\pm}). Thus, the NYW-covariant derivatives on χ_{\pm} is

$$\hat{\mathcal{D}}[\Omega_{\pm}, A_{\pm}] \chi_{\pm} = \mathcal{D}[\Omega_{\pm}, A_{\pm}] \chi_{\pm} + \beta \chi_{\pm}, \quad (3.17)$$

where

$$\mathcal{D}[\Omega_+, A_+] \chi_+^{a_1} := d\chi^{a_1} + \frac{i}{2} \Omega_+^i \gamma_i \chi^{a_1} + A^{a_1 b_1} \chi_{b_1}, \quad (3.18)$$

and similarly for $\mathcal{D}[\Omega_-, A_-] \chi_-$. From eqs. (2.16b) one finds

$$\gamma_{[i} \hat{\mathcal{D}}_{j]} [\Omega_{\pm}, A_{\pm}] \chi_{\pm} = \tau_{\pm} \epsilon_{ijk} \gamma^k \chi_{\pm}. \quad (3.19)$$

Contracting both sides on the left by γ^{ij} we end up with the following Dirac equations:

$$\mathcal{D}[\Omega_{\pm}, A_{\pm}] \chi_{\pm} = -3i \tau_{\pm} \chi_{\pm}, \quad (3.20)$$

while contracting both sides of (3.19) to the left by γ^i and using (3.20) one finds

$$\hat{\mathcal{D}}_i [\Omega_{\pm}, A_{\pm}] \chi_{\pm} = -i \tau_{\pm} \gamma_i \chi_{\pm}. \quad (3.21)$$

Equations (3.4) and (3.19) can all be derived from an action for two Dirac fields, χ_{\pm} , minimally coupled to two independent sets of CS connection fields, Ω_{\pm}, A_{\pm} ,

$$\begin{aligned} S = & \int \left[\frac{1}{2} \left(\Omega_{+i} \wedge d\Omega_+^i - \frac{1}{3} \epsilon^{ijk} \Omega_{+i} \wedge \Omega_{+j} \wedge \Omega_{+k} \right) - \frac{1}{2} \left(\Omega_{-i} \wedge d\Omega_-^i - \frac{1}{3} \epsilon^{ijk} \Omega_{-i} \wedge \Omega_{-j} \wedge \Omega_{-k} \right) + \right. \\ & + \left(A^{a_1 b_1} \wedge dA_{b_1 a_1} + \frac{2}{3} A^{a_1 b_1} \wedge A^{b_1 c_1} \wedge A^{c_1 a_1} \right) - \left(A^{a_2 b_2} \wedge dA_{b_2 a_2} + \frac{2}{3} A^{a_2 b_2} \wedge A^{b_2 c_2} \wedge A^{c_2 a_2} \right) - \\ & - \frac{2i}{\ell} \epsilon^{ijk} \bar{\chi}^{a_1} \left\{ \gamma_k \hat{\mathcal{D}}[\Omega_+, A^{a_1 b_1}] \chi_{a_1} + i \tau_+ \chi_{a_1} e_k \right\} \wedge e_i \wedge e_j - \\ & - \frac{2i}{\ell} \epsilon^{ijk} \bar{\chi}^{a_2} \left\{ \gamma_k \hat{\mathcal{D}}[\Omega_-, A^{a_2 b_2}] \chi_{a_2} + i \tau_- \chi_{a_2} e_k \right\} \wedge e_i \wedge e_j - \frac{1}{2} d(\Omega_{+k} \wedge \Omega_{-k}^k) \left. \right]. \end{aligned}$$

Note that the above action can be obtained from (2.17) using the Ansatz (1.2).

3.2 Fixing the NYW scaling

As already mentioned, the NYW symmetry can be used to set $\beta = 0$ locally on any open neighborhood of the world volume. Globally, this requires integrability of (3.6), which imposes a nontrivial condition on the topology of spacetime. Once the scale invariance has been used to set $\beta(x) = 0$, one can then use the remaining global NYW symmetry to fix either τ_+ or τ_- (which are constants) to some chosen value. It is useful to write the field equations in terms of the torsion-free Lorentz connection ω'^i

$$\omega'^i = \Omega_+^i + \tau_+ e^i = \Omega_-^i + \tau_- e^i. \quad (3.22)$$

The reader can easily verify that the Dirac equations in the two sectors can be recast in the form

$$\mathcal{D}[\omega', A_{\pm}]\chi_{\pm} = -\frac{3}{2}i\tau_{\pm}\chi_{\pm}, \quad (3.23)$$

where, as in the models discussed in [7, 12], the mass of the spinor fields are fixed in terms of the torsion

$$m_{\pm} = \frac{3}{2}\tau_{\pm}. \quad (3.24)$$

The Riemann tensor associated with ω' , using eq.s (3.4), (3.11), (3.12) and (3.13), reads

$$R^i[\omega'] = \frac{1}{2} \left(\frac{f^2}{\ell^2} + \tau^2 + \frac{\eta_{AB}\bar{\chi}^A\chi^B}{\ell} \right) \epsilon^{ijk} e_j \wedge e_k. \quad (3.25)$$

For $\beta = 0$, the coefficient of $\epsilon^{ijk} e_j \wedge e_k$ in (3.25) is a constant that defines an effective cosmological constant, which also receives a contribution from the fermion condensate (recall that f and τ are related by eq. (3.13)). The coefficient in front of this contribution depends on the choice of spin connection on the world volume. In particular, the residual global NYW symmetry can be used to identify the AdS₃ radius of the world volume, ℓ' , with the one on the target space, ℓ . This still allows for several choices of world-volume spin connection, which can be labeled by a real parameter λ . Identifying the gauge connection $\Omega_{(\lambda)}^i \equiv \omega^i + \frac{\lambda}{\ell} E^i$ with the tangent space connection $\Omega_{(\lambda)}^i \equiv \omega'^i + \frac{\lambda}{\ell} e^i$, yields

$$\tau = \frac{\lambda}{\ell}(f - 1), \quad (3.26)$$

which combined with (3.11) gives

$$\tau_{\pm} = \frac{1}{\ell} [\lambda(f - 1) \mp f]. \quad (3.27)$$

In this case eq. (3.13) implies

$$\lambda f(f - 1) = \frac{\ell}{2} (\bar{\chi}_+\chi_+ + \bar{\chi}_-\chi_-). \quad (3.28)$$

Under reflection λ changes sign, so that parity invariance requires $\lambda = 0$, which in turn implies $\bar{\chi}_+\chi_+ = -\bar{\chi}_-\chi_-$. This case is alternatively described by the limit $\ell \rightarrow \infty$ of vanishing cosmological constant. The cases $\lambda = \pm 1$ correspond to the choices $\Omega_{\pm}^i = \Omega_{\pm}^i$. In particular, for $\lambda = -1$, this identification includes the one assumed in [12], where the gauge super-group was defined by $p = 0$ and $q = 2$, and $\tau_- = 1/\ell$, $\tau_+ = -(2f - 1)/\ell$.

Note that the left-hand-side of (3.28) also vanishes for $f = 0$ and $f = 1$. The first case can be excluded on physical grounds since it would imply $E^i = 0$, which is singular. The second possibility, $f = 1$, implies $\bar{\chi}_+\chi_+ = -\bar{\chi}_-\chi_-$, which, as pointed out above, is the necessary condition for parity invariance. Moreover one can verify that the absolute value of the left hand side of eq. (3.28) has a minimum for $f = 1/2$. In this case, as it follows from eq. (3.27), choosing λ to be +1 or -1, implies that either χ_- or χ_+ are massless (i.e. $\tau_- = 0$ or $\tau_+ = 0$, respectively). In the next section we shall elaborate on these conditions in relation to the application of our construction to the effective description of graphene-like systems.

4 Interpretation in terms of graphene-like 2D materials

In the spirit of [7] we shall discuss an application of our construction to the effective long wavelength description of the electronic properties of graphene-like systems. From this perspective, the spin 1/2 fields χ_A , which satisfy the Dirac equations (3.20), describe the electron wave-functions. Let us recall few facts about the electronic structure of these materials.

A graphene sheet is a two-dimensional system of carbon atoms arranged in a honeycomb lattice [23, 24] (for review on the subject, see also [25–28]). From the perspective of high energy physics, graphene provides a real framework to study Dirac pseudoparticles at sub-light speed regime [25, 29–32], and many high-energy physics effects can be explored in a solid state system [26–28, 33–37].

The Dirac spinorial formulation emerges from the peculiar honeycomb structure, where a unit cell is made of two adjacent atoms belonging to inequivalent sublattices, labelled A and B, respectively. This means that we find two inequivalent sites per unit cell, the distinction not referring to different kinds of atoms — they are all carbon atoms — but to their topological inequivalence. The single-electron wave function is then conveniently described as a two-component Dirac spinor ζ which, in a basis where the gamma-matrices $\underline{\gamma}^i$ have the form

$$\underline{\gamma}^0 = -\sigma^3, \quad \underline{\gamma}^1 = -i\sigma^2, \quad \underline{\gamma}^2 = i\sigma^1, \quad (4.1)$$

can be written as

$$\zeta = \begin{pmatrix} \sqrt{n_A} e^{i\alpha_A} \\ \sqrt{n_B} e^{i\alpha_B} \end{pmatrix}. \quad (4.2)$$

Here n_A, n_B are the probability densities for the electron in the π -orbitals, referred to the A and B sublattices, respectively, and α_A, α_B the corresponding wave-function phases. In terms of ζ one can define the following two quantities:

$$n \equiv n_A + n_B = \zeta^\dagger \zeta, \quad \Delta n \equiv n_B - n_A = \bar{\zeta} \zeta, \quad (4.3)$$

where n is the total electron probability density while Δn is the asymmetry in the probability density between the two sublattices. This description is robust under changes of the lattice preserving the topological structure.

The Dirac physics is realized for low-lying energy pseudoparticle excitations: for energy ranges where the electron wavelength is much larger than the lattice length, the charge carriers see the graphene sheet as a continuum 2+1 dimensional spacetime. Moreover, quasiparticles with large wavelength are sensitive to sheet curvature effects, calling for a quantum Dirac field formulation in curved spacetime [34, 36].

Let us recall that isolated pristine graphene features massless Dirac equations for the pseudoparticles at the Dirac points. However, mass terms can be induced in several ways, for instance by switching on suitable local magnetic fluxes (see appendix B). Moreover, other graphene-like 2D materials exist where parity symmetry between the A and B sites is absent, and a mass gap is present, due to the different kind of atoms in the honeycomb

lattice. This is the case, for instance, of the boron nitride, where effective parity-violating mass terms emerge [38].¹⁴

The relation between the spin-1/2 fields of our model and ζ can be stated as follows:

$$\chi = \sqrt{\frac{\ell}{2}} U \zeta, \tag{4.4}$$

where the dimensionful constant $\sqrt{\frac{\ell}{2}}$ is needed in order for ζ to have the correct dimension of 1/(length) and the 2×2 matrix U relates the spinor basis used for χ (see appendix A) to the one defined above for ζ : $U^\dagger \gamma^i U = \underline{\gamma}^i$. The matrix U is readily found to be

$$U = \frac{1}{\sqrt{2}} \begin{pmatrix} 1 & 1 \\ -i & i \end{pmatrix}. \tag{4.5}$$

We shall restrict ourselves to the case in which supersymmetry is defined by even integers p and q , since this allows to arrange the real spinors χ_\pm into $p/2$ and $q/2$ Dirac spinors. The simplest choice would be the case $p = 2, q = 0$ or $p = 0, q = 2$, discussed in [7] and [12]. The next simplest case corresponds to $p = q = 2$, which will be discussed next.

An important consequence of (4.4), as first shown in [12] and derived on general grounds in the previous section, is that the quantity

$$\bar{\chi} \chi = \frac{\ell}{2} \bar{\zeta} \zeta = \frac{\ell}{2} (n_B - n_A), \tag{4.6}$$

by virtue of the last of eqs. (3.14), is constant for $\beta = 0$, in which case the difference $n_B - n_A$ in the probability densities is a constant index whose relevance will be further explored in future work.

Let us elaborate now on a consequence of eq. (4.6) in light of the discussion in subsection 3.2. Equation (3.28) implies the following bounds:

$$\begin{aligned} \lambda > 0, \quad n_A &= -\frac{4\lambda}{\ell^2} f(f-1) + n_B \geq -\frac{4\lambda}{\ell^2} f(f-1) \geq \frac{\lambda}{\ell^2}, \\ \lambda < 0, \quad n_B &= \frac{4\lambda}{\ell^2} f(f-1) + n_A \geq \frac{4\lambda}{\ell^2} f(f-1) \geq \frac{|\lambda|}{\ell^2}. \end{aligned} \tag{4.7}$$

In the two cases we find a lower bound in the probability densities of one of the two sublattices.

In our model the spinors are split into the + and - sectors and $\bar{\chi} \chi$ in (4.6) should be understood as

$$\bar{\chi} \chi \equiv \bar{\chi}_+ \chi_+ + \bar{\chi}_- \chi_- = \frac{\ell}{2} (n_B - n_A), \tag{4.8}$$

so that we can write

$$n_A = n_A^{(+)} + n_A^{(-)}, \quad n_B = n_B^{(+)} + n_B^{(-)}, \tag{4.9}$$

¹⁴A possibility for producing a parity violating mass gap in a graphene monolayer is to deposit it on a suitable substrate, for instance of boron nitride [39] or silicon carbide [40], inducing in this way local on-site potentials spoiling the original parity invariance between A and B sites.

where $n_A^{(\pm)}$, $n_B^{(\pm)}$ are the probability densities related to the A and B sublattices in the + and - sectors. In the context of graphene-like systems, the + and - sectors, in the $p = q$ case, can be interpreted as referring to the \mathbf{K} , \mathbf{K}' valleys. This will be discussed in the next subsection. For $p \neq q$ the interpretation of the model is more obscure and we shall put forward possible interpretations in a particular case. Note that the case $\lambda = 0$, which implies $\bar{\chi}_+\chi_+ = -\bar{\chi}_-\chi_-$, and $n_A = n_B$, can be realized as a non-trivial relation between the probability densities in the + and - sectors.

4.1 The $p = q$ case and the \mathbf{K} , \mathbf{K}' Dirac points

Let us now restrict to the case $p = q$, in which the parity symmetry discussed in section 2.2 emerges in the model. Since $E^i = f e^i$, the action of the \mathcal{O}_Y -parity on E^i naturally extends to e^i :

$$e^i \rightarrow \tilde{e}^i = \mathcal{O}_Y^i e^i, \tag{4.10}$$

provided f is invariant: $\tilde{f} = f$. Consistency of eqs. (2.18), (2.19) and (4.10) with the Ansatz (1.2) implies the following transformation rule for the spin-1/2 fields

$$\chi_{\pm} \rightarrow \tilde{\chi}_{\pm} = -\sigma^1 \chi_{\mp}. \tag{4.11}$$

One can verify for instance that $e_i \gamma^i \chi_{\pm} = \tilde{e}_i \sigma^1 \gamma^i \tilde{\chi}_{\mp}$, consistently with the transformation property of the ψ_{\pm} . Invariance under reflections of the expression (3.2) for torsion implies

$$\beta \rightarrow \tilde{\beta} = \beta, \quad \tau_{\pm} \rightarrow \tilde{\tau}_{\pm} = -\tau_{\mp}. \tag{4.12}$$

A specific world-volume background, characterized by certain torsion components, is parity invariant provided:

$$\tilde{\tau}_{\pm} = \tau_{\pm} \Rightarrow \tau_+ = -\tau_- . \tag{4.13}$$

It is also straightforward to verify that, under reflections,

$$\eta_{AB} \bar{\chi}^A \chi^B = \bar{\chi}_+\chi_+ - \bar{\chi}_-\chi_- \quad \text{and} \quad \bar{\chi}\chi = \bar{\chi}_+\chi_+ + \bar{\chi}_-\chi_-, \tag{4.14}$$

are a scalar and a pseudo-scalar, respectively. Moreover, the field equations are invariant while the Lagrangian density is, as expected, odd. Equations (2.18), (2.19) and (4.10) implement the reflection symmetry over the Y-axis on the tangent space to the world volume. In particular the two Dirac equations (3.23) are mapped into one another. An analogous discussion applies to the reflection over the X-axis in the tangent space to the world volume (see last paragraph of section 2.2). In this case the transformation properties of the spinors are: $\chi_{\pm} \rightarrow \tilde{\chi}_{\pm} = -\sigma^3 \chi_{\mp}$.

The \pm sectors, which are related by a reflection symmetry in one spatial axis, can be naturally associated with the \mathbf{K} , \mathbf{K}' valleys of graphene. To motivate this, we recall that \mathbf{K} , \mathbf{K}' are the two inequivalent points in the first Brillouin zone (FBZ) of the reciprocal lattice, which also has a honeycomb geometry. We describe the elementary hexagons related to the honeycomb lattice and to the FBZ as in figure 1.

The relativistic behavior of the charge carriers can be inferred, in the momentum space, from the linear dispersion relation between the energy and the quasi-momentum at the

Figure 1. Honeycomb lattice and first Brillouin zone (FBZ).

vertices of the first Brillouin zone. Close to the Fermi energy, the electrons in graphene have linear energy bands, like relativistic massless particles and the three dimensional plot of these two dimensional bands produce the so-called Dirac cones. For every momentum lying within the Brillouin zone, the Hamiltonian has two eigenvalues with opposite signs: the positive (negative) eigenvalue corresponds to the conduction (valence) band of graphene. The conduction and valence bands touch each other at the conical apices, located at the corners of the hexagonal FBZ. The latter are then split into two equivalence classes (referred to as “valleys”) and, as a result, electrons in graphene possess an additional pseudo-spin number, the *valley*. These properties are shared with other 2D graphene-like materials, which further allow the inclusion of effective mass terms.

Consistently with our description of the honeycomb lattices (see figure above), the reflection with respect to the Y-axis exchanges the A and B sites. The points \mathbf{K} and \mathbf{K}' are mapped into each other if the reflection is combined with a time-reversal transformation, so that the resulting effect on a momentum vector is $k_x \rightarrow k_x$, $k_y \rightarrow -k_y$. As mentioned above, this symmetry, which is present in pure graphene, is absent in 2D materials with inequivalent A and B sites. This feature implies the presence, for such materials, of a parity-violating Semenoff mass term in the effective Dirac equation.

In the absence of curvature, it is known that the Dirac equations in momentum space in the two valleys, in our conventions, read (setting $\hbar = v_F = 1$) [25]:

$$\begin{aligned}
 \mathbf{K} : \quad & E_{\mathbf{q}} \chi_{\mathbf{K}}(\mathbf{q}) = (\alpha^1 q^1 + \alpha^2 q^2 + m_{\mathbf{K}} \gamma^0) \chi_{\mathbf{K}}(\mathbf{q}), \\
 \mathbf{K}' : \quad & E_{\mathbf{q}} \chi_{\mathbf{K}'}(\mathbf{q}) = (\alpha^1 q^1 - \alpha^2 q^2 + m_{\mathbf{K}'} \gamma^0) \chi_{\mathbf{K}'}(\mathbf{q}),
 \end{aligned} \tag{4.15}$$

where $\alpha^\ell \equiv \gamma^0 \gamma^\ell$ ($\ell = 1, 2$) and the two equations are computed in the two-momenta $\mathbf{K} + \mathbf{q}$ and $\mathbf{K}' + \mathbf{q}$, with $|\mathbf{q}| \ll |\mathbf{K}|, |\mathbf{K}'|$. The Hamiltonian matrices on the right hand sides of equations (4.15) have eivengalues $+|E_{\mathbf{q}}|$ and $-|E_{\mathbf{q}}|$. The above two equations, in configuration space, read:

$$\begin{aligned}
 \mathbf{K} : \quad & i \partial_t \chi_{\mathbf{K}}(x) = (-i\alpha^1 \partial_x - i\alpha^2 \partial_y + m_{\mathbf{K}} \gamma^0) \chi_{\mathbf{K}}(x), \\
 \mathbf{K}' : \quad & i \partial_t \chi_{\mathbf{K}'}(x) = (-i\alpha^1 \partial_x + i\alpha^2 \partial_y + m_{\mathbf{K}'} \gamma^0) \chi_{\mathbf{K}'}(x).
 \end{aligned} \tag{4.16}$$

By general covariance, the generalization of equations (4.16) to a curved background, in the presence of minimal couplings to a gauge potential, is obtained by replacing partial derivatives by covariant ones:

$$\begin{aligned}
 \mathbf{K} : \quad & i \mathcal{D}_t[\omega', A_{\mathbf{K}}] \chi_{\mathbf{K}}(x) = (-i\alpha^1 \mathcal{D}_x[\omega', A_{\mathbf{K}}] - i\alpha^2 \mathcal{D}_y[\omega', A_{\mathbf{K}}] + m_{\mathbf{K}} \gamma^0) \chi_{\mathbf{K}}(x), \\
 \mathbf{K}' : \quad & i \mathcal{D}_t[\omega', A_{\mathbf{K}'}] \chi_{\mathbf{K}'}(x) = (-i\alpha^1 \mathcal{D}_x[\omega', A_{\mathbf{K}'}] + i\alpha^2 \mathcal{D}_y[\omega', A_{\mathbf{K}'}] + m_{\mathbf{K}'} \gamma^0) \chi_{\mathbf{K}'}(x),
 \end{aligned}
 \tag{4.17}$$

where $A_{\mathbf{K}}(x)$ and $A_{\mathbf{K}'}(x)$ denote the configuration-space representation of the gauge fields about the two Dirac points. By comparing (4.17) with eqs. (3.23), we can consistently identify the spinor field $\chi_{\pm}(x)$ with $\chi_{\mathbf{K}}(x)$, $\chi_{\mathbf{K}'}(x)$, up to an overall normalization, as follows

$$\chi_{\mathbf{K}}(x^\mu) = \chi_+(x^\mu), \quad \chi_{\mathbf{K}'}(x^0, x^1, x^2) = \sigma^1 \chi_-(-x^0, x^1, x^2),
 \tag{4.18}$$

provided we also identify:

$$A_{\mathbf{K}} = A_+, \quad A_{\mathbf{K}'} = A_-,
 \tag{4.19}$$

and the mass gaps at the two valleys with the mass parameters m_{\pm} of χ_{\pm} , see eq. (3.24),

$$m_{\mathbf{K}} = m_+ = \frac{3}{2} \tau_+, \quad m_{\mathbf{K}'} = m_- = \frac{3}{2} \tau_-.
 \tag{4.20}$$

This motivates the identification of the \pm sectors in our model with the two valleys, and the corresponding mass gaps with the torsion parameters of our model.

Note that applying spatial reflection with respect to the X-axis maps eqs. (4.15) into each other, provided $m_{\mathbf{K}'} = -m_{\mathbf{K}}$. This implies that $m_{\mathbf{K}'} + m_{\mathbf{K}}$ is parity-odd, while $m_{\mathbf{K}'} - m_{\mathbf{K}}$ is parity-even.

4.1.1 Microscopic interpretation

Mass terms can be included in graphene-like systems by generalizing the tight binding microscopic model (see appendix B) and opening mass gaps at the Dirac points. The generation of a gap at Dirac points was first discussed in 1984 by Semenoff, introducing a mass term through an on-site deformation $\pm M$ breaking sublattices equivalence [38].

Another model was proposed by Haldane, with the introduction of a periodic local magnetic flux density with zero net flux over the honeycomb hexagon [41]. The corresponding physical system is represented introducing in the microscopic Hamiltonian second-neighbor hopping terms with a phase factor $e^{\pm i\varphi}$, the phase sign according to the ‘‘chirality’’ of the electron path, i.e. depending on whether the hopping is clockwise or anticlockwise w.r.t. the hexagonal cell. The phase φ (Aharonov-Bohm phase) induced by the local fluxes can be taken as a parameter of the model. As discussed in appendix B, the degeneracy of the bands at the Dirac points is lifted either by non-zero M or non-zero Aharonov-Bohm phase contribution, and the fermion masses in the two inequivalent valleys turn out to be

$$m_{\mathbf{K}} = M - 3\sqrt{3} t_2 \sin \varphi, \quad m_{\mathbf{K}'} = M + 3\sqrt{3} t_2 \sin \varphi,
 \tag{4.21}$$

where the coefficient t_2 is the hopping amplitude between next-to-nearest neighbors [41] (see appendix B).

Using eq. (4.20) the physical quantities expressed by the Semenoff local potential term M and Haldane contribution $3\sqrt{3}t_2 \sin \varphi$ can be related to the fermion masses m_{\pm} of our macroscopic model. To see this, let us use eqs. (3.11) to write:

$$\tau_{\pm} \equiv \frac{1}{2}(\tau_+ + \tau_-) \pm \frac{1}{2}(\tau_+ - \tau_-) = \tau \mp 2\frac{f}{\ell}. \quad (4.22)$$

As discussed above (see in particular eq. (4.13)), the first term is parity odd, while the second is parity even. From eqs. (4.20), (4.21) and (4.22), the following identification can be made:

$$M = \frac{3}{2}\tau, \quad \sqrt{3}t_2 \sin(\varphi) = \frac{f}{\ell}. \quad (4.23)$$

This is consistent with the property of the Semenoff and Haldane mass terms to be parity odd and even, respectively. Indeed, parity is broken by a Semenoff-type contribution, that could be generated by an asymmetry between the A and B sites. Hence, the action of parity amounts to an interchange of n_A with n_B . The above identification is therefore consistent with the fact that, in light of eq. (3.13), τ is proportional to $\bar{\chi}\chi$ which is in turn proportional to $n_A - n_B$.

As for the Haldane-type mass contribution, the identification (4.23) suggests a relation between the ratio f/ℓ and the Berry phase parameters. Its meaning deserves a separate investigation which we leave for a future work.

4.2 A different model for graphene

Let us now briefly discuss a different application of our model to graphene-like materials, which makes contact with the analysis in [17]. In the latter the authors generalize the original model of [7] by considering a superalgebra of the form $A(1, 1) = \text{SU}(2|1, 1)$ whose bosonic subgroup is $\text{SU}(1, 1) \times \text{SU}(2)$, with respect to which the supersymmetry generators have the following transformation property:

$$Q_{IA\alpha} \in \left(\frac{\mathbf{1}}{\mathbf{2}}, \frac{\mathbf{1}}{\mathbf{2}} \right) \oplus \left(\frac{\mathbf{1}}{\mathbf{2}}, \frac{\mathbf{1}}{\mathbf{2}} \right), \quad (4.24)$$

where $I = 1, 2$ is a ‘‘flavour’’ index labelling the two irreducible representations in the above direct sum, A and α run over the doublet representations of $\text{SU}(2)$ and $\text{SU}(1, 1)$, respectively. Applying the AVZ Ansatz to the spinor 1-forms $\psi^{IA\alpha}$ dual to $Q_{IA\alpha}$, one ends up with four real 2-spinors $\chi^{IA} = (\chi^{IA\alpha})$ which can be grouped into two Dirac ones $\chi^A \equiv \chi^{1A} + i\chi^{2A}$. In [17] the doublet index A refers to the \mathbf{K} and \mathbf{K}' valleys and the $\text{SU}(2)$ internal symmetry group is naturally gauged by construction. This allows the authors to describe topological features of graphene such as *grain boundaries*. We emphasize here that this theoretical construction is substantially different from the one described in the previous subsection, in that the ‘‘valley’’ pseudo-spin is not associated with two different ‘‘ \pm ’’ sectors of the AdS_3 Achucarro-Townsend supergravity, but with just one of the two, since no supersymmetry is assumed in the other (as it is the case for the original model of [7]). We also emphasize that the approach pursued here is a *top-down* one.

Although a supergroup of the form $\text{SU}(2|1, 1)_+ \times \text{SO}(2, 1)_-$ is not comprised in our class of models, the closest we can get to the construction of [17] corresponds to choosing

$p = 4$ and $q = 0$. In this case the supergroup we start from is $\text{OSp}(4|2)_+ \times \text{SO}(2, 1)_-$, whose bosonic subgroup is $\text{SO}(4) \times \text{SL}(2, \mathbb{R})_+ \times \text{SL}(2, \mathbb{R})_-$. By writing the R-symmetry group in the equivalent form $\text{SO}(4) = \text{SU}(2)_1 \times \text{SU}(2)_2$, the supercharges can be characterized as transforming in the following real irreducible representation

$$Q_{IA\alpha} \in \left(\frac{\mathbf{1}}{\mathbf{2}}, \frac{\mathbf{1}}{\mathbf{2}}, \frac{\mathbf{1}}{\mathbf{2}} \right), \quad (4.25)$$

where now $I = 1, 2$ and $A = 1, 2$ are the doublet indices of the two factors $\text{SU}(2)_1$ and $\text{SU}(2)_2$ of the R-symmetry group. Consequently, upon implementing the AVZ Ansatz, the index structure of the resulting spinors is $\chi^{IA\alpha}$, formally the same as in the model of [17] described above, with the difference that now the index I is no longer a flavour one but it is acted on by the gauge group $\text{SU}(2)_1$ which was absent in the construction of [17], while $\text{SU}(2)_2$, acting on the A index, should be identified with the R-symmetry group of [17]. Therefore we expect that most of the applications of the model of [17] to the study of the topological features of graphene should also hold for our $\text{OSp}(4|2)_+ \times \text{SO}(2, 1)_-$ model. The main difference is the presence in the latter of additional gauge vectors $A_\mu^{IJ} = A_\mu^{JI}$, associated with $\text{SU}(2)_1$. It is tempting to identify these vectors with the true spin-connection, and the corresponding group $\text{SU}(2)_1$ with the true spin of the π -electrons in the honeycomb layer. From the Marauer-Cartan equations of the superalgebra, upon using the AVZ Ansatz, we derive, apart from the Dirac equations for $\chi^{IA\alpha}$, the following equations for the curvature and gauge field strengths:

$$\begin{aligned} R_+^i &= \frac{i}{\ell} \chi^{IA\alpha} \chi^{JB\beta} \epsilon_{IJ} \epsilon_{AB} \epsilon_{\alpha\beta} \epsilon^{ijk} e_j \wedge e_k, \\ \mathcal{F}^{AB} &\equiv dA^{AB} - \frac{1}{2} \epsilon_{CD} A^{AC} \wedge A^{DB} = -\frac{i}{\ell} \chi^{IA\alpha} \chi^{JB\beta} \epsilon_{IJ} (C\gamma^i)_{\alpha\beta} \epsilon_{ijk} e^j \wedge e^k, \\ \mathcal{F}^{IJ} &\equiv dA^{IJ} - \frac{1}{2} \epsilon_{KL} A^{IK} \wedge A^{LJ} = -\frac{i}{\ell} \chi^{IA\alpha} \chi^{JB\beta} \epsilon_{AB} (C\gamma^i)_{\alpha\beta} \epsilon_{ijk} e^j \wedge e^k, \end{aligned}$$

where $\mathcal{F}^{IJ} = \mathcal{F}^{JI}$ and $\mathcal{F}^{AB} = \mathcal{F}^{BA}$ are the field strengths associated with the internal symmetry groups $\text{SU}(2)_1$ and $\text{SU}(2)_2$, respectively. Interpreting the former as the true spin group, the corresponding field strength would describe the true spatial curvature of the two-dimensional sheet.

Note that if we choose the fermion field χ to have the following special ‘‘factorized’’ form $\chi^{IA\alpha} = v^{IA} \chi^\alpha$, where χ^α are Grassmann numbers while v^{IA} are real ones, in the above equations $\mathcal{F}^{AB} = \mathcal{F}^{IJ} = 0$ and the fermion field ceases to be a source for the gauge field strengths. We refrain from studying the features of this model any further here, leaving it to a future work.

5 Concluding remarks

Here we have seen how the extension of unconventional supersymmetry to the $\text{OSp}(p|2) \times \text{OSp}(p|2)$ superalgebra can be instrumental in describing the electronic properties of graphene-like systems in the \mathbf{K} and \mathbf{K}' valleys and thus physical situations in which the

symmetry between them is broken. These can be realized, for instance, by breaking reflection or time-reversal symmetries through the Semenoff or Haldane-type mass terms, as produced by the presence of suitable substrate and magnetic fields. One of the main results of this work was to embed this effective description in an \mathcal{N} -extended four-dimensional supergravity. This sets the stage of a holographic analysis which will be pursued in a future work.

There is a different application of our construction to the description of graphene, which makes contact with the work by Iorio and Pais [17], and which we just touched upon here.

As a final comment, we observe that a graphene sheet is “relativistic” in the sense of Fermi velocity v_F playing the role of analogue speed of light for the charge carriers. However, in our top-down approach the speed of light, as coming from the $D = 4$ supergravity model, is naturally identified with the true speed of light, c . Actually, this issue can be dealt with in different ways. We could either think of the $D = 4$ supergravity as already analogue, or we could instead define a more general relation between the two frames E^i and e^i than the one assumed here in (3.7), of the form $E^i = f \mathcal{M}^i_j e^j$. By choosing, for instance, $\mathcal{M} = \text{diag}(\alpha^2, 1, 1)$, we can introduce an analogue speed of light in the world volume $\hat{c} = \alpha c$. The mathematical implications of such assumption are under investigation by one of the authors [42].

We also leave to a future investigation the construction of explicit solutions, including topologically non-trivial configurations, to the equations of our model and the derivation from them of explicit phenomenological predictions.

A $\text{OSp}(\mathcal{N}|4)$ algebra and conventions

In this appendix we review the ortho-symplectic superalgebra and, while doing so, we state the conventions used in this paper.

The whole algebra is given by the following relations

$$\begin{aligned}
 [L_{AB}, L_{CD}] &= \kappa_{AD}L_{BC} - \kappa_{AC}L_{BD} + \kappa_{BC}L_{AD} - \kappa_{BD}L_{AC}, \\
 [T_{AB}, T_{CD}] &= \delta_{AD}T_{BC} - \delta_{AC}T_{BD} + \delta_{BC}T_{AD} - \delta_{BD}T_{AC}, \\
 [L_{AB}, Q_A^\alpha] &= -\frac{1}{2}(\tilde{\Gamma}_{AB})^\alpha_\beta Q_A^\beta, \\
 [T_{AB}, Q_C^\alpha] &= 2\delta^D_{[A}\delta_{B]C}Q_D^\alpha, \\
 \{Q_A^\alpha, Q_B^\beta\} &= \frac{1}{2\ell}(\tilde{\Gamma}^{\mathcal{EF}}C_5)^{\alpha\beta}\delta_{AB}L_{\mathcal{EF}} - \frac{1}{\ell}C_5^{\alpha\beta}T_{AB}.
 \end{aligned}
 \tag{A.1}$$

The first two properties describe the bosonic subalgebra of the subgroup $O(\mathcal{N}) \times SO(2, 3)$, where

$$\begin{aligned} \mathcal{A}, \mathcal{B}, \dots &= 0, 1, 2, 3, 4, \\ \kappa_{\mathcal{AB}} &= \text{diag}(+, -, -, -, +), \end{aligned} \tag{A.2}$$

and

$$A, B, \dots = 1, \dots, \mathcal{N}. \tag{A.3}$$

The other three relations extend the bosonic subalgebra to a supersymmetric one and necessarily involve the fermionic generators Q_A^α : they are Majorana spinors in the fundamental representation of $SO(\mathcal{N})$. Being spinors, they also have a Lorentz index α in the spinorial representation, which means that $\alpha, \beta, \dots = 0, 1, 2, 3, 4$. One can show that all these relations satisfy Jacobi identities, which in turn means that this is indeed an algebra.

We now clarify the conventions for the Dirac matrices: if $i = 0, 1, 2$, then

$$\begin{aligned} \Gamma^i &= \sigma_1 \otimes \gamma^i, & \gamma^0 &= \sigma_2, & \gamma^1 &= i\sigma_1, & \gamma^2 &= i\sigma_3, \\ \Gamma^3 &= i\sigma_3 \otimes \mathbf{1}, & \Gamma^5 &= i\Gamma^0\Gamma^1\Gamma^2\Gamma^3 = -\sigma_2 \otimes \mathbf{1}. \end{aligned} \tag{A.4}$$

with

$$\{\Gamma^a, \Gamma^b\} = 2\kappa^{ab}\mathbf{1}_{4 \times 4}, \tag{A.5}$$

where $\kappa^{ab} = \text{diag}(+, -, -, -)$ and $a, b, \dots = 0, 1, 2, 3$.

The $\tilde{\Gamma}_{\mathcal{A}}$ matrices appearing in (A.1) are related to the $D = 4$ gamma matrices Γ_a by

$$\tilde{\Gamma}_a := i\Gamma_a\Gamma_5, \quad \tilde{\Gamma}_4 := \Gamma_5, \tag{A.6}$$

in such a way that they satisfy

$$\tilde{\Gamma}_{ab} = \Gamma_{ab}, \quad \tilde{\Gamma}_{a4} = i\Gamma_a. \tag{A.7}$$

At last, the charge conjugation matrix C_5 appearing in the algebra is defined as

$$C_5 := \tilde{\Gamma}_0\tilde{\Gamma}_4 = \Gamma_0, \tag{A.8}$$

with the straightforward properties

$$C_5 = C_5^{-1} = -C_5^t = -C_5^*, \quad C_5^{-1}\tilde{\Gamma}_{\mathcal{A}}C_5 = (\tilde{\Gamma}_{\mathcal{A}})^t. \tag{A.9}$$

Notice that C_5 behaves as the usual 4-dimensional charge conjugation when acting on Γ_a matrices

$$C_5^{-1}\Gamma_aC_5 = -(\Gamma_a)^t. \tag{A.10}$$

In these cases we will just indicate the charge conjugation matrix as C .

Finally, the Dirac conjugate of a 4-d spinor is given by

$$\bar{\Psi} = -i\Psi^\dagger\tilde{\Gamma}_0\tilde{\Gamma}_4 = \Psi^\dagger\Gamma_0, \tag{A.11}$$

whereas a Majorana spinor satisfies the reality property

$$\Psi = -C_5\Psi^t = \Psi^*. \tag{A.12}$$

Conventions in $D = 3$. We choose the mostly minus convention for the signature of the three dimensional spacetime and $\epsilon^{012} = \epsilon_{012} = 1$. The Lorentz covariant derivatives are defined on vectors E^i as

$$\mathcal{D}[\omega]E^i := dE^i + \omega^{ij}E_j = dE^i - \epsilon^{ijk}\omega_j E_k, \quad (\text{A.13})$$

where $\omega^i := \frac{1}{2}\epsilon^{ijk}\omega_{jk}$, while on spinors ψ as

$$\mathcal{D}[\omega]\psi := d\psi + \frac{1}{4}\omega^{ij}\gamma_{ij}\psi = d\psi + \frac{i}{2}\omega^i\gamma_i\psi. \quad (\text{A.14})$$

B Microscopic description for graphene-like systems

Pure graphene quantum states can be formulated in terms of the so-called *tight-binding model*, describing electrons hopping in the (single-state per site) honeycomb lattice. In the limit of very far apart ions, the single-particle eigenstates refer to an electron affected by a single ion, resulting in a set of lattice sites with a single-level state. Within this model, electrons can tunnel to their first neighbor atoms, with a hopping amplitude t_1 (for graphene one has $t_1 \simeq -2.7$ eV). The electronic system is described by the single orbital, tight-binding Hamiltonian:

$$H_1 = t_1 \sum_{\langle i,j \rangle} c_i^\dagger c_j, \quad (\text{B.1})$$

where the creation (annihilation) operator $c_i^\dagger = c^\dagger(\mathbf{r}_i)$ ($c_i = c(\mathbf{r}_i)$) acts on particle site \mathbf{r}_i , and the sum $\langle i, j \rangle$ runs on nearest neighbors sites $\mathbf{r}_i, \mathbf{r}_j$.

B.1 Massive deformations

The above massless formulation is in general robust, since it comes out at the level of non-interacting system and is protected by combination of parity and time-reversal symmetry of the framework. However, mass terms for 2D, graphene-like systems can be obtained from generalization of a tight binding microscopic model, opening mass gaps at the Dirac points. This gap generation was first discussed by Semenoff, introducing a mass term through an on-site staggered potential $\pm M$ spoiling sublattices equivalence [38] and breaking parity symmetry of the theory. Another model was proposed by Haldane, including local magnetic fields over the honeycomb hexagon, breaking time-reversal symmetry of the model.

Haldane model. The formulation of the Haldane model [41] was motivated by the realization of a quantum anomalous Hall effect (topological, quantized insulating phase), in the absence of Landau level structure. This can be achieved by the introduction of periodic local magnetic flux densities, with zero net flux over the cell. The physical system is represented introducing in the microscopic Hamiltonian second-neighbor hopping terms with unimodular phase factor, the phase sign depending on the “chirality” of the electron path (according to whether the hopping is clockwise or anticlockwise w.r.t. the cell). The microscopic Hamiltonian can be written

$$H = H_1 + H_2 = H_1 + t_2 \sum_{\langle i,j \rangle_{(2)}} e^{i\varphi\alpha_{ij}} c_i^\dagger c_j + \epsilon_i M \sum_i c_i^\dagger c_i, \quad (\text{B.2})$$

where H_1 is the tight binding Hamiltonian and H_2 accounts for the local magnetic fields and for a Semenoff-type parity-breaking term. The first sum in H_2 runs on second nearest neighbors sites, t_2 being the hopping amplitude, while the second term is the Semenoff contribution coming from on-site potential energy M , the prefactor $\epsilon_i = \epsilon_{\pm} = \pm 1$ depending on whether the site i is on the first or second sublattice. The Aharonov-Bohm phase φ due to the local magnetic fluxes is taken as a parameter of the model and the factor $\alpha_{ij} = \pm 1$ gives the chirality of the path related to the second neighbor hopping.¹⁵

If we define a basis $(\zeta_A(\mathbf{k}), \zeta_B(\mathbf{k}))$ of two-component spinors of Bloch states constructed on the two sublattices A and B, after Fourier-transform the Hamiltonian in the \mathbf{k} -space reads:

$$\mathcal{H}(\mathbf{k}) = t_1 \sum_i (\cos(\mathbf{k} \cdot \mathbf{d}_i) \sigma_1 + \sin(\mathbf{k} \cdot \mathbf{d}_i) \sigma_2) + 2 t_2 \cos(\varphi) \sum_i \cos(\mathbf{k} \cdot \mathbf{d}_i^{(2)}) \mathbb{1} - 2 t_2 \sin(\varphi) \sum_i \sin(\mathbf{k} \cdot \mathbf{d}_i^{(2)}) \sigma_3 + M \sigma_3, \tag{B.3}$$

where σ_i are the Pauli matrices, while \mathbf{d}_i and $\mathbf{d}_i^{(2)}$ are the displacement vectors to the first and second nearest neighbors sites, respectively. The degeneracy of the bands at the Dirac points is lifted either by non-zero M or non-zero $t_2 \sin(\varphi)$, and the fermion masses in the two inequivalent valleys are [41]

$$m_i = m_{\pm} = M \mp 3\sqrt{3} t_2 \sin \varphi. \tag{B.4}$$

If we restrict to time-reversal invariant case, $t_2 \sin(\varphi) = 0$, the two masses m_+ and m_- are equal and the system behaves as a Semenoff insulator.

The Haldane model can provide an effective description also of specific 2D honeycomb lattices where the time-reversal symmetry is broken without the presence of local magnetic fields [43, 44].
