Rolling Contact Fatigue (RCF);
Stress Intensity Factors (SIFs)

Abstract The surface-initiated Rolling Contact Fatigue (RCF) including pitting and micro-pitting is one of the key issues affecting the reliability of tribological components such as gears and bearings used in various devices. In this work, a surface-initiated crack Finite Element (FE) model which considers the effect of lubricant on crack faces was developed to investigate surface-initiated RCF using an automatic crack propagating Python script. Different lubricating states, initial crack parameters and loading conditions were simulated to analyze the evolution of crack propagation and the Stress Intensity Factors (SIFs). The RCF crack propagation path and life were predicted by employing the Maximum Tangential Stress (MTS) criterion coupled with the Paris's law. A typical RCF failure is predicted in the numerical simulation. Results reveal that the lubricating pressurization dominates the surface-initiated RCF. In addition, the initial crack angle has a significant effect on the RCF crack propagation path and the fatigue life.

1. Introduction

Rolling Contact Fatigue (RCF), as one of the dominating factors leading to failures of rotating mechanical components such as gears and bearings, greatly affects the reliability and safety of high-performance machineries including aero-engine, wind turbine, car reducers and railway rails. RCF is

mainly dominated by surface or subsurface-initiated cracks. The subsurface-initiated failure, such as gear pitting and tooth internal flank fracture, normally occurs due to material inclusions,^{1,2} poor material hardness and residual stress gradients,³⁻⁵ etc. The surface-initiated failure type, including micro-pitting as given in Fig. 1,⁶⁻⁸ is the result of complicated interactions of loading conditions, surface topography,^{9,10} lubrication,¹¹⁻¹³ material microstructure and inclusions, etc. Currently, the subsurface-initiated failure is effectively suppressed due to the strict control of material defects and the improvement of case-hardening technologies.¹⁴ Therefore, the surface-initiated failure draws more attention as it extremely restricts the fatigue performance of modern mechanical systems.

Way¹⁵ was one of the pioneers to study surface-initiated failure for rolling contact through the experimental method.

C, m	Material constants, $C = 4.71 \times 10^{-14}$, $m = 5.42$	$\Delta\sigma_{\text{FL}}$	Fatigue limit, $\Delta\sigma_{\text{FL}} = 500 \text{ MPa}$
E	Equivalent elastic modulus, $E = 115.4 \text{ GPa}$		
K_1	Opening mode (Mode I) stress intensity factor, $\text{MPa}\cdot\text{mm}^{1/2}$		

43 He suggested that the hydraulic pressure has a great influence
 44 on the surface crack propagation in lubricated or mixed lubri-
 45 cated rolling contact cases. The penetration of oil into crack
 46 surface leads to the opening mode (Mode I) rather than the
 47 shear mode (Mode II). Based on the fracture mechanics, Keer

et al.¹⁶⁻¹⁹ extensively studied the surface and subsurface crack
 under rolling/sliding conditions in order to predict the crack
 propagation behavior. Miller et al.²⁰⁻²² focused on the short
 crack propagation considering the influence of other impacts
 such as the crack length, shot-peening, hydrogen element,

48
 49
 50
 51
 52

Fig. 1 Pitting, micro-pitting of rolling elements.⁶⁻⁸

etc. Results showed that shot-peening significantly decreases the short crack growth rate. Then, Bold et al.²³ experimentally and numerically studied the RCF crack propagation for large cracks (with length more than 10 mm), which mainly occurs in rails. Guo et al.²⁴ summarized some basic criteria to predict the crack propagation direction under mixed-mode condition and pointed out that the Maximum Tangential Stress (MTS) criterion is widely used for opening mode dominated crack. Ren et al.²⁵ numerically simulated the surface initiated crack propagation path under lubricated contact condition for a rolling gear. However, the fatigue crack propagation life was missed in this model. In 2008, Bogdanski and Lewicki²⁶ explored the Liquid Entrapment Mechanism (LEM) on a surface breaking crack based on a three-dimensional Finite Element (FE) model. In the LEM frame, the entrapped oil volume was assumed to be constant to calculate the oil hydraulic pressure. Maya-Johnson et al.²⁷ experimentally investigated the crack growth mechanism of rail steels (R370CrHT) under dry and lubricated RCF conditions. The effect of material inclusions on the crack propagation was also explored. Recently, considering both the fluid pressurization and entrapment effects, Ancellotti et al.^{28,29} numerically investigated the lubricated rolling-sliding contact fatigue. They found that the effect of pressurization on the crack propagation shows similar phenomenon with that of the entrapment case for short crack. However, the RCF crack propagation behavior is still not fully recognized due to the complex non-proportional loading history in comparison with the simple tensile loading and the instability of pure shear mode crack propagation.³⁰ Besides, the fatigue crack growth path and life, as the two important indicators of the RCF crack, are somewhat ignored in most previous work. Therefore, a comprehensive investigation on the fatigue crack growth behavior under lubricated rolling contact case needs to be addressed.

In the current work, a FE model which considers the effect of lubricant on crack faces is used to investigate the surface-initiated rolling contact fatigue using an automatic crack propagating Python script. The FE based contact pressure rather than the ideal Hertzian pressure assumption is adopted to obtain more accurate results. The uniform hydraulic pressure coupled with the pressurization mechanism²⁹ are utilized to investigate the fatigue crack propagation for lubricant contact. The algorithm of interaction integral is adopted to calculate the Stress Intensity Factors (SIFs). The MTS criterion and the Paris's law are employed to reconstruct the surface-initiated crack propagation and predict the fatigue life, respectively. This work provides a new surface-initiated crack propagating algorithm and lays a foundation for a further exploration of more complex RCF crack growth problems.

2. Numerical methodology

2.1. Finite element model

The RCF crack normally occurs in gears, bearings, rails, etc., under repeated rolling-sliding. A numerical rolling contact model carrying a surface inclined crack is developed to investigate the typical RCF crack growth problem. The commonly used carburized steel material (18CrNiMo7-6) with the elastic modulus 210 GPa and the Poisson's ratio 0.3 is adopted. A schematic diagram of the surface-initiated crack RCF model

is illustrated in Fig. 2. The equivalent elastic modulus and Poisson's ratio of RCF model (with infinite half plane) are $E = 115.4$ GPa and $\nu = 0.3$ based on the Hertzian contact theory. In Fig. 2, a surface-initiated crack (crack length $a_0 = 0.02$ mm) with the inclining angle θ_0 is utilized to represent the crack body. x and y are the coordinate axes of the global coordinate system; x_0 and y_0 are the coordinate axes of the local coordinate system in the crack tip, respectively; θ_1 is the crack propagation direction; $p_{(x)}$ and b are the contact pressure distribution (from $-b < x < b$) and the half contact width, respectively; $q_{(x)}$ is the traction distribution; o is crack mouth; p_{liq} is hydraulic pressure.

The interacting counterpart of the infinite half plane moves from left to right on the surface. Starting from $x = -3b$, the contact pressure $p_{(x)}$, passes through the crack mouth and finally moves to the position of $x = 3b$ with 100 time-step in the FE simulation. The total rolling distance $6b$ ensures a complete loading stress history (from the engage-in to the recess point) for the crack to simulate a complete meshing cycle. It is worth noting that the commonly used Hertzian contact pressure is strongly idealistic and deviates from the actual pressure profile, especially for heavy loading conditions. Therefore, four contact pressure loading cases based on the FE calculation, listed in Table 1,³¹ are programmed in this work.

The effect of surface friction is represented by means of the traction distribution $q_{(x)}$, which is expressed as

$$q_{(x)} = fp_{(x)} \quad (1)$$

where f is the frictional coefficient between two contacting surfaces. p_{liq} represents the hydraulic pressure applied on the crack faces, and is assumed to correspond with the contact pressure in the crack lip based on the pressurization mechanics. Therefore, it has

$$p_{\text{liq}} = p_{(x=0)} \quad (2)$$

The fluid may be sealed in the crack and further results in a complex crack fluid pressure distribution, especially for long crack cases.¹¹ However, considering that the initial crack length is much smaller than the half contact width b , the above function can be taken as a reasonable simplification of the pressurization mechanism.¹¹ It should be noted that this is one of the simplest assumptions for crack pressure and may overestimate the actual effect of fluid pressure.²⁵ In addition, the crack face is closed after the contact pressure passing through the surface crack position. However, considering that the crack growth is dominated by the pressurization mechanism in the loading process, the crack closure effect³² caused by the unloading process is neglected.

Fig. 2 Schematic diagram of surface-initiated crack RCF model.

Table 1 Maximum pressure and half contact width under different loading cases.³¹

Loading case	1	2	3	4
Maximum contact pressure p_{\max} (MPa)	817	1110	1212	1300
b (mm)	0.60	0.80	1.00	1.20

161 Fig. 3 illustrates the FE model with a initial crack. A finite
 162 computational domain $20\text{ mm} \times 10\text{ mm}$ is employed to repre-
 163 sent the infinite half plane to decrease the calculation expense
 164 while keep the accuracy. A circular region with a radius of
 165 0.008 mm , located in the crack tip, is partitioned for fine ele-
 166 ment meshing. The mesh size in the circular region and the
 167 crack surface is set to be 0.002 mm to ensure convergence.
 168 Gradually coarser meshes away from the critical area are gen-
 169 erated to reduce the computational cost. The element number
 170 for the initial model is 23341. The stress in the crack tip is infi-
 171 nite when the crack is opening and loaded, representing the
 172 stress singularity characteristics.³³ Therefore, the singular ele-
 173 ment type specifying to crack calculation is arranged in the
 174 crack tip and the CPE4R element type is set in the remaining
 175 area. The FE model is re-meshed after each crack propagation
 176 step. Hence, the element number increases slightly for each
 177 crack propagation process due to the use of remeshing
 178 method. The loading cycle shown in Fig. 3 is applied in the
 179 FE model for fatigue simulation.

180 **2.2. Determination of crack propagation**

181 Two vital factors, namely the crack propagation direction and
 182 the crack propagation rate, are involved in this solving pro-
 183 cess. Owing to the effect of the oil hydraulic pressure, which
 184 transmits the shear mode dominated crack propagation into
 185 the opening mode, the widely used MTS criterion can be uti-
 186 lized to predict the surface-initiated crack propagation direc-
 187 tion. Based on this assumption, the crack propagation
 188 direction θ is supposed to satisfy³⁴

189
$$K_1 \sin\theta + K_2(3\cos\theta - 1) = 0 \tag{3}$$

192 where K_1 and K_2 are the opening and shear mode SIFs, respec-
 193 tively. The algorithm of interaction integral is adopted to cal-
 194 culate the SIFs. The derivation procedure is given in the
 195 Appendix. Then, the expected extending angle can be derived
 196 as
 197

198
$$\theta = 2 \tan^{-1} \frac{-2K_2}{K_1 + \sqrt{K_1^2 + 8K_2^2}} \tag{4}$$

199 The other indispensable part, namely the crack propagation
 200 rate da/dN , is calculated by the Paris's law:³⁵

201
$$\frac{da}{dN} = C(\Delta K_{\text{eff}})^m \tag{5}$$

202 where C and m are the material constants and are set to be
 203 4.71×10^{-14} and 5.42 , respectively;³⁶ ΔK_{eff} is the amplitude
 204 of the effective SIF K_{eff} and equals to the maximum K_{eff} for
 205 one loading cycle, namely $\Delta K_{\text{eff}} = \max(K_{\text{eff}}) - \min(K_{\text{eff}})$. The
 206 effective SIF can be expressed as³⁷

207
$$K_{\text{eff}} = \left(K_1 - 3K_2 \tan \frac{\theta}{2} \right) \cos^3 \frac{\theta}{2} \tag{6}$$

208 It should be noted that SIFs vary during one loading cycle,
 209 and further results in the change of crack propagation direc-
 210 tion according to Eq. (3). Therefore, the time-varying angle θ
 211 for one loading cycle is determined based on such a criterion
 212 where the crack growth rate reaches to the maximal (da/dN)
 213 $(\theta)_{\max}$.³⁸

214 It is worth noting that the classical Paris's law is only valid
 215 for long fatigue crack growth where the crack length is longer
 216 than the threshold crack length a_{th} .^{39,40}

217
$$a_{\text{th}} = \frac{1}{\pi} \left(\frac{\Delta K_{\text{th}}}{\Delta \sigma_{\text{FL}}} \right)^2 \tag{7}$$

Fig. 3 Meshing of simulation model.

where $\Delta\sigma_{FL}$ is the fatigue limit; ΔK_{th} is the SIF threshold. The fully reversed tensile fatigue limit of the steel material used is measured as about 500 MPa. ΔK_{th} used is set as³⁶ $\Delta K_{th} = 80 - \text{MPa}\cdot\text{mm}^{1/2}$. Therefore, the Paris's law can be used when the crack length exceeds $a_{th} = 0.008$ mm. After that, the number of repeated loading cycles ΔN for a specific crack propagation length Δa can be calculated as

$$\Delta N = \frac{da}{dN} \Delta a \quad (8)$$

where Δa is set to be 0.02 mm, equals to the length of the initial crack. Based on the fracture mechanics, the fatigue failure occurs when ΔK_{eff} reaches a critical value K_c , namely the fracture toughness. The magnitude of $K_c = 630 \text{ MPa}\cdot\text{mm}^{1/2}$ for the steel material is used.³⁶ Finally, the fatigue crack propagation life N_p for gear RCF can be calculated. During simulation, some more loading cycles have been conducted after the predefined fatigue failure to form an obvious crack propagation path. However, these repeated loading cycles have negligibly small effect on the fatigue life according to Eqs. (5) and (8).

The numerical scheme for the fatigue crack propagation simulation is depicted in Fig. 4, where superscript i represents the i th loading cycle. The crack coupled FE model is developed based upon the parameters of the material and the crack. The stress and strain responses are captured after the pressure moves from $-3b$ to $3b$. SIFs are calculated in the following step based on the interaction integrals, and further, the crack propagation direction and growth rate can be obtained. After that, if ΔK_{eff} is less than K_c , an updated crack is formed for next crack propagation. Otherwise, the fatigue crack propagation simulation is finished.

3. Results and analyses

The singularity characteristic in the crack tip probably leads to the non-convergence phenomenon of crack tip stress even for an extremely fine mesh case. Therefore, the simulation model is verified through the comparison of the SIFs distributions given in Fig. 5(a) and 5(b) for different local mesh sizes, namely 1, 2, 4 μm , under Load case 2. The horizontal axis (x) represents the distance to the crack lip in the contact surface. The difference of the magnitude of K_I decreases from 5.7% to 2.5% when the local mesh size changes from 4 μm to 2 μm compared with the result of the finest case. This phenomenon presents the convergence of the developed FE model. Hence, the local mesh size of 2 μm coupled with Load case 2 are adopted for the following simulation.

3.1. Effect of lubricating states

The evolutions of opening and shear mode SIFs during one loading cycle are depicted in Fig. 6(a) and (b), respectively. It should be noticed that investigates the effect of the lubricating states not merely the hydraulic pressure on the crack face. That is to say, the variation of friction as the lubrication state changes needs to be considered as well. Therefore, the frictional coefficient f is set to be 0.08⁴¹ representing the lubricated case. The rest different friction coefficients from 0.1 to 0.4 represent the non-lubricated conditions, where the hydraulic pressure is absent. On one hand, it can be observed that both the two SIFs display as positive values before approaching the contact center. Besides, with the increasing of the frictional coefficient f , the magnitude of both SIFs rises. On the other

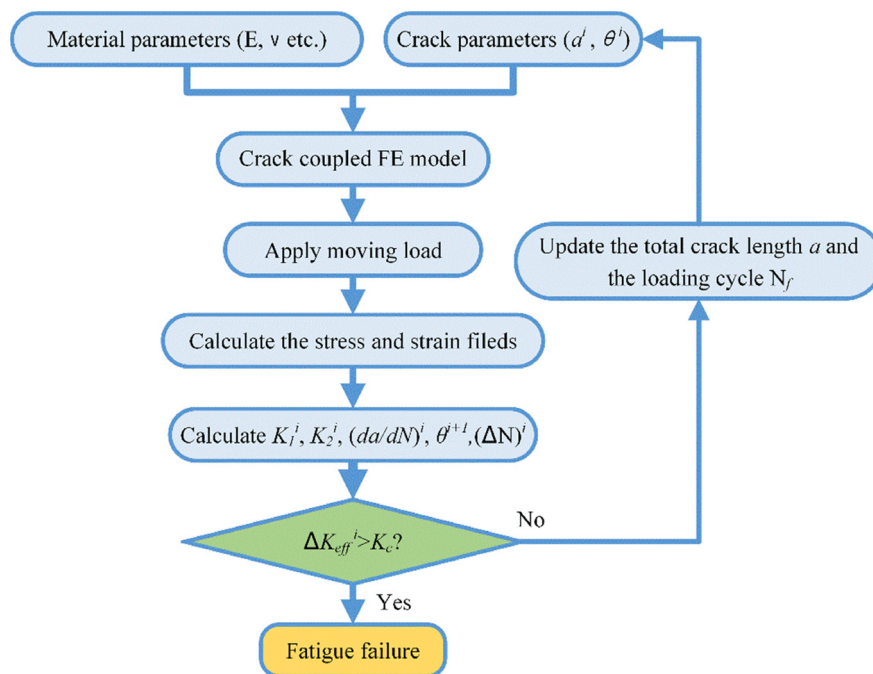

Fig. 4 Algorithm flow chart of fatigue crack propagation simulation.

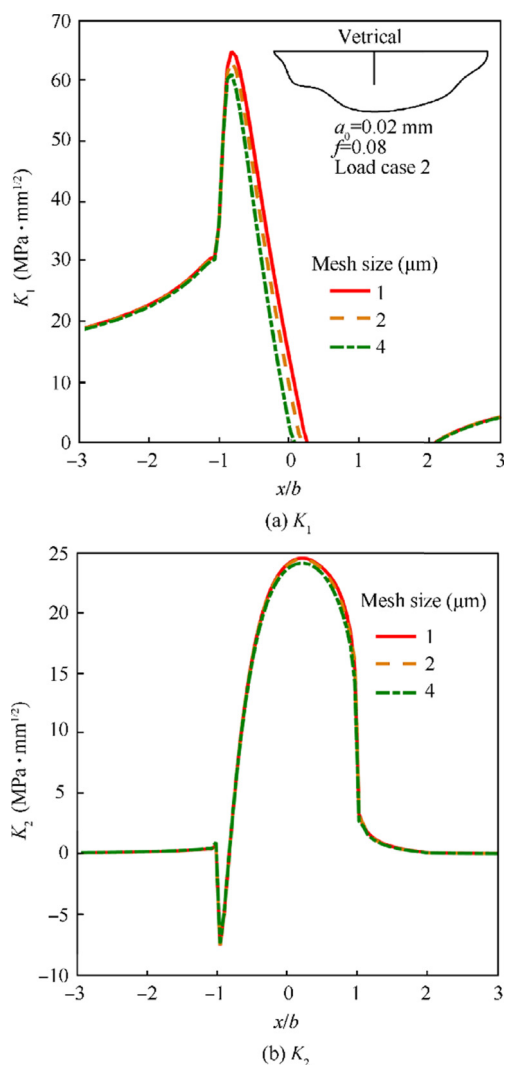

Fig. 5 Convergence verification of simulation model.

285 hand, K_1 rises sharply while K_2 declines remarkably for the
 286 lubricated case compared with the non-lubricated condition.
 287 This is because the hydraulic pressure tends to open the crack
 288 faces and further increases the value of K_1 .

289 Fig. 7 depicts the amplitude of the effective SIF under these
 290 two conditions. It is clear that the change of ΔK_{eff} almost linearly
 291 corresponds to f for non-lubricated cases. A higher value
 292 of f would result in a larger magnitude of ΔK_{eff} . Nevertheless,
 293 the crack opening effect caused by the lubricant pressure rises
 294 the possibility of crack propagation. For instance, the value of
 295 ΔK_{eff} for the lubricated case is twice that of the non-lubricated
 296 case with $f = 0.1$.

297 3.2. Effects of initial crack parameters

298 Fig. 8(a) illustrates the evolution of K_1 during one loading
 299 cycle for different initial crack angles (θ_0). According to the
 300 evolutions of K_1 , a relative larger initial crack degree would
 301 keep the crack faces opening for a longer time during a complete
 302 loading cycle. Meanwhile, θ_0 has a significant effect on
 303 K_2 , as displayed in Fig. 8(b). The maximum of K_2 rises from

Fig. 6 Evolution of two SIF components under different conditions.

Fig. 7 Amplitude of effective SIF under different conditions.

304 16.0 MPa·mm^{1/2} to 26.5 MPa·mm^{1/2} when the initial crack
 305 direction changes from 30° to 75°. In addition, the correspond-
 306 ing minimum value increases from -15.5 MPa·mm^{1/2} to
 307 5.0 MPa·mm^{1/2}. In other words, the positive part of K_2
 308 becomes more important as the initial crack direction
 309 increases.

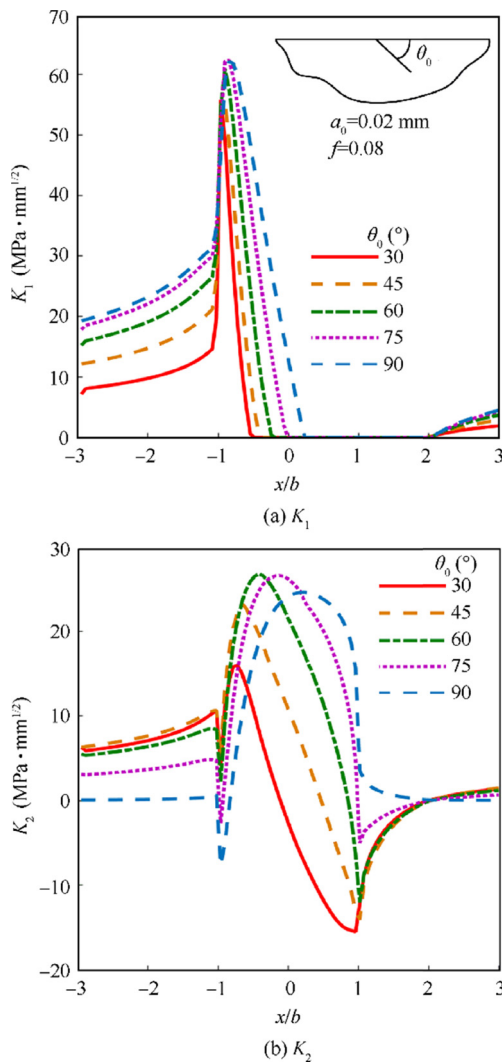

Fig. 8 Evolution of SIF components with different initial crack angles.

Fig. 9 Amplitude of effective SIF and predicted crack propagation direction under lubricated conditions for different initial crack angles.

Fig. 9 shows the amplitude of the effective SIF and the predicted crack propagation direction for different θ_0 . What can be easily seen is that when the angle between the initial crack direction and the surface is very small, such as 15° or 165° , the amplitude of the effective SIF is considerably large compared with other cases. The crack tends to propagate to the surface for such small initial angles according to the predicted crack propagation angle θ_1 . This is because the crack faces are more likely to open for a small initial crack angle and result in the departure of near surface materials due to the effect of hydraulic pressure. However, the value of SIF increases from $61.1 \text{ MPa} \cdot \text{mm}^{1/2}$ to $66.7 \text{ MPa} \cdot \text{mm}^{1/2}$ and then decreases to $43.0 \text{ MPa} \cdot \text{mm}^{1/2}$ when the initial crack angle increases from 30° to 150° . The peak value of $66.7 \text{ MPa} \cdot \text{mm}^{1/2}$ appears with the initial crack angle around 60° . The predicted propagation angle is negative for the range of $\theta_0 = 30^\circ - 90^\circ$ and positive for the range of $\theta_0 = 90^\circ - 150^\circ$. That is to say, the crack would firstly propagate to the core area beneath the surface for these cases.

Evolutions of SIFs for different initial crack lengths under one loading cycle are depicted in Fig. 10. It is obvious to see

Fig. 10 Evolution of SIFs components with different initial crack lengths.

Fig. 11 Contour plot of ΔK_{eff} for different initial crack parameters, including θ_0 and a_0 .

that the initial crack length a_0 has a significant effect on the amplitude of SIFs with similar evolution curves. The amplitude of K_1 dramatically rises from $35 \text{ MPa}\cdot\text{mm}^{1/2}$ to $270 \text{ MPa}\cdot\text{mm}^{1/2}$ when the initial crack length increases from 0.02 mm to 0.10 mm . The amplitude of K_2 also rises from $23.0 \text{ MPa}\cdot\text{mm}^{1/2}$ to $96.5 \text{ MPa}\cdot\text{mm}^{1/2}$. Besides, the position of the peak value of SIFs shifts to the right side as the initial crack length increases.

A comprehensive effect of the initial crack parameters, including the crack length and the angle, on ΔK_{eff} is plotted in Fig. 11. High ΔK_{eff} is arrested when the angle between

the initial crack direction and the surface is small. This phenomenon becomes more significant with the increasing of the initial crack length a_0 . In addition, the unsymmetrical characteristic is captured in Fig. 11 even though the presented angles are symmetric about the initial crack direction ($\theta_0 = 90^\circ$), namely a vertical crack. This is because entirely different stress histories would emerge in the crack tip for these geometrically symmetric cracks during one complete loading cycle, which further forms different evolutions of SIF components.

3.3. Effect of loading condition

The loading amplitude is an extremely vital factor influencing the RCF behavior. The variation of the normal loading amplitude results in the change of the half contact width b and the maximum contact pressure p_{max} . Table 1 gives the corresponding data for different loading cases used.

The maximum principal stress (σ_1), as a key stress parameter to represent the crack opening trend, is illustrated in Fig. 12 for different loading cases when the contact pressure reaches $x = -b$. Despite the singularity characteristic of the stress response in the crack tip, the stress maps have a similar shape for all loading cases. Besides, the stress around the crack tip rises as the loading amplitude increases. In other words, the crack propagates more easily for a higher loading amplitude.

Fig. 12 Maximum principal stress for different load cases when contact pressure reaches $x = -b$ and initial angle $\theta_0 = 30^\circ$.

Fig. 13 Evolutions of SIFs components under lubricated conditions with different loading amplitudes.

It is clear from Fig. 13 that the amplitudes for both K_1 and K_2 rise sharply as the load increases. This is because the stress fields near the crack tip encounter a considerable growth for a heavy load condition. Besides, it is interesting to find that the positions of the maximum and minimum values for K_1 and K_2 during one loading cycle are keeping away from the contact center as the load increases. This phenomenon is caused by the change of the half contact width. In practical, the extreme values always occur near the positions where the contact area approaches or leaves the crack mouth.

3.4. Prediction of RCF crack propagation path and life

The effects of initial crack angle, length and normal loading amplitude have been investigated in Sections 3.2 and 3.3. Section 3.4 focuses on the prediction of the crack propagation path and life. Several initial crack angles (30° , 45° , 60° and 90°) with the same initial crack length 0.02 mm and load condition (Load case 2) are chosen to investigate the crack propagation. The crack increment has great effect on the predicted crack path and life. Hence, the crack propagation increment

for the first ten loading cycles is set to be a sufficiently small value of 0.02 mm and extends to 0.04 mm after the 10th loading cycle to save the time expense.

Fig. 14 depicts the stress maps of σ_1 for different crack propagation states when the contact pressure reaches $x = -b$ under the initial angle $\theta_0 = 30^\circ$. It is obvious that the maximum value of σ_1 increases sharply with the growth of crack length a . The tremendous growth of σ_1 indicates that the crack would propagate much more easily with the increasing of crack length. It is worth noting that the stress response can only show the crack opening tread due to the singular characteristic rather than the real stress response during crack propagation.

Fig. 15 illustrates the evolutions of the effective SIF amplitude with the increase of crack length for different initial crack angles. For the initial crack angle $\theta_0 = 30^\circ$ case, ΔK_{eff} grows slowly for crack lengths within 0.20 mm while rises dramatically afterwards. In contrast, ΔK_{eff} in other cases increase very slowly. That is to say, when ΔK_{eff} is to be determined, the branched crack can be approximately replaced by a straight crack for short cracks. It is worth noting that when ΔK_{eff} exceeds the fracture toughness, the Paris's law is not applicable as the rate of crack advance tends towards infinity and the crack will propagate instantaneously. However, it has a negligibly small effect on the fatigue life.

Evolution of the propagation rates with the increase of crack length is depicted in Fig. 16. The crack growth rate generally rises with the crack length for all cases, which has a similar trend with the experimental results published in Ref. 42. Furthermore, according to Eq. (5), the growth rate is strongly affected by ΔK_{eff} . Hence, it is reasonable that the growth rate becomes larger for the initial crack angle $\theta_0 = 30^\circ$ compared with the rest cases under the same crack length.

Fig. 17 depicts fatigue crack propagation paths for different initial crack angles and reveals that the initial crack angle affects the RCF fatigue crack growth path to a large extent. Cracks propagate to the core for all cases in the first several propagation steps. While, for the case of $\theta_0 = 30^\circ$, the crack begins to grow to the surface after reaching the deepest position around 0.072 mm, and finally forms a typical surface-initiated RCF failure.

The RCF fatigue crack propagation lives (N_p) for these four cases are listed in Table 2. Similar with the crack growth rate, the initial crack angle θ_0 significantly affects the fatigue crack propagation life. For example, N_p changes from 1.28×10^7 to 0.87×10^7 , with a 32% drop, when the initial crack angle rises from 30° to 60° . This phenomenon can be explained through Eq. (4) and Fig. 9. The fatigue crack propagation rate is strongly affected by ΔK_{eff} . Even a slight increase of ΔK_{eff} would sharply increase the propagation rate, and further reduce the fatigue life. Besides, the first several crack propagation steps dominate the fatigue life. Hence, according to Fig. 9, the predicted RCF crack propagation lives are rational. It is worth noting that the fatigue life is calculated based on the $da/dN(\theta)_{\text{max}}$ criteria. The simulation result requires verification through future experimental studies.

4. Discussion

In engineering practice, the initial crack could have some complex shapes such as c-shape crack⁴³ and semi-elliptical crack.⁴⁴

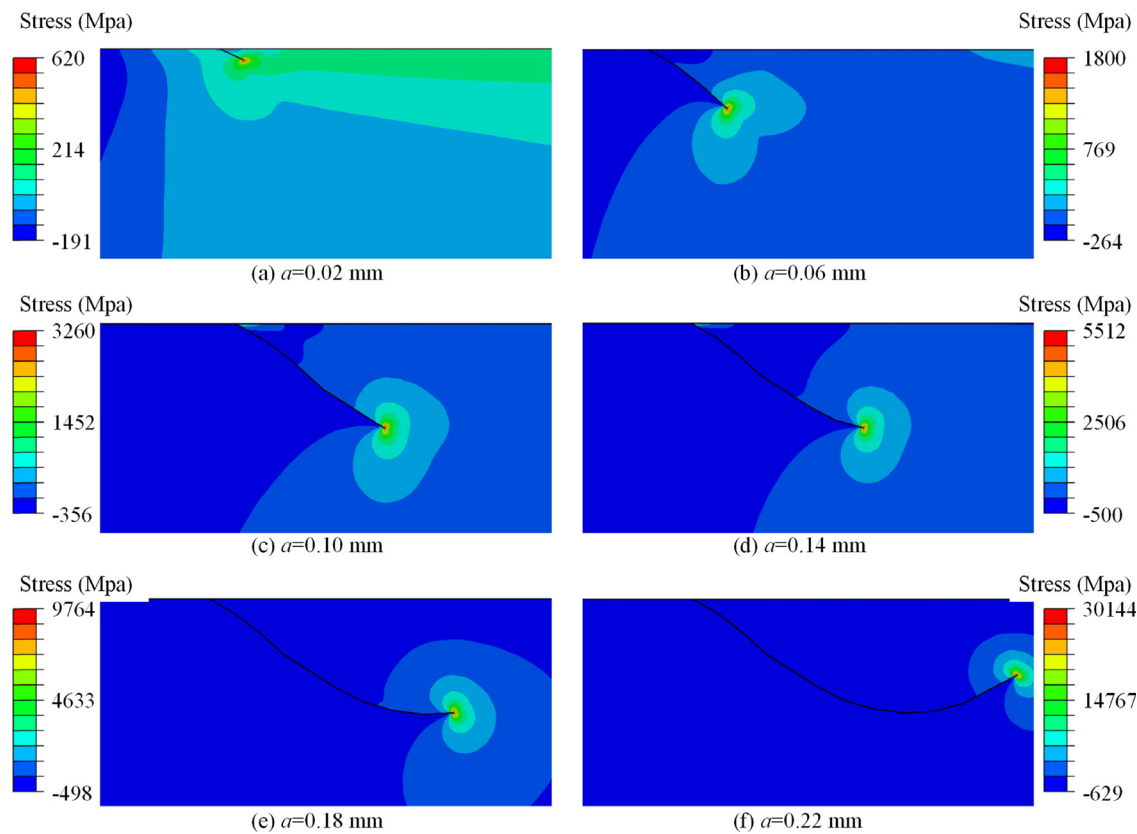

Fig. 14 Stress maps of σ_1 for different crack propagation states when contact pressure reaches $x = -b$ under initial angle $\theta_0 = 30^\circ$.

Fig. 15 Evolution of effective SIF amplitude with increase of crack length.

Fig. 16 Evolution of propagation rates with increase of crack length.

445 An idealized initial crack (straight crack)^{14,45} is utilized for
 446 crack propagation prediction. The difference of crack shapes
 447 would influence the SIFs calculation, and further affect the
 448 crack propagation for long crack. However, the initial crack
 449 length used currently is small enough to minimize the influence
 450 of crack shape. In addition, a straight crack is convenient for
 451 obtaining a general evolution of crack propagation.

452 Both the surface traction and the hydraulic pressure are
 453 taken into consideration when the effect of lubricating state
 454 is investigated in Fig. 6. This is because during the engineering

455 practice, the existence of lubricant would reduce the surface
 456 friction and form the hydraulic pressure on the crack face.
 457 Therefore, it is necessary to consider these two factors rather
 458 than the hydraulic pressure only. In addition, the fact that
 459 K_2 decreases for the lubricated condition in Fig. 6 is valid only
 460 for the case that the initial crack length is much smaller than
 461 the half contact width. This is because the lubrication
 462 decreases the friction coefficient between crack faces, and fur-
 463 ther enhances the shear mode crack growth when the crack
 464 length approaches to the contact width. Therefore, the pro-
 465 posed methodology does not take this effect into account.

Fig. 17 RCF fatigue crack propagation paths for different initial crack angles.

Table 2 RCF fatigue crack propagation lives for different initial crack angles.

θ_0 ($^\circ$)	N_p (10^7)
30	1.28
45	1.08
60	0.87
90	1.06

466 In Fig. 8(a), what is interesting is the phenomenon that the
 467 maximum K_1 for all cases occurs near the position of $x = -b$.
 468 This is because the invasion of lubricant results in the hydraulic
 469 pressure on the crack faces, which further dramatically rises
 470 the value of the opening mode SIF when the contact pressure
 471 firstly reaches the crack lip at $x = -b$. However, the crack
 472 faces changes to closed because the crack length is much less
 473 than the half contact width after that position, leading to the
 474 aforementioned phenomenon.

475 The phenomenon that the peak value of ΔK_{eff} for $\theta_0 = 30^\circ$ –
 476 150° emerges around in 60° is worth discussing. In reality, this
 477 may be the combining result of the hydraulic pressure, the contact
 478 pressure and the friction force. The contact pressure
 479 would weaken the influence of the hydraulic pressure on the
 480 crack face when the vector directions of these two pressure
 481 parameters are gradually approaching to each other. There-
 482 fore, the peak value of K_1 does not occur for small angles,
 483 for example, $\theta_0 = 30^\circ$ and $\theta_0 = 150^\circ$. Besides, the friction
 484 force changes the amplitude of K_2 for different θ_0 . Hence, coupled
 485 with the value of K_1 , this interesting phenomenon is
 486 finally observed.

487 In Fig. 16, the difference between $\theta_0 = 30^\circ$ and other cases
 488 become more significant with the increasing of the crack
 489 length. This phenomenon can be explained through Fig. 18.
 490 As the crack grows, shown in Fig. 18(a) and (c), the loading
 491 area for the hydraulic pressure increases, which further arising
 492 the impact of the hydraulic pressure on the crack face consid-
 493 ering that the contact pressure keeps constant. Besides, for a
 494 smaller initial crack angle, the crack tends to open easier com-
 495 pared with Fig. 18(b) and (d). This combined effect results in a
 496 larger ΔK_{eff} for a small initial angle. In addition, once ΔK_{eff}
 497 exceeds the fracture toughness, the fatigue crack propagation
 498 failure occurs, and ΔK_{eff} would encounter dramatic increase
 499 for the following loading cycles.

500 The developed numerical model is verified based on the
 501 meshing size check without the comparison with experimental
 502 results. Therefore, a robust experimental verification of the
 503 current model is recommended. Another important issue is
 504 that the crack size considered in this work is with the micron
 505 scale, which has the same magnitude with the material
 506 microstructure grain size⁴⁶ and surface roughness.⁴⁷ Therefore,
 507 the homogeneous material and smooth surface assumption
 508 may be limitation when predicting the short crack propagation
 509 for RCF problems. A numerical model considering the effect
 510 of material microstructure and surface roughness would be
 511 more preferred.

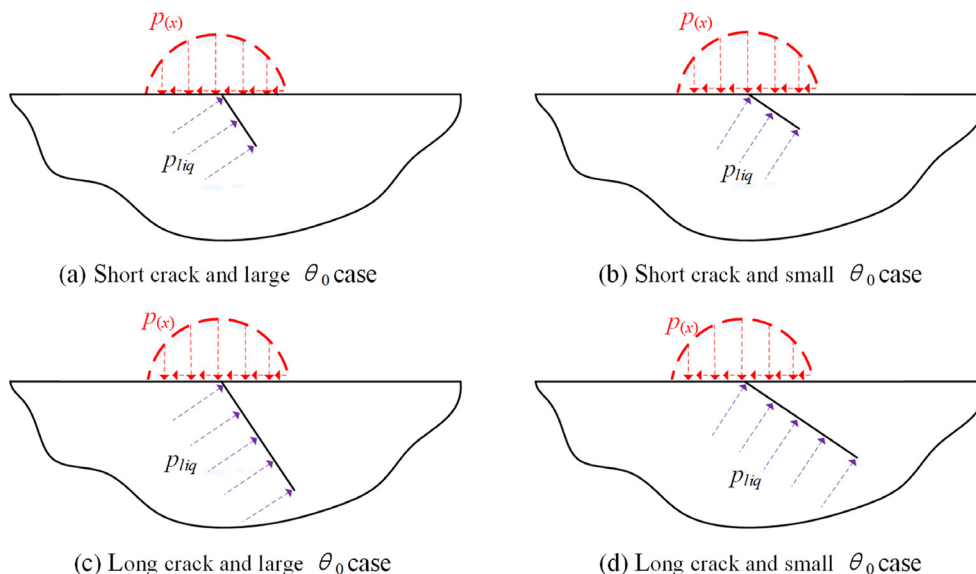

Fig. 18 Loading state for different crack lengths and different initial crack angles.

5. Conclusions

- (1) Under the lubricated condition, the hydraulic pressure on crack faces caused by lubrication would sharply increase the opening mode stress intensity factor. Meanwhile, the lubrication between contacting surface decreases the frictional coefficient and further results in the decreasing of the shear mode SIF for short crack.
- (2) The initial surface-initiated crack angle has a significant effect on the RCF crack propagation path. With a small initial crack angle, the crack grows to the core in the beginning, and then propagates towards the surface till a typical RCF spalling failure is formed. The crack may propagate deeper with a larger initial crack angle.
- (3) The fatigue life mainly depends on the early propagation period. Besides, the initial crack angle has a significant effect on RCF crack propagation life. The RCF crack propagation life decreases 32% as the initial angle increases.

Appendix

SIFs are calculated based on the interaction integrals. A brief introduction about this method is shown, the detailed derivation can be found in Ref. 48. Based on the linear elastic fracture mechanics, the present real state (State 1, stress, strain and displacement are $\sigma_{ij}^{(1)}$, $\varepsilon_{ij}^{(1)}$ and $u_i^{(1)}$) coupled with an auxiliary state (State 2, $\sigma_{ij}^{(2)}$, $\varepsilon_{ij}^{(2)}$ and $u_i^{(2)}$) are utilized to obtain SIFs. The interaction integral $I^{(1+2)}$ in the superimposed state (State 1 + State 2) is expressed as

$$I^{(1+2)} = \int_A \left(\sigma_{ij}^{(1)} \frac{\partial u_i^{(2)}}{\partial x_1} + \sigma_{ij}^{(2)} \frac{\partial u_i^{(1)}}{\partial x_1} - w^{(1,2)} \delta_{1,j} \right) \frac{\partial q}{\partial x_i} dA \quad i, j = 1, 2 \quad (\text{A1})$$

where A is the integral domain which should surrounds the crack tip; x_1 and x_2 are the local coordinate axes x and y in the crack tip; $\delta_{1,j}$ is the Kronecker's delta; q is the weight function and suffers specific values in the crack tip and boundary;⁴⁹ $w^{(1,2)}$ is the interaction strain energy and can be given as

$$w^{(1,2)} = \sigma_{ij}^{(1)} \varepsilon_{ij}^{(2)} \quad (\text{A2})$$

Furthermore, SIFs have the following connection with the interaction integral under the plane strain assumption:

$$I^{(1+2)} = \frac{2(1-\nu^2)}{E} (K_1^{(1)} K_1^{(2)} + K_2^{(1)} K_2^{(2)}) \quad (\text{A3})$$

Making the auxiliary state satisfy the pure opening mode asymptotic fields with $K_1^{(2)} = 1$. That is to say

$$\begin{cases} K_1^{(2)} = 1 \\ K_2^{(2)} = 0 \end{cases} \quad (\text{A4})$$

Then, combining Eqs. (A3) and (A4), the present opening mode SIF can be derived as

$$K_1^{(1)} = \frac{E}{2(1-\nu^2)} I^{(1+\text{mode I})} \quad (\text{A5})$$

Similarly, the model II SIF can be obtained as

$$K_2^{(1)} = \frac{E}{2(1-\nu^2)} I^{(1+\text{mode II})} \quad (\text{A6})$$
