## 1 ABSTRACT

1
,
_

In this work, the solubility of thymoquinone, R-(+)-pulegone and 1-octen-3-ol in 3 supercritical CO2 is determined in a range of conditions typical of supercritical fluid 4 processes such as extraction, fractionation and impregnation. These compounds were 5 selected based in their insecticidal activity which may enable to apply them as 6 biopesticides. Solubility was measured using a semicontinuos method in the temperature 7 8 range of 45-65°C and pressure of 8-12 MPa, at a CO<sub>2</sub> flowrate of 0.05-0.10 g/min, which was verified to be low enough to ensure saturation. Solubilities were predicted 9 using the Group Contribution Equation of State (GC-EoS) and compared to the 10 experimental results, with a good agreement. Consistency of the data was tested using 11 the density-based Chrastil equation. 12

14 **Key words:** solubility, thymoquinone, *R*-(+)-pulegone, 1-octen-3-ol, supercritical carbon dioxide, GC-EoS.

### 1. Introduction

7
,

1

Essential oils and many of their volatile components show a wide range of bioactive 3 properties, and therefore they are currently used in cosmetic, perfume, sanitary and oral 4 care products, as well as in agronomic industry, as food preservatives and additives, and 5 in pharmaceutical formulations [1], besides their use in traditional medicine since ancient 6 7 times. In this work, the solubility of three selected bioactive compounds in supercritical CO<sub>2</sub> 8 (scCO<sub>2</sub>), namely thymoquinone, R-(+)-pulegone and 1-octen-3-ol, naturally occurring in 9 several essential oils, is presented. The chemical structures of these compounds are 10 shown in **Table 1**. Thymoquinone is extracted from several plants, such as *Nigella sativa* 11 (black cumin) [2], Origanum vulgare L. [3], Monarda didyma (scarlet bee balm), 12 13 Monarda fistulosa (wild bergamot) [4], Thymus pulegioides, Thymus serpyllum, Thymus vulgaris, Satureja hortensis, Satureja montana, Eupatorium cannabinum and Juniperus 14 15 communis [5], among others. This compound is claimed to show antioxidant, antiinflammatory, anticancer, antimicrobial, hepatoprotective, immunomodulatory, and 16 antiparasitic activities [6][7][8], which explains the interest of its recovery from herbs. R-17 (+)-pulegone is a monoterpene ketone present in the essential oil of many mint species, 18 19 sometimes in a very high percentage [9]. For example, it is the major constituent of Mentha pulegium [10], Minthostachys verticillata [11] and, in minor concentration, is 20 also present in peppermint oil (Mentha piperita) [9] and Zuccagnia punctata [12], among 21 22 others. Toxicity effects of pulegone have been observed in mice, rats and humans because it is oxidized by cytochrome P450 to reactive metabolites such as menthofuran 23 [13][14]. Consequently, pulegone is subject to several regulations as flavouring agent by 24 the European Parliament and limitations in its use as cosmetic ingredient [13]. Finally, 1-25

1 octen-3-ol (also known as "mushroom alcohol") is a volatile compound present in several plant species such as Lantana camara [15], Premna integrifolia [16], Epilobium 2 parviflorum [17], in essential oils extracted with scCO<sub>2</sub> from rosemary [18] and lavender 3 [19], etc. It is also used as a spoilage indicator in stored cereals because it is one of the 4 most important flavor components produced by mushrooms [20]. 5 Besides other specific properties, these compounds have been selected in this work 6 mainly due to their potential use as biopesticides. With the aim to reduce the use of 7 chemical insecticides and establish limits on the application of synthetic pesticides 8 (organophosphates, chlorates and carbamates) to agricultural products, biopesticides 9 appear as "green" alternatives, with low impact on human health and environment and 10 high selectivity [21]. Although the direct replacement of synthetic pesticides by 11 biopesticides on field faces important technological and economical barriers, there are 12 13 several other promising applications for this kind of compounds [22], such as pest control in confined places (for example, silos and other storing places of grains and 14 15 derivative products) and active food packaging materials. Moreover, the increasing restrictions to the use of synthetic pesticides promotes the development of integrated pest 16 management (IPM) systems, combining the effect of different physical, chemical and 17 biological agents for pest control, in which biopesticides can find application 18 opportunities [23]. Finally, the increasing market of "organic" or "bio" food represents 19 another interesting niche of application. Insecticidal activity of thymoquinone and R-(+)-20 pulegone (alone and in combination), as well as 1-octen-3-ol, against the corn weevil 21 22 (Sitophilus zeamais) has been reported by Herrera et al. [24]. Abdelli et al. [10] present a valorization of pulegone-rich M. pulegium essential oil as an effective natural bio-agent 23 with antimicrobial and insecticidal properties. Rossi et al. [11] have reported insecticidal 24 and repellent activity to *Musca domestica* with *M. verticillata* essential oil and pulegone. 25

1 1-Octen-3-ol has a broad spectrum of action against different genera of fungi [25] 2 because it plays a role as a self-inhibitor [26], blocking the germination process. Owing to this, 1-octen-3-ol, as well as other fungal volatile compounds, have been proposed as 3 protecting agents against pathogenic species in sustainable agriculture [27] and for 4 preventing post-harvest fungal growth in the food industry [28]. 5 Several studies have been reported in the literature regarding supercritical processing of 6 these compounds, or extracts containing them. For example, Goñi et al. [29] have 7 recently studied the scCO<sub>2</sub>-assisted impregnation of low density polyethylene films with 8 thymoquinone and R-(+)-pulegone, for developing active packaging materials or delivery 9 10 devices for protecting seeds, kernels and derivatives from insect pests, showing the importance of the fluid phase concentration on impregnation yield and kinetics. Morover, 11 Sovová et al. [4] have investigated the  $scCO_2$  extraction of thymoquinone from M. 12 13 didyma and M. fistulosa, concluding that this procedure yields extracts with higher thymoquinone content than conventional hydrodistillation. The same conclusion has 14 15 been pointed out by Grosso et al. [30] for S. montana extracts, and by Solati et al. [31] for N. sativa seed oil. Gurgenova et al. [32] have studied the recovery of thymoguinone 16 from N. sativa seed oil by continuous scCO2 extraction, using a mixture of 17 thymoquinone and rapeseed oil as model system. For this purpose, they have obtained 18 dynamic and static equilibrium data of this system [33], as well as some binary data for 19 the [thymoquinone + CO<sub>2</sub>] system near the critical point of the mixture at 50°C [34]. 20 Finally, scCO<sub>2</sub> countercurrent fractionation can also be applied as an alternative 21 22 methodology to reduce the content of pulegone and other related ketones in mint essential oils, as well as to recover active compounds from dementholized mint oils, as 23 demonstrated in a previous work [35]. In this sense, Madzimbamuto et al. [36] have 24 studied the scCO<sub>2</sub> fractionation of buchu oil in order to remove or reduce its naturally 25

	ACCEPTED MANUSCRIPT
1	high and undesired percentage of pulegone, reporting high pressure binary equilibrium
2	data of its main components and CO <sub>2</sub> .
3	The knowledge of the solubility of the compounds of interest in scCO <sub>2</sub> constitutes a key
4	parameter in supercritical processes, as it determines the amount of fluid required or the
5	highest concentration that can be obtained in the fluid phase in an impregnation, particle
6	formation, fractionation or extraction system. Based on this, in the present work the
7	solubility of thymoquinone, $R$ -(+)-pulegone and 1-octen-3-ol in $scCO_2$ was measured
8	using a semicontinuous method at different temperature and pressure conditions, which
9	are representative of the typical operation ranges, and results were modeled using the
10	Group Contribution Equation of State (GC-EoS) [37], with the objective of providing
11	useful data for the design and optimization of supercritical processes. This model has
12	been successfully applied in previous works concerning fractionation of essential oils

[35][38]. It has proven a very good capability for predictive phase equilibrium

calculations of assymetric mixtures at high pressure conditions. Besides, it allows

calculation of other equilibrium properties which are useful for process design (fugacity

coefficients, phase envelopes, etc.) which cannot be obtained, for example, by empirical

18

## 2. Materials and methods

or semi-empirical solubility methods.

20

21

19

## 2.1. Materials

- 23 The solutes and solvents used in this work, including their purity, source, CAS number,
- molecular weight, normal melting point and chemical structure, are reported in **Table 1**.
- 25 Food grade ethanol (96% v/v, Porta Hnos., Argentina) was used for cleaning the

- 1 experimental equipment. All these chemicals were used directly without further
- 2 purification.

3

4 2.2. Experimental setup and procedure

- 6 Solubility measurements were performed using a dynamic or "gas saturation" method in
- 7 a high pressure equipment schematically represented in **Fig. 1**, and described in detail in
- 8 a previous work [35]. In brief, it consists in a stainless steel column (inner diameter: 0.9
- 9 cm, height: 30 cm) connected to a CO<sub>2</sub> delivery system. The column is externally heated
- by an aluminium jacket and a set of electrical clamp resistances connected to a PID
- 11 temperature controller (DH 101, Dhacel, Argentina), with a precision of ± 0.1 °C.
- 12 Pressure is measured with a pressure transducer (CS-PT300 Xian Chinastar M&C Ltd.,
- 13 China) within a range of  $\pm 0.1$  MPa.
- In a typical measurement, the column is filled with 0.5 mm diameter glass beads mixed
- with the compound whose solubility is to be determined (~1 g in all cases). Glass wool
- 16 filters are placed at the column inlet and outlet in order to support the glass beads and
- avoid entrainment of solute droplets or particles. After loading the column, it is slowly
- 18 filled with CO<sub>2</sub> directly from the tank, until reaching the saturation pressure at the
- prevailing ambient conditions. CO<sub>2</sub> is allowed to flow by 20-30 min in order to remove
- 20 the air initially present in the column. At this point, the heating system is turned on and
- 21 the system is allowed to equilibrate at the desired operation temperature. Meanwhile,
- 22 CO<sub>2</sub> from the tank is cooled to approx. 1°C in a coil inmersed in an ice-water bath, and
- 23 stored as a liquid in the pressure generator cylinder (HiP, USA). Once the temperature is
- stable, CO<sub>2</sub> is fed from the pressure generator to the column until reaching the desired
- operation pressure. Immediately before entering the column, CO<sub>2</sub> goes through a pre-

1 heating coil kept at the desired operation temperature. This operation is performed 2 slowly, and several adjustements may be necessary until the system conditions are in equilibrium. After a static period of 2 h, during which the system is allowed to 3 equilibrate with all valves closed, the dynamic extraction step is performed by opening 4 slowly the inlet and outlet valves and keeping a constant flow of CO<sub>2</sub>. The flow rate is 5 adjusted to the desired value and controlled at regular intervals by a bubble gas meter. 6 The outlet stream is depressurized in a micrometering valve (Swagelok, USA) heated by 7 an electrical tape in order to avoid condensation or deposition of solid particles due to the 8 rapid cooling of CO<sub>2</sub>. After some minutes of stabilization, the solute trap is connected to 9 the outlet valve. In the case of R-(+)-pulegone and 1-octen-3-ol, this trap consisted of a 10 glass U-tube partially filled with metallic mesh and immersed in a -40°C silicone oil 11 cooling bath (RE-107, Lauda, Germany). U-tubes are thoroughly cleaned with ethanol 12 13 and compressed air, and dried in an oven at 115°C before each use. The amount of solute recovered in the trap during a certain period is determined gravimetrically by measuring 14 15 the mass increase of the trap in an analytical balance (Ohaus Adventurer Pro, New Jersey, USA, d=0.1 mg). The corresponding amount of CO<sub>2</sub> is determined volumetrically 16 by the bubble gas meter at ambient temperature, pressure and humidity conditions. In the 17 case of thymoquinone, due to the difficulties in recovering this solid compound in the U-18 tubes, the trap was replaced by a glass flask filled with a certain volume of 2-propanol 19 (previously saturated with CO<sub>2</sub>). The geometry of this flask allows the CO<sub>2</sub> stream to 20 bubble from the bottom into the solvent, which dissolves the extracted solute. The 21 stripped gas is measured in the bubble flow meter. During measurements, the flask is 22 immersed into the cooling bath in order to minimize solvent evaporation. After solute 23 collection, the solution is analyzed in a UV-visible spectrophotometer (Lambda 25, 24 Perkin-Elmer, USA) at 252 nm, and the amount of solute is calculated from a calibration 25

1	curve. From this information, the solubility of each compound in scCO <sub>2</sub> was calculated
2	as mole fraction (y2). The experimental procedure was validated by reproduction of
3	reported solubility data of D-limonene (for the U-tube trap) and diphenylamine (for the
4	solvent trap), as will be shown in the Results and discussion section.
5	Solubility was measured at 45, 55 and 65°C and in a pressure range of approx. 8.0-12.0
6	MPa for $R$ -(+)-pulegone and 1-octen-3-ol, which are typical conditions in supercritical
7	CO <sub>2</sub> processes. In the case of thymoquinone, as its melting temperature is about 45°C
8	[39], solubility was measured at 50 and 60°C. Although a melting point depression
9	induced by CO <sub>2</sub> might be expected, temperatures above this value were selected in order
10	to ensure liquid-fluid equilibrium conditions. Measurements were performed at
11	increasing pressure and constant temperature, and each isotherm was determined by
12	duplicate. Some points were also replicated independently. Therefore, all measurements
13	are reported as an average of 2 to 4 replicates.
14	In addition, the optimal CO <sub>2</sub> flow rate was determined, in order to ensure that the outlet
15	fluid stream is saturated with solute. In fact, if the flow rate is too high, thermodynamic
16	equilibrium may not be achieved, and the solubility underestimated. Therefore,
17	preliminary measurements were performed using D-limonene in order to determine a
18	flow rate value (or range) where the observed solubility is maximum.
19	
20	3. Thermodynamic modeling
21	
22	3.1. GC-EOS model
23	
24	Modeling of the binary solubility of the different compounds in scCO <sub>2</sub> was performed
25	using the Group Contribution Equation of State (GC-EoS) [37]. This model is based in

1 the calculation of the Helmholtz free energy considering two contributions to non-2 ideality: a free-volume or repulsive term (calculated from molecular properties) and an attractive term (calculated using a group contribution approach). The model equations 3 4 are detailed in **Appendix A**. The GC-EoS model has been successfully applied to the calculation of high pressure phase equilibria of a broad range of compounds using a 5 limited number of functional groups and binary interaction parameters. 6 The critical properties and the group contribution structure of the studied compounds are 7 presented in Tables 2 and 3, respectively. Except for CO<sub>2</sub>, the critical temperatures and 8 pressures were estimated using the group contribution method of Joback [40]. CO<sub>2</sub> 9 critical properties, as well as its density at different temperature and pressure conditions, 10 were taken from the NIST Chemistry Webbook database [41]. The critical diameter  $(d_c)$ 11 of the pure compounds was adjusted from a vapor pressure point. The pure group, binary 12 13 interaction and binary non-randomness parameters used in this model are presented in Tables 4–6. The most recent available version of the GC-EoS parameter matrix was used 14 15 [42]. For the correct representation of pulegone, an olefinic group >C=C< was necessary, which is not defined in the current parameter matrix. Instead of defining a new group, the 16 existing >C=CH- group and its corresponding set of parameters were used, modifying 17 only the q parameter value (number of surface segments) by subtracting the contribution 18 of one H atom. This approach has been previously applied in similar cases [35][38]. In 19 the case of the binary interaction parameters between the ketone group and the olefinic 20 groups, not available in the revised matrix, they were taken from our own previous 21 adjustments [38]. The carbonyl groups in thymoquinone were represented using the 22 cyC=O group previously defined by Barrera et al. [43]. 23 Calculations were performed in each case by solving a multiphase flash at fixed 24 temperature and pressure with the subroutine GCTHREE [44] in a Fortran environment, 25

- and were completely predictive, as no information from our experimental results was
- 2 used for parameter adjustment. The model deviation was calculated in terms of the
- 3 percent average relative deviation (ARD%), defined according to Eq. 1.

4

$$ARD\% = \frac{1}{N} \left( \sum_{i=1}^{N} \frac{\left| y_2^{calc} - y_2^{exp} \right|}{y_2^{exp}} \right) \times 100$$
 (1)

5

- 6 where N is the number of experimental data points, and  $y_2^{calc}$  and  $y_2^{exp}$  represent the
- 7 calculated and experimental solubility (in mole fraction).

8

9 3.2. Chrastil equation

10

- 11 The well known density-based equation of Chrastil [45] adapted to liquid solutes was
- used as a test for checking the consistency of the data. This model correlates the
- solubility of a substance (S, in kg/m³) with the pure CO<sub>2</sub> density and temperature,
- according to Eq. 2.

15

$$S = \rho^k e^{\left(\frac{a}{T} + b\right)} \tag{2}$$

16

- where  $\rho$  is in kg/m<sup>3</sup>, T in K, and k, a and b are constant parameters. This equation can be
- rewritten in terms of the solute mass fraction (*Y*), according to Eq. 3.

$$\ln Y = (k-1)\ln \rho + \frac{a}{T} + b \tag{3}$$

- According to this expression, a plot of  $\ln Y$  vs.  $\ln \rho$  should be linear. The equation
- 2 parameters were fitted by minimizing the deviation with the experimental data,
- 3 calculated as ARD%.

4

### 4. Results and discussion

6

5

As previously mentioned, the dynamic method was validated by reproduction of 7 solubility data of D-limonene and diphenylamine in scCO<sub>2</sub> reported in the literature. 8 These preliminary measurements involved the determination of the flow rate required for 9 the saturation of the CO<sub>2</sub> stream in the extraction column. For that purpose, several runs 10 were performed at fixed temperature and pressure conditions and varying the CO<sub>2</sub> flow 11 rate, and the mole fraction of D-limonene in the fluid phase was quantified. Fig. 2 shows 12 13 results obtained at 60°C and 8.2 MPa. As can be seen, the observed values are nearly constant below a flow rate of approx. 0.11 g/min, and decrease at higher rates, indicating 14 15 that equilibrium is not achieved above this value, due to mass transfer limitations. From this information, all measurements in this work were performed at CO<sub>2</sub> flow rates within 16 the range of 0.05-0.10 g/min. It has to be noted that the maximum saturation flow rate 17 may depend on the CO<sub>2</sub>/substrate ratio inside the extractor, and therefore change with the 18 loaded amount and with CO<sub>2</sub> density. In this case, considering the initial loading of 1 g 19 of substrate, the cell volume and the temperature and pressure conditions tested, this ratio 20 was in the range of 1.2 to 3.1 g/g in all experiments. 21 **Table 7** shows the solubility values of *D*-limonene in scCO<sub>2</sub> obtained in this work using 22 the gravimetric method at different temperature and pressure conditions, which are 23 graphically compared to the values reported by other authors [46][47][48][49][50] in **Fig.** 24 3. Similarly, **Table 8** shows the solubility of diphenylamine in scCO<sub>2</sub> obtained in this 25

1	work with both the spectrophotometric and the gravimetric methods, compared with
2	literature data [51] in Fig. 4. A good agreement between our data and the values from the
3	literature is observed, taking into account the dispersion of the data, especially at lower
4	pressure values. Note that these data have been obtained using different methods: Akgün
5	et al. [46] applied a static method with chromatographic analysis of both phases; Sovová
6	et al. [47] used a dynamic method with gravimetric quantification in a cooled U-tube;
7	whereas Chang and Chen [48] determined the equilibrium compositions from density
8	data measured in a densimeter with recirculation. In the case of Leeke et al. [49], a high
9	pressure cell with recirculation and sampling was used for equilibrium measurements,
10	while Matos et al. [50] determined the limonene concentration in the gas phase
11	gravimetrically in a static high pressure cell.
12	Table 9 shows the experimental solubility values for thymoquinone at 50 and 60°C, as
13	well as the GC-EoS predictive calculations. Results are graphically presented in Fig.
14	5(a). As can be seen, a good agreement is observed between the GC-EoS predictions and
15	the experimental values (ARD% of 20.8 and 13.8, at 50 and 60°C, respectively).
16	Solubility increases about one order of magnitude in the studied pressure range, from
17	approx. $10^{-4}$ to $10^{-3}$ (mole fraction). The occurrence of a "cross-over" point, where the
18	temperature dependence of the solubility inverts, can also be noticed at a pressure value
19	between 8.5 and 9.0 MPa, correctly predicted by the model. Fig. 5(b) shows the
20	solubility values as a function of pure CO2 density, as well as the correlations using the
21	equation of Chrastil. A very good linear behavior is observed, with both isotherms
22	overlapping, indicating that the Chrastil parameters are practically independent of
23	temperature for this compound. There are few data in the literature concerning this
24	particular system. Gurgenova et al. [34] have determined the critical pressure of the [CO <sub>2</sub>
25	+ thymoquinone] mixture at 50°C by direct observation in a sapphire cell, being approx.

1	10.3 MPa. Although our data show a two-fold increase in solubility from 10.0 to 10.5
2	MPa at this temperature, we cannot ascertain that this corresponds to the critical point.
3	Although the GC-EoS model correctly represents the solubility behavior below this
4	pressure, it predicts biphasic conditions above this limit. These authors have also
5	reported dynamic and static solubility data of thymoquinone in near-critical and
6	supercritical CO <sub>2</sub> [33]. Their interest was to study the fractionation of thymoquinone
7	from black cumin seed oil by scCO2 extraction, and therefore they used a mixture of
8	thymoquinone and rapeseed oil as model system, instead of pure thymoquinone.
9	Although they claim that rapeseed oil solubility in CO2 is negligible at the tested
10	conditions, the fact that measurements are performed on a ternary system, and not a
11	binary one, has important effects on the observed phase equilibrium. On the one hand,
12	they report a marked dependence of solubility on the concentration of thymoquinone in
13	the liquid feed. On the other, they observe solubility values of $0.7-5.4 \times 10^{-5}$ (mole
14	fraction), at 28 and 38°C and pressures as high as 12 MPa. This indicates that the
15	presence of the rapeseed oil, although practically not extracted in the supercritical phase,
16	extends the heterogeneous region to higher pressure levels and yields even lower
17	solubilities, with respect to the binary system. The difference between binary and
18	multicomponent solubilities, which can be significant, has been previously pointed out
19	by the authors for other terpenic mixtures [38].
20	The experimental and predicted solubility values of $R$ -(+)-pulegone in sCO <sub>2</sub> at 45, 55
21	and 65°C are presented in <b>Table 10</b> and <b>Fig. 6(a)</b> . In this case, an exponential increase of
22	solubility with pressure can be seen, as well as an increase of the heterogeneous region
23	limits to higher pressure levels when increasing the temperature. The one order of
24	magnitude increase observed at the highest pressure values, especially at 45 and 55°C,
25	although typical in liquid-fluid equilibria near the critical region of the mixture, may also

1 indicate the occurrence of a single phase (complete miscibility). In order to check this 2 hypothesis, mass balances were performed in order to estimate the global concentration inside the extractor column at these conditions (considering the amounts of pulegone 3 extracted in previous measurements and the losses during system stabilization), which 4 was found to be about the same order of magnitude of the observed solubility values, 5 although somewhat higher (0.02-0.03, mole fraction). Madzimbamuto et al. [36] have 6 reported high pressure equilibrium data for the [CO<sub>2</sub> + pulegone] system at various 7 temperatures (from 35 to 75°C). Although they present mainly bubble points and the gas-8 phase data are scarce, their results suggest that the critical pressure of the mixture is near 9 9.5 MPa at 45°C, which is in agreement with our observations. At 55°C, the critical 10 pressure seems to be near 11.5 MPa and therefore it seems probable that we have 11 measured a single phase at 10.5 MPa. At 65°C, they observe that the critical pressure is 12 13 around 13.5 MPa, therefore our own measurements correspond entirely to gas-phase solubilities. Although the GC-EoS model correctly describes the solubility behavior, 14 15 higher deviations are observed for this compound (ARD% up to 43.9%). These differences, which increase at higher pressure, can be a consequence of the errors in the 16 prediction of equilibrium pressures in the near-critical region of the mixture. In this 17 sense, the effect of CO<sub>2</sub> density starts to override the effect of solute vapor pressure and 18 the solubilities become higher at lower temperatures. Fig. 6(b) suggests a significant 19 deviation from the expected linear dependence between the logarithm of the solubility 20 and the logarithm of CO<sub>2</sub> density, especially at 45°C, which may be due to experimental 21 22 errors near the critical point of the mixture or to the above-mentioned possibility of having single phase conditions at the highest tested pressure. A temperature-dependence 23 of Chrastil parameters is also observed, as the isotherms present different slope and 24 intercept. 25

1	Finally, Table 11 and Fig. 7(a) show the experimental and calculated solubility values
2	for 1-octen-3-ol at 45, 55 and 65°C. The same one order of magnitude exponential
3	increase of solubility with pressure is observed from 8 to 11 MPa (from approx. 10 <sup>-3</sup> to
4	10 <sup>-2</sup> ). Globally, GC-EoS predictions are in good agreement with the observed behavior at
5	45 and 55°C (showing ARD% values of 7.3 and 18.1%), with higher deviations at 65°C
6	(31.5%). It can also be noticed that the experimental solubility decreases with
7	temperature at a given pressure in the whole studied range, although the model predicts
8	the occurrence of "cross-over" points. Within the studied pressure range, no sharp
9	increase of solubility is observed (as was the case for $R$ -(+)-pulegone), indicating that
10	measurements were taken relatively far below the critical point of the mixture. This
11	extension of the heterogeneous region limits to higher pressure levels could be due to
12	association effects which may be important in this alcohol. Fig. 7(b) indicates a good
13	correlation between solubility and CO <sub>2</sub> density at the three studied temperatures. A
14	certain temperature-dependence of the Chrastil parameters can also be observed for this
15	compound. Although there are other studies in the literature regarding high pressure
16	equilibrium of different C <sub>8</sub> alcohols and CO <sub>2</sub> [52], to the best of our knowledge, this is
17	the first report of 1-octen-3-ol solubility data in scCO <sub>2</sub> .

## **5. Conclusions**

The solubility of thymoquinone, R-(+)-pulegone and 1-octen-3-ol in supercritical carbon dioxide were determined experimentally using a semicontinuos method in the temperature range of 45–65°C and a pressure range of approx. 8–12 MPa. The equation of Chrastil, used to test the consistency of the data, showed good results, with a temperature-dependence of the Chrastil parameters for R-(+)-pulegone and 1-octen-3-ol.

- 1 The GC-EoS model was used to predict the behavior of the three studied systems,
- 2 achieving a good representation of the solubility conditions, though deviations tend to
- 3 increase towards the critical region of the mixtures.

## 1 Appendix A. GC-EoS model equations.

2

- 3 The GC-EoS model computes the residual Helmholtz energy  $(A^{res})$  by two additive
- 4 contributions: a repulsive or free volume term  $(A^{fv})$  and an attractive term accounting for
- 5 intermolecular forces  $(A^{att})$ :

6

$$A^{res} = A^{fv} + A^{att} (A.1)$$

7

- 8 The free volume term is modeled using a Carnahan-Starling type hard sphere expression,
- 9 developed by Mansoori and Leland [53]:

10

$$\frac{A^{fv}}{RT} = 3\left(\frac{\lambda_1\lambda_2}{\lambda_3}\right)(Y-1) + \left(\frac{\lambda_2^3}{\lambda_3^2}\right)(-Y+Y^2 - \ln Y) + n\ln Y \tag{A.2}$$

11

12 where:

13

$$Y = \left(1 - \frac{\pi\lambda_3}{6V}\right)^{-1} \tag{A.3}$$

$$\lambda_k = \sum_{i}^{NC} n_i d_i^k \tag{A.4}$$

14

- V is the total volume, NC the number of components in the mixture,  $n_i$  is the number of
- moles of component i, n is the total mole number and  $d_i$  is the temperature dependent
- 17 hard sphere diameter of each component, calculated as:

$$d_i = 1.065655 d_{c,i} \left[ 1 - 0.12 \exp\left(\frac{-2T_{c,i}}{3T}\right) \right]$$
(A.5)

1

- where  $d_{c,i}$  is the pure component critical hard sphere diameter. This parameter can be
- 3 fitted to a vapor pressure point, or calculated from the pure compound critical properties
- 4  $(T_c \text{ and } P_c)$  as:

5

$$d_{c,i} = \left(\frac{0.08943RT_{c,i}}{P_{c,i}}\right)^{1/3} \tag{A.6}$$

6

- 7 The attractive term is a group contribution version of a NRTL type expression with
- 8 density dependent mixing rules:

9

$$\frac{A^{att}}{RT} = -\frac{z}{2} \sum_{i}^{NC} n_i \sum_{j}^{NG} v_j^i q_j \sum_{k}^{NG} (\theta_k g_{kj} \tilde{q} \tau_{kj} / RTV) / \sum_{l}^{NG} \theta_l \tau_{lj}$$
(A.7)

10 where:

11

$$\theta_j = \left(\frac{q_j}{\tilde{q}}\right) \sum_{i}^{NC} n_i \nu_j^i \tag{A.8}$$

$$\tilde{q} = \sum_{i}^{NC} n_i \sum_{j}^{NG} \nu_j^i q_j \tag{A.9}$$

$$\tau_{ij} = \exp\left(\frac{\alpha_{ij}\Delta g_{ij}\tilde{q}}{RTV}\right) \tag{A.10}$$

$$\Delta g_{ij} = g_{ij} - g_{jj} \tag{A.11}$$

- 1 NG is the number of groups, z is the coordination number of any segment (set to 10),  $v_j^i$
- 2 is the number of groups of type j in molecule i,  $q_j$  is the number of surface segments
- assigned to group j,  $\theta_k$  is the surface fraction of group k,  $\tilde{q}$  is the total number of surface
- 4 segments,  $g_{ij}$  is the attraction energy parameter between groups i and j ( $g_{ij} = g_{ji}$ ), and  $\alpha_{ij}$  is
- 5 the binary non-randomness parameter  $(\alpha_{ij} \neq \alpha_{ji})$ . The binary interaction parameters
- 6 between unlike groups are calculated as:

7

$$g_{ij} = k_{ij} (g_{ii}g_{jj})^{1/2}$$
  $(k_{ij} = k_{ji})$  (A.12)

8

9 with the following temperature dependences:

10

$$g_{jj} = g_{jj}^* \left[ 1 + g_{jj}' \left( \frac{T}{T_j^*} - 1 \right) + g_{jj}'' \ln \left( \frac{T}{T_j^*} \right) \right]$$
 (A.13)

$$k_{ij} = k_{ij}^* \left[ 1 + k_{ij}' \ln \left( \frac{2T}{T_i^* + T_j^*} \right) \right]$$
 (A.14)

11

- where  $g_{jj}^*$  is the interaction parameter for the pure group j at the reference temperature
- 13  $T^*_{j}$ .
- 14 The detailed description of this model can be found in the works by Skjold-Jørgensen
- 15 [37].
