ABSTRACT

Achieving large-scale commercial exploitation of ocean *wave energy* inherently encompasses the design and deployment of arrays of wave energy converters (WECs), in an effort to reduce the associated levelised cost of energy. In this context, understanding the interactions between devices in a controlled WEC array is hence essential to achieve optimal layout configurations, as well as to provide guidance on the area required for array installation, reliability, life-time, and overall cost of the farm. Successful achievement of these vital objectives for the wave energy industry has been constantly aided by the use of appropriate *numerical models*. Regardless of the specific modelling approach adopted, model *reliability* is always a major concern: Numerical models need to be able to represent reality to be useful in supporting the different stages of development, hence providing significant results for decision making. To test reliability of a model, experimental results are an invaluable asset for validation.

Recognising the striking absence of real-world data concerning arrays of WEC systems, and its inherent value for model validation and data-based modelling purposes, we present, in this paper, an experimental campaign fully conducted with the sole objective of generating and providing an open-access dataset on WEC farms: *SWELL* (Standardised Wave Energy converter array Learning Library). The generated dataset, included alongside this manuscript, comprises an approximate total of ~3000 variables and more than ~10⁸ datapoints, for up to 5 devices in 9 diverse WEC array layouts with different levels of interaction, and 19 carefully selected operating conditions. Four different categories of tests are considered, providing measures of key variables required for model validation and data-based modelling tasks. As such, *SWELL* provides a crucial resource to achieve confidence in numerical modelling, helping towards creating reliable tools for decision making in the WEC field, hence effectively supporting the pathway towards effective commercialisation of ocean wave energy.

1. Introduction

The global energy demand has increased drastically over the course of both 20th and 21st centuries, continuously raising major concerns on the issue of future energy provision, with current predictions of an increase of nearly 50% between 2018 and 2050 [1]. With a (fortunately) growing awareness of the social and environmental challenges posed by fossil energy, and pressure to honour emission limits in the pathway towards a low-carbon energy society, a great deal of attention has turned to the effective and efficient use of renewable sources, in an effort to secure future energy needs [2, 3, 4, 5].

The potential of ocean renewable energies, to provide a major support in this quest, is already well-recognised across the globe, generating significant interest from governments and public entities, developers, and investors, all keen to provide assistance in effectively exploiting the many advantages of this renewable source. In particular, within the field of ocean renewables, the vast energy potential from ocean waves, *i.e. wave energy*, is, to date, largely untapped. With an estimation of an exploitable power resource of 30.000 [TWh/year] [6, 7, 8], wave energy can effectively provide a substantial contribution to the energy mix, being of a higher density than *e.g.* solar and wind power [9], consistently available (up to 90% of the time) [10], and highly predictable [11], with a negligible impact on the ocean environment when harvested properly [12, 13].

 nicolas.faedo@polito.it (N. Faedo)
ORCID(s):

52 Although early efforts towards wave energy extraction date back to the 19th century (see *e.g.* [14]), availability of
53 commercial harvesters remains elusive [15]. This can be attributed to a number of factors, including the rather diverse
54 stochastic nature of the wave resource as a function of the location in the globe, survivability requirements in what
55 can be considered a highly hostile environment, and a consequent lack of technology convergence towards an optimal
56 wave energy converter (WEC) design/concept. This almost immediately translates to a higher levelised cost of energy
57 (LCoE) with respect to sister renewables [15, 16], hindering effective and wide-spread commercialisation of WEC
58 systems.

59 As it is well-established within the field, reducing the associated LCoE, and hence achieving large-scale commercial
60 exploitation of wave energy, inherently encompasses two fundamental stepping stones. The first key enabler is linked to
61 the use and development of appropriate control system technology, able to maximise the energy extracted by the WEC
62 systems from the wave resource, while observing the underlying physical limitations characterising the device [17, 18].
63 Briefly summarising, the control problem for WEC systems consists in appropriate (and autonomous) manipulation of
64 the force/torque exerted by the power take-off (PTO) system acting on the converter, in such a way that the energy
65 conversion output is maximised, according to the current wave climate. Multipliers characterising the increase in
66 energy absorption performance by means of appropriate control have been reported to be in the range of 2 to 4 (see
67 *e.g.* [19, 20, 21]), with a degree of performance enhancement which ultimately depends on the particular nature of the
68 WEC device and associated PTO system, and the specific control algorithm implemented [22].

69 The second key enabler to lower the LCoE, together with suitable control technology, is the deployment of WEC
70 systems in array configurations (also often referred to as ‘parks’ or ‘farms’), in an effort to reduce the associated costs
71 (per device) of installation, operation, and maintenance, and ultimately to meet the required demands of installed
72 capacity [23, 24, 25, 26]. Such arrays involve the deployment from a few to hundreds of WEC systems in a common
73 area, arranged systematically according to a given layout configuration, typically designed in terms of row/column-like
74 arrangements. In this context, a deep and detailed knowledge of the behaviour of WEC arrays is, hence, of paramount
75 importance to achieve efficient farm configurations.

76 In particular, understanding the interaction effects between devices in a controlled WEC array is essential to achieve
77 optimal layout configurations, as well as to provide insight on the effective area required for installation, reliability,
78 life-time, and overall cost of the farm. As a matter of fact, WEC interactions can affect the overall performance of the
79 array, having either positive or negative effects on the power absorption capabilities of neighbouring devices (see *e.g.*
80 [27]) and, ultimately, on the associated LCoE [28]. Furthermore, given their capabilities of altering the surrounding
81 wave field, it is equally important to measure the environmental impact that a given array can generate on proximal and
82 distal wave climates [29, 30]. Successful achievement of these vital objectives for the wave energy industry has been
83 constantly and consistently aided by the use of appropriate *numerical* (also referred to as ‘*mathematical*’) *models*.

84 Mathematical models are of immeasurable value towards achieving commercialisation of WEC systems (and, in
85 fact, absolutely crucial for virtually every branch of science), having the capabilities of giving insight and understanding
86 on the behaviour of WECs in a set of pre-defined operating conditions. With a model in hand, one can predict the impact
87 of a variety of design choices (*e.g.* number and inter-distance between devices, effective layout configuration, mid- and
88 far-field effects, power take-off (PTO) system ratings, among others), being able to provide systematic information
89 on how to manipulate, control, and optimise a given WEC array system outside the boundaries of physical reality,
90 so as to achieve, as close as the application permits, a desired set of performance specifications. In essence, the
91 enormous potential of mathematical models in wave energy can be attributed to the fact that these can be simulated in
92 hypothetical situations and environments, subject to operating conditions that can be dangerous in reality, and without
93 incurring in high costs before a process has been optimised accordingly. In fact, the latter has overseen the fall of a
94 significant number of WEC companies, often not following a systematic development protocol supported by the use of
95 appropriate numerical models, due to the high costs associated with full-scale device prototype construction, testing,
96 commissioning, and de-commissioning.

97 Available standardised development protocols for WEC systems [25, 26, 31], often based on the well-known
98 Technology Readiness Level (TRL) scale, unanimously agree on the use of numerical models to support the pathway
99 towards commercialisation, starting from early stages (TRL 1-2), all the way up to full-scale WEC farm development,
100 with different suggested (increasing) degrees of model fidelity. As such, a significant effort has been made by the
101 research community towards comprehensive modelling of WEC farms, covering the full spectrum from low- to
102 high-fidelity numerical simulation (see *e.g.* [29, 32, 33]). The low-fidelity end of the spectrum is well-populated,
103 mostly by techniques based on so-called potential flow theory [32, 34], where linear assumptions are virtually always
104 adopted. While indeed on the low-fidelity side, these models are extremely popular due to their representational and

105 computational convenience, being ideal for *e.g.* preliminary performance assessment, and a vast variety of control-
106 oriented studies [18, 22]. Examples of this type of modelling approach for WEC arrays include [35, 36, 37, 38].
107 On the contrary, the high-fidelity end of the WEC array modelling spectrum often considers sophisticated numerical
108 techniques, such as those based on Computational Fluid Dynamics (CFD), aiming at describing highly complex
109 (nonlinear) phenomena, at the (potentially large) expense of computational power. Examples of modelling techniques
110 belonging to this end of this spectrum are [39, 40, 41]. We further note that recent efforts have been done within the
111 community towards the release of open-source design tools for WEC arrays, particularly within the European project
112 DTOcean+ [42], which tackles development of numerical tools for structured innovation, stage-gating, and evaluation
113 of wave farms.

114 Regardless of the specific technique/type of modelling approach considered, *model reliability* is always a major
115 concern. In other words, numerical models need to be able to effectively represent reality to be useful in supporting
116 the different stages of development, hence providing significant results for decision making [25, 26]. In this context,
117 to test the reliability of a model, experimental results are an invaluable asset for *validation*. Furthermore, beyond the
118 world of model validation, the availability of experimental data opens up the possibility to *data-based modelling* of
119 WEC systems, where real-world information is directly fed into the modelling process, very much in the spirit of
120 system identification [21, 43]. In spite of the significant value that such crucial information can have in supporting the
121 pathway towards WEC commercialisation, publicly available datasets for WEC array experiments are incredibly scarce
122 (if not inexistent), ostensibly due to the underpinning cost for small-scale prototype construction and instrumentation,
123 and overall testing complexity. As a matter of fact, the number of real-world testing experiments on farm prototypes is
124 reduced in itself (see *e.g.* the recent review paper [44]), let alone the data available for public use.

125 A number of well-established studies, effectively providing numerical datasets and benchmark cases for a single
126 (stand-alone) WEC device, do exist within the state-of-the-art, and have been adopted with a great deal of success
127 - see *e.g.* [45] and [46]. As a matter of fact, recent efforts have been done within the community towards effective
128 and open sharing of full scale testing experience, with large projects such as *e.g.* OPERA [47], offering two years of
129 open-sea data of both a floating WEC and a shoreline wave power plant. Nonetheless, availability of experimental
130 datasets for the case of WEC arrays still remains elusive: to the best of the authors' knowledge, a single study [48]
131 has been performed in the literature with the actual aim of providing an open-access dataset¹ on WEC farms for the
132 development community. We note, although, that most of the effort in [48] has been only allocated in characterising the
133 resulting (modified) wave field, for diverse WEC array configurations, disregarding a number of key variables required
134 for validation and data-based model generation (such as *e.g.* effective wave force in the conversion degree-of-freedom
135 (DoF)), limiting the scope of application of the generated experimental data to a subset of the modelling community.
136 Furthermore, the devices in [48] have been tested without an actual PTO system, and a simple mechanical damping
137 has been fashioned for each prototype, to emulate a (passive - see Section 4.4) control action. Finally, note that, as
138 per the discussion provided at the beginning of this section, WEC systems require active control to maximise energy
139 absorption, so validation of farm models under controlled conditions is of absolute importance for layout optimisation
140 and overall performance assessment of a given configuration. We further clarify that the difference between controlled
141 and uncontrolled behaviour can be substantial, with the former presenting larger device motion (and hence wave field
142 interference), due to the action of the energy-maximising controller, which often enlarges the WEC operational space to
143 maximise power absorption [22]. This fact, which can initially seem to be harmless within model validation/data-based
144 modelling procedures, triggers a number of nonlinear effects that are not necessarily captured by models based on linear
145 potential theory, hence potentially invalidating a family of models which would otherwise be considered validated in
146 uncontrolled conditions [50].

147 Recognising the striking absence of real-world data concerning arrays of WEC systems, and its inherent value
148 for model validation and data-based modelling purposes, we present, in this paper, an experimental campaign fully
149 conducted with the sole objective of generating and providing an open-access dataset on WEC farms for any potential
150 stakeholder, both within the academic, and industrial wave energy communities. The generated dataset, from now on
151 termed *SWELL* (Standardised Wave Energy converter array Learning Library), included alongside this manuscript, is
152 constructed on the basis of four different main tests, and comprises an approximate total of ~ 3000 variables and more
153 than $\sim 10^8$ datapoints, for up to 5 devices in 9 diverse WEC array layouts with different levels of interaction, and 19
154 carefully selected operating conditions (featuring regular, bimodal, irregular, and white noise sea states). In particular,
155 as specifically discussed within Section 4, both the inherent synergy between the proposed standardised tests, and

¹We do clarify that, at the moment of writing of this paper, the dataset of the experimental campaign conducted in [48] seems not to be open-access, but only available via specific request to the authors (see [49]).

156 corresponding layout configurations (chosen to maximise knowledge on the interaction between different devices in a
157 diverse set of operating conditions - see Section 2.4), facilitate a well-posed learning procedure, able to characterise
158 the main effects within WEC array systems under uncontrolled and controlled conditions, for different “levels” of
159 interaction, recreated via the specific set of layouts considered. Within this experimental campaign, conducted in the
160 wave tank facilities available at Aalborg University (Denmark), a small-scale (1:20) Wavestar-like [51] prototype is
161 chosen as the baseline device, as depicted in Figures 1 and 3, effectively featuring an electric (direct drive) PTO system.
162 We note that the choice of this system is not arbitrary, and is motivated by the large number of previous studies available
163 on the (isolated) prototype [52, 53, 54, 55], being also featured as the baseline system for the so-called Wave Energy
164 Control Competition (WEC³OMP) [56]. As such, vast, transparent, and (virtually always) public information is readily
165 available for this prototype within the WEC literature.

166 Four different categories of tests are considered to generate SWELL, providing measures of key variables required
167 for model validation and data-based modelling tasks, including (but not limited to) free-surface elevation at different
168 strategic points within the basin, force induced by the waves (*i.e.* wave excitation force), uncontrolled motion, and
169 behaviour under the action of energy-maximising control, for each device, layout, and operating conditions considered.
170 This is, to the best of our knowledge, the largest dataset characterising arrays of WEC systems available in the literature,
171 including a wide variety of WEC layouts and realistic PTO effects (including energy-maximising control), tested in
172 different scenarios following a consistent protocol, designed to suit the necessities associated with a vast number
173 of modelling tasks. As such, the generated dataset SWELL provides a paramount resource to achieve confidence in
174 numerical modelling, helping towards creating reliable tools for decision-making in the WEC field, hence effectively
175 supporting the pathway towards commercialisation of ocean wave energy.

176 The remainder of this paper is organised as follows. Section 2 details the experimental setup considered, including
177 wave tank facilities, baseline prototype and instrumentation, layout configurations, and PTO systems. Section 3 offers a
178 detailed account of the sea states (operating conditions) considered, and the underlying criteria adopted for their choice
179 within the experimental campaign. Section 4 provides an account of each test performed, including sample results to
180 illustrate the dataset. Section 5 discusses the ordering and structure of SWELL, with specific reference to each of the
181 variables present within the dataset, and their connection with the tests performed. Finally, Section 6 encompasses the
182 main conclusions of this experimental campaign.

Figure 1: Photographs of the experimental setup designed for the WEC array experimental campaign, from different angles.

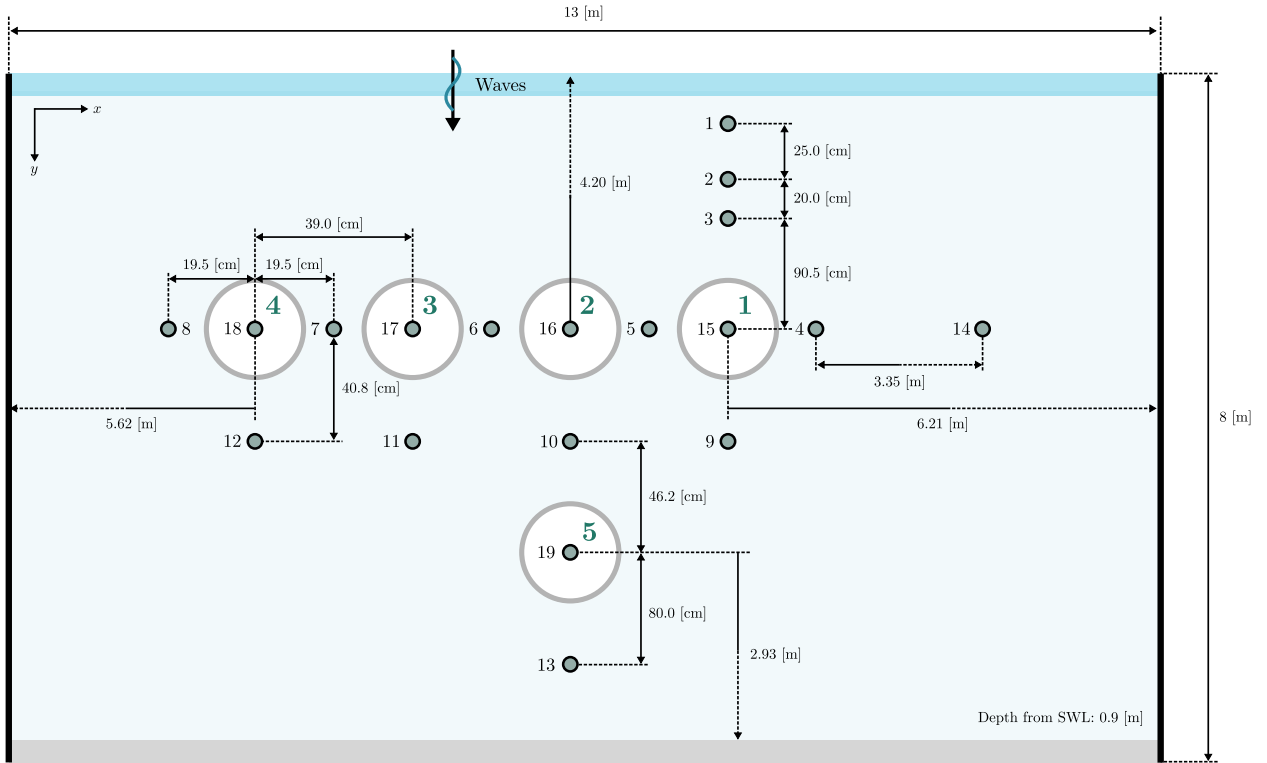

Figure 2: Schematic representation of the wave basin at the Ocean and Coastal Engineering Laboratory, in Aalborg University. The schematic includes the position associated with each device within the tank, and the location of the wave gauges used for free-surface elevation acquisition (grey-numbered circles in Figure). The acronym SWL stands for still water level. Note that gauges 15, 16, 17, 18 and 19 are only present for Test 1 (see Section 4).

183 2. Experimental setup and layout design

184 This section is dedicated to provide a detailed description of the experimental setup considered, as presented in
 185 Figure 1, including the Aalborg University wave tank specifications, baseline WEC system, equipment associated
 186 with each device and characterisation of PTO systems, WEC and wave gauges disposition within the wave tank, and
 187 considered array layout specifications. For the latter, we provide explicit motivation for the choice of each layout
 188 considered, with emphasis on specific aspects which are fundamental within validation/data-based modelling activities.

189 2.1. Wave tank specifications

190 The wave tank facilities, used to fulfil the objectives of this experimental campaign and effective generation of
 191 SWELL, are those available at the Ocean and Coastal Engineering Laboratory in Aalborg University, Denmark. The
 192 dimensions associated with the basin are as described in the schematic presented² in Figure 2. In particular, the available
 193 facilities comprise a basin of 19.3 [m] × 14.6 [m] × 1.5 [m] (length × width × depth), with an active test area of 13 [m]
 194 × 8 [m] (length × width). The wave tank is equipped with a state-of-the-art long-stroke segmented wavemaker system
 195 (custom-made by VTI [57]) with active absorption, composed of 30 individually controlled wave paddles, capable of
 196 producing a large variety of sea state conditions with high accuracy. Within this study, the water depth within the tank
 197 has been fixed to 0.9 [m], while the wavemaker is set to generate long-crested waves, *i.e.* parallel with respect to (w.r.t.)
 198 the x -axis, and with a direction of 0° on the y -axis, as indicated within Figure 2. In addition to the active absorption
 199 capabilities provided by the wavemaker system, the basin is equipped with passive wave absorption elements, built
 200 in stainless steel and hot galvanised stretch metal sheets. Finally, wave generation is performed using the in-house
 201 designed software AwaSys [58], which provides the wavemaker with an associated paddle movement reference for
 202 each tested wave, for effective wave realisation within the tank.

²Note that Figure 2 simply represents a schematic representation of the setup, and objects are not in-scale with respect to the tank dimensions.

203 **2.2. Prototype WEC and acquisition system**

204 The baseline WEC system, chosen for this array experimental campaign, is a 1:20 scale of the Wavestar wave energy
 205 conversion system [51]. The single unit of this prototype, which can be appreciated in Figure 3, essentially comprises
 206 a floater mechanically hinged to an out-of-the-water fixed reference point (point A in Figure 3). At the equilibrium
 207 position, the floater arm stands at approx. 30° w.r.t. the still water level (SWL). Note that the WEC is free to move in
 208 a single DoF. The main set of parameters associated with the single baseline prototype can be found in Table 1. The
 209 PTO (actuator) system is an electrical, direct-drive, linear motor (*LinMot Series P01-37 x 240F*), sitting on the upper
 210 structural joint composing the device (see Figure 3). The corresponding drive is a *LinMot E1200*, with a force rating
 211 up to ± 200 [N].

Figure 3: Photo of the baseline Wavestar prototype unit for the WEC array experimental campaign (left) and associated schematic representation (right). The acronym SWL stands for still water level.

212 Although translational displacement (associated with the PTO system) can be directly obtained as an output of the
 213 PTO driver, it is also measured via a dedicated laser position sensor (*MicroEpsilon ILD-1402-600*) for redundancy
 214 (see Figure 3), while the total force exerted on the PTO axis is measured by means of a *S-beam Futek LSB302* load
 215 cell. The system is equipped with a dual-axis accelerometer (*Analog Devices ADXL203*) sitting on top of the prototype
 216 floater, which, together with the translational motion measurements, is explicitly used to derive measures of rotational
 217 motion (*i.e.* angular displacement and velocity) about the fixed reference point A (see the schematic in Figure 3).

218 The data acquisition flow adopted is shown in Figure 4. The target PC is a Speedgoat Real-time Target Machine
 219 [59], which includes all the corresponding modules to handle input/output (I/O) variables, connected via a standard
 220 Ethernet to the host PC, transferring data using a user datagram protocol (UDP). Acquisition is consistently performed
 221 at a sampling rate of 200 [Hz], for all the acquired variables within the totality of the experimental campaign.

Figure 4: Schematic illustration of used software and hardware architecture.

Table 1
Main WEC parameters.

Parameter	Value (including units)
Floater mass	4 [kg]
Mass moment of inertia w.r.t. A	1 [kg m ²]
Floater draft	0.110 [m]
Floater diameter at SWL	0.256 [m]
Equilibrium position w.r.t. point A θ_A^0	0.523 [rad]
Distance points A-C L_{AC}	0.412 [m]
Distance points C-B L_{CB} (in eq.)	0.381 [m]
Distance points A-B L_{AB}	0.200 [m]
Distance points A-E L_{AE}	0.484 [m]
Distance points A-E in y	0.437 [m]
Distance points A-E in z	0.210 [m]
Centre of gravity in y	0.415 [m]
Centre of gravity in z	-0.206 [m]
Centre of buoyancy in y	0.437 [m]
Centre of buoyancy in z	-0.321 [m]
Arm mass	1.157 [kg]
Arm moment of inertia w.r.t. A	0.060 [kg m ²]

222 From now on, and, in particular, throughout Section 4, we use the following convention w.r.t. the WEC prototype
 223 main variables, all of which (either by direct measurement or reconstruction/estimation) are effectively part of the
 224 associated open-access dataset SWELL³:

225 (M) Measured variables:

226 z_{PTO} : Linear displacement (in [m]) of the PTO motor. This can be measured either via the incorporated driver
 227 sensor, or the laser sensor on top of the PTO axis.

228 \ddot{z}_E : Linear acceleration (in [m/s²]) of the WEC floater at point **E**. This can be measured by virtue of the
 229 accelerometer on top of the floater.

230 f_B : Force (in [N]) at point **B**. This can be measured directly by the load cell sitting on the PTO axis.

231 (E) Reconstructed/estimated variables:

232 τ_A : Torque (in [Nm]) w.r.t. point **A**.

233 θ_A : Angular displacement (in [rad]) of the WEC prototype w.r.t. point **A**.

234 $\dot{\theta}_A$: Angular velocity (in [rad/s]) of the WEC prototype w.r.t. point **A**.

235 $\ddot{\theta}_A$: Angular acceleration (in [rad/s²]) of the WEC prototype w.r.t. point **A**.

In particular, τ_A , θ_A , and $\ddot{\theta}_A$ can be reconstructed using the set of measured variables listed above in (M), *i.e.*

$$\begin{aligned}
 \tau_A &= f_B \cos \left(\sin^{-1} \left(\frac{L_{AC}^2 - L_{AB}^2 - (L_{CB} + z_{PTO})^2}{-2L_{AB}^2 (L_{BC} + z_{PTO})} \right) \right) L_{AB}, \\
 \theta_A &= \theta_A^0 - \sin^{-1} \left(\frac{(L_{CB} + z_{PTO})^2 - L_{AC}^2 - L_{AB}^2}{-2L_{AC}L_{AB}} \right), \\
 \ddot{\theta}_A &= \frac{\ddot{z}_E}{L_{AE}}.
 \end{aligned} \tag{1}$$

236 Table 2 offers a summary of the considered sensor/actuation equipment, and their corresponding measurement
 237 capabilities/uncertainty (as per each associated manufacturer datasheet), for each of the variables listed in (M). The

³From now on, the dependence on t is dropped when clear from the context.

Table 2

Instrumentation and corresponding measurement capabilities.

Sensor/actuator	ID	Measurement variable	Uncertainty
Linear motor	LinMot Series P01-37 x 240F	Linear position z_{PTO}	± 0.05 [mm]
Laser position sensor	MicroEpsilon ILD-1402-600	Linear position z_{PTO}	± 80 [μ m]
Load cell	S-beam Futek LSB302	Force at point B f_B	± 0.125 [N]
Accelerometer	Analog Devices ADXL203	Linear floater acceleration at point E \ddot{z}_E	± 0.01 [m/s ²]
Wave gauges	VTI WG-8CH	Wave elevation at 19 points in the basin	± 0.04 [mm]

238 only variable in (E) which cannot be directly computed via the measured quantities in (M) is the velocity of the system
 239 w.r.t. point **A**, *i.e.* $\dot{\theta}_A$, requiring effective estimation. To do this with the available measures, described in the paragraph
 240 immediately above, we employ standard methodologies for sensor fusion, and we leverage a Kalman Filtering (KF)
 241 technique (see *e.g.* [60]) to provide estimates of $\dot{\theta}_A$ when needed.

242 2.3. Wave gauges and devices positioning

243 Measurements of free-surface elevation are obtained by using wave probes (WP), also often called wave gauges,
 244 of a resistive-type (*VTI WG-8CH*). In particular, 19 WPs have been considered within this experimental campaign,
 245 located at strategic points within the wave tank, as can be appreciated in Figure 2.

246 The set of WPs {1, 2, 3}, aligned w.r.t. the centre line of device 1 (D1), is placed in a column-like pattern, with
 247 different inter-distances between WP 1 - WP 2 and WP 2 - WP 3. WPs 4 to 8 are strategically placed in the middle
 248 position between each set of devices, allowing for an explicitly measure of *e.g.* radiated waves between bodies, whose
 249 intensity naturally depends on the specific layout considered (discussed within this section in the following paragraphs).
 250 WPs 9 to 13 are located behind (w.r.t. the wave generation direction) each of the devices considered, providing further
 251 information on the resulting wave field for each test and layout employed within this campaign. WPs 15 to 19, which
 252 are potentially among the most relevant set of probes, give information on the free-surface elevation at the centre
 253 position of each device involved. This is particularly useful for I/O modelling, including *e.g.* parametric structures for
 254 control/estimation purposes (see *e.g.* [21, 43]). Note that WPs 15 to 19 are only effectively present within the basin
 255 whenever the devices are not in place, *i.e.* for measuring free-surface elevation corresponding with each considered
 256 sea state without the presence of the WECs in the tank (see Test 1 in Section 4). Finally, WP 14 is used as a ‘control’
 257 probe for all the tests performed, and is placed in an area away from the active device zone.

258 Regarding device positioning, 5 prototypes (D1 to D5) are considered and placed within the wave basin for this
 259 WEC array experimental campaign, each mounted on a gantry by means of a supporting structure (see Figure 1). D1
 260 to D4 are placed in a row-like formation, with a distance of 39 [cm] from centre to centre of adjacent devices. Note
 261 that this corresponds to approximately 1.5 times the diameter of the prototype floater (see Table 1), resulting in an
 262 inter-device distance (floater edge-to-edge) of approximately 1 radius, *i.e.* 13 [cm]. Each device can be lifted out of
 263 the basin manually, hence allowing for testing of different layout configurations by simply pulling a specific set of
 264 devices out of the water. Finally, we note that D5, which is mounted on the rear side of the gantry, is placed in a
 265 ‘flipped’ position w.r.t. devices D1 to D4 (see Figure 1). This specific placement has been pursued with the objective
 266 of providing a heterogeneous array configuration in an effort to enrich the results (and, hence, the associated dataset),
 267 *i.e.* the response of D5 will be naturally different from that of D1 to D4.

268 2.4. Array layout design

269 We consider 9 different layout configurations (L0 to L8) involving up to 5 different devices operating simultaneously
 270 within the basin, as schematically illustrated within Figure 5. The choice of these layouts is, naturally, not arbitrary, as
 271 detailed in the following. We first note that the testing set is comprised of two layouts with a single device (L0 and L8),
 272 three with two devices (L1 to L3), two with three prototypes (L4 and L5) and, finally, one layout with 4 and 5 WECs
 273 operating within the basin (L6 and L7, respectively).

274 L0, which, as discussed within Section 1, has been considered previously in the modelling/validation literature for
 275 this specific Wavestar prototype (see *e.g.* [53, 56, 61, 62]), is chosen as the baseline case, and is essentially comprised of
 276 a standard single device configuration. Given the mounting and positioning of D5 (see Section 2.3), L8 is considered to
 277 provide data to characterise, in a stand-alone fashion, the heterogeneous component among devices. L1 to L3 constitute
 278 the first set of tested layouts with more than a single WEC prototype. These layouts are designed with essentially the
 279 same formation, but with different inter-device distances. The underpinning design for L1 to L3 allows for a direct

Figure 5: Full set of layouts considered within the WEC array experimental campaign presented in this study.

280 characterisation of the effect of interactions between devices as a function of the distance between bodies, which is
 281 fundamental to understand constructive/destructive effects within WEC array configurations (see *e.g.* [27, 63, 64, 65]).
 282 L4 and L5 incorporate a third device into the basin, and are designed as a natural ‘extension’ of L1 and L2. Note that,
 283 while L4 includes a device in-between D1 and D3 (*i.e.* in a row-like formation), L5 considers a triangle-like shape,
 284 incorporating D5 into the wave tank. Finally, L6 offers a four-device row formation, essentially comprised of all the
 285 devices used in L0 to L4, *i.e.* D1 to D4, while L7 represents the potentially most complex case from a modelling and
 286 configuration perspective, including all 5 devices, operating simultaneously within the basin.

287 2.5. Characterisation of PTO dynamics

288 Since the considered WEC prototype systems are, effectively, designed to represent a scaled version of the Wavestar
 289 wave energy converter, they incorporate an actual PTO actuator (linear motor - see Section 2.2) accordingly. These
 290 motors, which are able to exert a force along their axis, can essentially operate in two different modes, *i.e.* force and
 291 position control. In the case of the former, adopted within the presented experimental campaign, a target (reference)
 292 PTO force u_{PTO}^{ref} (as in Figure 6) is sent to each associated driver which, via a dedicated proportional-integral-derivative
 293 (PID) controller, attempts to effectively tracking the requested force, providing a signal u_{PTO} to the WEC system. We
 294 emphasise, at this point, that there exists a clear distinction between the PTO driver controller, whose only objective is
 295 that of force reference tracking (as described immediately above), and what it is termed ‘WEC controller’ in Figure 6,
 296 which is in charge of providing a reference force to the PTO system so as to maximise energy extraction from the wave
 297 resource (see the discussion provided in Section 1). The latter is also considered explicitly within this experimental
 298 campaign, as detailed throughout Section 4.4.

299 Though the final objective of this paper is that of providing a dataset characterising real WEC array prototypes, *i.e.*
 300 in real-world conditions, we do appreciate that a large part of the WEC modelling community is focused on numerical
 301 representation and validation of the hydrodynamics pertaining to such devices in idealised conditions, *i.e.* without the
 302 incorporation of a (realistic) PTO system. With this in mind, we provide, within this section, both a discussion and
 303 experimental characterisation of these linear motors, and hence the overall PTO dynamics, for the benefit of the reader
 304 and potential users of SWELL.

305 With the exception of Tests 1 and 2 (as listed in Section 4), the linear motor is always required to operate in force
 306 control conditions. As such, we tune the parameters of the associated force (driver) controller to achieve a sufficiently
 307 large bandwidth, being able to effectively track any of the force signals required during the campaign, *i.e.* such that,
 308 ideally, $u_{PTO}^{ref} \approx u_{PTO}$ (see also Figure 6). In this way, we guarantee that the associated motor dynamics interfere as
 309 little as possible with those characterising the mechanical energy conversion process of the WEC system. Naturally,
 310 since we are dealing with real-world systems, the PID tuning procedure has to be achieved by accepting a suitable
 311 compromise between effective bandwidth and *e.g.* stability and noise amplification (the interested reader is referred to
 312 *e.g.* [66] for a detailed discussion). In other words, the linear motor cannot be controlled to be arbitrarily fast, as one
 313 would be able to do within idealised (simulation) conditions.

314 The driver PID tuning procedure has been performed in-situ, by using standard I/O tests and associated techniques
 315 (see *e.g.* [67]). The dataset includes an experimental characterisation of the I/O behaviour of each (driver-controlled)
 316 linear motor, obtained by means of chirp experiments (see *e.g.* [68]). In particular, a set of chirp driver reference force
 317 signals with amplitudes in the set $\{15, 17.5\}$ [N] and frequency content within 0.1 [rad/s] and 15 [rad/s] (which covers
 318 accordingly the frequency range characterising the WEC operating conditions - see Section 3) has been injected into

Figure 6: Schematic illustration of the PTO system and associated control architectures.

319 each individual PTO motor as u_{PTO}^{ref} , generating a set of corresponding force outputs u_{PTO} . By way of example, Figure
 320 7 shows an I/O pair for a chirp test with a reference amplitude of 17.5 [N], applied to the linear PTO motor associated
 321 with D2.

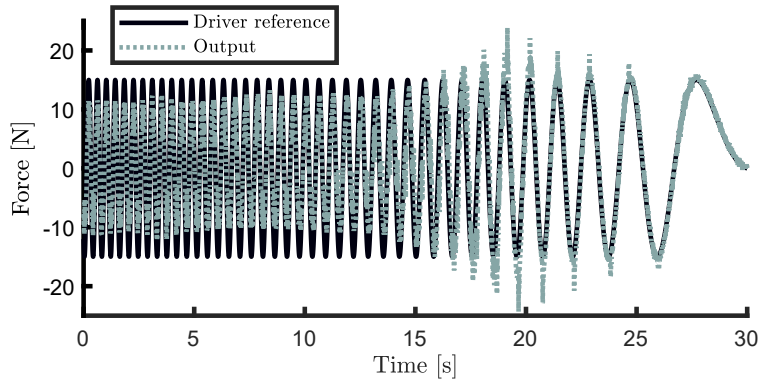

Figure 7: Example I/O pair for the PTO chirp tests provided as part of the dataset, executed on the motor associated with D2.

322 Another potentially relevant component, which is inevitably present in this type of PTO systems, are friction
 323 effects. In fact, the sharp ‘peaks’ that can be seen in the chirp test presented within Figure 7, are directly linked
 324 to such phenomena: the PTO motor ‘sticks’ to the axis at low speeds, presenting a typical dead-zone behaviour
 325 (see *e.g.* [69]). While these effects are effectively minimised by appropriate tuning of the driver internal controller,
 326 a PI structure is, clearly, not sufficient to fully counteract friction. Nonetheless, as discussed previously within this
 327 paragraph, friction effects become potentially relevant at very low speeds, which do not normally occur in operating
 328 conditions for the WEC device (especially when u_{PTO}^{ref} is designed according to energy-maximising control conditions,
 329 where both displacement and velocity tend to be higher in order to maximise energy absorption - see Section 4.4).

330 Nonetheless, aiming to provide a dataset as comprehensive as possible, a characterisation of these friction effects
 331 is also included within SWELL (see Section 5), performed in terms of slow and fast motion tests for each PTO system
 332 associated with all five devices. These tests are executed by moving the floater (and hence the motor axis) manually,
 333 both at low and high speeds (see *e.g.* [44]). Exploiting motion and measured force, these tests incorporate, within the
 334 dataset, an experimental characterisation of both static and dynamic friction effects associated with each PTO actuator.
 335 By way of example, Figure 8 shows a time-snippet of such test performed on the PTO system of D2, where both slow
 336 and fast motions (and associated measured force on the motor axis) can be effectively appreciated.

Figure 8: Example I/O pair for the friction tests provided as part of the dataset, executed on the motor associated with D2.

Table 3

Waves tested within the presented experimental campaign.

ID	Type	Period [s]	Height [m]	γ	#R	Length [s]
RSS1	Regular	0,8	0,05	-	1	60
RSS2	Regular	0,9	0,05	-	3	60
RSS3	Regular	1	0,05	-	1	60
RSS4	Regular	1,2	0,05	-	3	60
RSS5	Regular	1,5	0,05	-	1	60

Total number of waves tested: 19

337 3. Definition of sea states

338 This section provides a description of the sea states considered within the campaign, emphasising the underlying
 339 motivation for their choice, and potential use for different modelling/validation tasks. A total of 12 sea states are
 340 considered, with a different number of realisations (#R) depending on the specific operating condition. Four types of
 341 sea states are included within SWELL, as briefly listed below:

- 342 ○ *Regular sea state (RSS)*: Waves generated with a monochromatic spectrum, *i.e.* deterministic, with one single
 343 component at a specific frequency.
- 344 ○ *Bimodal sea state (BMSS)*: Waves generated with a bichromatic spectrum, *i.e.* deterministic, with two selected
 345 components in frequency.
- 346 ○ *Irregular sea state (ISS)*: Waves generated in terms of a representative stochastic representation. In particular,
 347 JONSWAP spectra [70] are considered within this study, as further discussed within Section 3.3.
- 348 ○ *White noise sea state (WNSS)*: Waves generated in terms of a constant spectral density in a pre-defined
 349 frequency range.

350 A detailed discussion on each type of sea state is provided below, while a summary of the operating conditions
 351 considered within this paper is offered within Table 3.

3.1. Regular sea states

Though regular waves can be limiting from a representational perspective, *i.e.* they emulate sea state conditions with a single frequency component, these can still be useful to achieve a number of modelling/validation objectives. First of all, having a single frequency component allows for ‘decoupling’ of a certain number of effects, which can be easily masked in the irregular wave case. For instance, nonlinearities tend to be more clear in regular-type of tests since, being the wave input composed of a single component, any nonlinear behaviour would generate a set of sub- or super-harmonics of such a frequency⁴, clearly appreciated in system motion. Furthermore, regular waves also represent a useful tool for preliminary analysis of energy-maximising WEC controllers, being the designer able to verify a set of well-known optimality conditions almost straightforwardly (*e.g.* phase locking between wave excitation and WEC velocity [19, 72]). Finally, monochromatic waves are commonly used when modelling extreme wave conditions, and are hence useful for performing validation of *e.g.* stress models [73].

Figure 9: Theoretical spectra for the regular wave conditions used within this experimental study.

Within this study, and hence SWELL, five different regular wave conditions are considered (RSS1 to RSS5 - see Table 3), with frequency components selected strategically w.r.t. the device response, and a constant wave height. In particular, Figure 9 shows the theoretical spectrum associated with each RSS condition (solid lines), normalised w.r.t. that with the highest energy, for representational purposes. The dashed line in Figure 9 represents the magnitude associated with the torque-to-motion (*i.e.* input: wave excitation torque - output: floater angular velocity) frequency-response map for the baseline Wavestar prototype system described in Section 2.2, computed using a BEM solver⁵. Note that waves are chosen to cover the typical operational space for this system, including resonance (RSS2), low (RSS3, RSS4 and RSS5), and high (RSS1) frequency behaviour. In addition, note that different number of realisations #R has been considered, depending on the specific RSS. Though these sea states are effectively deterministic, the choice of generating more than a single realisation for a subset of these operating conditions is performed to equip the dataset SWELL with information on the capabilities of the wavemaker system to reproduce a given sea state in different runs. Finally, we note that a constant wave height has been chosen in order to provide analogous results for all (frequency) conditions. The specific choice of wave height has been done by considering any limitations associated with the wave generation system which, according to the period, can accurately generate waves within the basin up to a certain height limit.

3.2. Bimodal sea state

As discussed within Section 3.1, sea states composed of a finite number of components, although not realistic in practice, can be useful for identification of complex phenomena characterising WEC systems. Bimodal sea states represent a natural extension of the regular wave case, by incorporating an additional frequency component. These wave conditions which, in practice, are linked to a combination of wind- and swell-seas, can be used within the scope of modelling/system dynamics to *e.g.* infer measures of nonlinear behaviour of the system by quantifying the validity of the principle of superposition for these specific components [75], or even to provide an estimation of the class of functions characterising the nonlinearities of the WEC [71, 76]. Furthermore, while high-fidelity numerical wave tanks are virtually always able to generate regular waves with great precision, these is not necessarily the case for

⁴Presence of either sub- or super- harmonics intrinsically depends on the stability nature of the system (see *e.g.* [71]).

⁵The open-source BEM software NEMOH [74] has been used to compute the associated prototype frequency-response map.

387 polychromatic sea states [77, 78], so that bimodal sea states can represent a useful ‘intermediate’ case between regular
 388 and irregular conditions for numerical validation purposes.

Figure 10: Theoretical spectra for the bimodal wave condition used within this experimental study.

389 Within this experimental campaign, we consider a single bimodal sea state (BMSS - see Table 3), with one
 390 frequency component placed at the resonance behaviour of the WEC prototype (equivalent to RSS2), and a low-
 391 frequency contribution (equivalent to RSS4). An equal energy method (see *e.g.* [79]) has been employed to characterise
 392 the associated theoretical spectrum, which can be appreciated within Figure 10 (normalised w.r.t. the frequency placed
 393 at the system resonance).

394 3.3. Irregular sea states

395 As it is virtually always the case within the marine/ocean engineering community, realistic waves can be represented
 396 in terms of a set of stochastic descriptions, with an associated (dense) spectrum (see *e.g.* [80]). While different models
 397 can be used to characterise ocean waves, a particularly well-used representation is that provided by the so-called
 398 JONSWAP spectrum [70], describing wind-generated seas with fetch limitations. Within such a stochastic description,
 399 three main parameters can be identified, *i.e.* significant wave height H_s , peak wave period T_p , and peak-enhancement
 400 factor γ .

Figure 11: Theoretical spectra for the irregular wave conditions used within this experimental study.

401 Three irregular sea states (ISS1 to ISS3) are considered within this experimental campaign, as described within
 402 Table 3. The parameters for these conditions have been directly adopted from the benchmark control case established
 403 by the WEC³OMP [56], and aim to represent diverse operating sea states for both uncontrolled, and controlled device
 404 motion conditions. The theoretical spectra (normalised w.r.t. ISS2) associated with these sea states can be appreciated
 405 in Figure 11. Two narrow-banded conditions (ISS1 and ISS2) are considered, with different peak periods and associated
 406 significant wave heights. Finally, ISS3 represents a broad-banded operating case, with significant energy content
 407 covering low-, resonance, and high-frequency components. Note that two different realisations are considered for each
 408 ISS, so as to provide the dataset with diverse (time-domain) representations for each operating condition.

3.4. White noise waves

While irregular sea states, as described within Section 3.3, can effectively represent realistic wave conditions, these might not be fully useful for *e.g.* control-oriented modelling/validation. In particular, since WEC systems have to operate in potentially (very) different sea states, having diverse spectral content and characterisation, modelling/validation of *e.g.* WEC controllers for a broad range of operating scenarios can become difficult (and time-consuming - especially in *e.g.* CFD-based models) with a limited number of irregular sea states tests. Aiming to resolve this issue, we employ, within this experimental campaign, sea states described in terms of white noise spectra, *i.e.* with a constant spectral density function in a sufficiently large (yet banded) frequency range. The latter has to be large enough to thoroughly cover the typical WEC operating conditions, hence guaranteeing representativity of the associated dataset for a large number of operating scenarios.

Figure 12: Theoretical spectra for the white noise wave conditions used within this experimental study.

In particular, three different white noise sea states (WNSS1 to WNSS3) are considered within this experimental campaign, as described within Table 3, and presented in Figure 12. While, as can be appreciated from Figure 12, the frequency range, which effectively contains the main dynamics of the baseline WEC prototype, remains constant for WNSS1, WNSS2 and WNSS3, their energy increases progressively. This is performed to provide information on how a higher energy content (which effectively translates to larger free-surface elevation points in time) has an effect on the system response, hence supplying data on any relevant nonlinear behaviour affecting the WEC prototypes according to each tested layout.

4. Tests design and sample results

Having described the baseline prototype and array layouts in Section 2, and the considered sea states for experimental generation of SWELL within the Aalborg University wave tank in Section 3, we proceed to describe in detail the specific set of tests considered, and their associated nature and synergy. Four different tests have been designed, in which either all, or a subset of the considered sea states and WEC array layouts (see Table 4) are involved:

Test 1 *Free-surface elevation*: Test designed to provide the wave elevation (time-domain) signal for each sea state and realisation considered within this experimental campaign, at the probe locations described in Figure 2. Note that, as further detailed within Section 4.1, this test is effectively independent on the layout definitions provided in Section 2.4.

Test 2 *Wave excitation*: Test designed to provide the wave excitation force/torque associated with each generated free-surface elevation, for each sea state and realisation considered within this experimental campaign, and each WEC array layout specified within Section 2.4.

Test 3 *Uncontrolled device motion*: Test designed to provide *uncontrolled* WEC device motion (displacement, velocity and acceleration) associated with each generated free-surface elevation, for each sea state and realisation considered within this experimental campaign, and each WEC array layout specified within Section 2.4.

Test 4 *Controlled device motion*: Test designed to provide *controlled* WEC device motion (displacement, velocity and acceleration) associated with each generated free-surface elevation, for each sea state and realisation considered within this experimental campaign, and each WEC array layout specified within Section 2.4.

Table 4

Executed tests as a function of both sea states and WEC array layouts considered. The symbol ● indicates that the tests have been performed on L0 to L8, while those with ○ have been considered on L0 to L5.

WNSS1	●	●	●	-
WNSS2	●	●	●	-
WNSS3	●	●	●	-

Each test is described in detail in a specific section (Sections 4.1 to 4.4), following this paragraph. Specific emphasis in the connection and synergy between Tests 1, 2, 3 and 4 is made within Section 4.5. We further clarify that the objective of this section is not that of providing a comprehensive analysis of the dataset provided within this paper, but to introduce the nature of the tests and a set of sample results, used to illustrate their execution.

4.1. Test 1: Free-surface elevation

This test has the final objective of providing a measure, within SWELL, of the time-series associated with free-surface elevation for each of the sea states (and realisations) listed in Section 3. These measures are taken at diverse points (in space) within the wave tank, according to the description provided within Section 2.3. Note that, for this particular test, no device is present within the tank, so that the wave probes WP 15, 16, 17, 18 and 19 effectively measure free-surface elevation at the centre point of each WEC system when in operating conditions (see Figure 2).

To illustrate the effective measurement of free-surface elevation, Figure 13 shows the time-traces associated with RSS1 to RSS5 and that of BMSS, as measured by WP 1, and the magnitude associated to their respective fast Fourier transform (FTT). Note that the wavemaker is effectively able to produce these waves with high precision, having their energetic content effectively concentrated in either a single component (RSS - first four from the top) or in two separate frequencies (BMSS - bottom), coinciding well with their theoretical description (see Section 3). To further extend the example provided by Figure 13, Figure 14 illustrates measurements obtained by WP 1 for ISS1-1, ISS2-1, ISS3-1, and the three white noise wave conditions (WNSS1, WNSS2 and WNSS3). A good agreement with the theoretical spectrum can also be qualitatively appreciated from Figure 14, for all the analysed cases.

To demonstrate the repeatability of the wavemaker, Figure 15 shows a time-snippet (of approximately two wave periods) associated with the three realisations tested of RSS2 and RSS4, as measured by WP 1. A very good agreement can be appreciated between all separate wave generation experiments, showing the capabilities of the wavemaker to consistently generate the same wave in diverse frequency points.

We discuss one last issue within this section, which is that of wave probe alignment. As can be appreciated in Figure 2, a large set of probes has been placed in a row-like formation, so as to measure the wave elevation consistently in-between devices, and their centre points. By way of example, Figure 16 shows measurements of free-surface elevation for WP 15, 16, 17 and 18, placed at the central position of D1, D2, D3 and D4, respectively, for ISS1-1. As it can be appreciated, the measurements show a very good agreement, both in a point-to-point comparison (top), and w.r.t. their normalised correlation (bottom), using WP 15 as the 'target' signal (*i.e.* computed w.r.t. WP 15). Note that the latter shows a maximum correlation point at ≈ 0 [s] (in lag), effectively validating the placement of the probes within the wave tank.

Nonetheless, though ideally the same signal, one can realise, from Figure 16 (top), that the measurements of WP 15, 16, 17 and 18 present slight differences between each other. This can be at least partially explained by any reflections

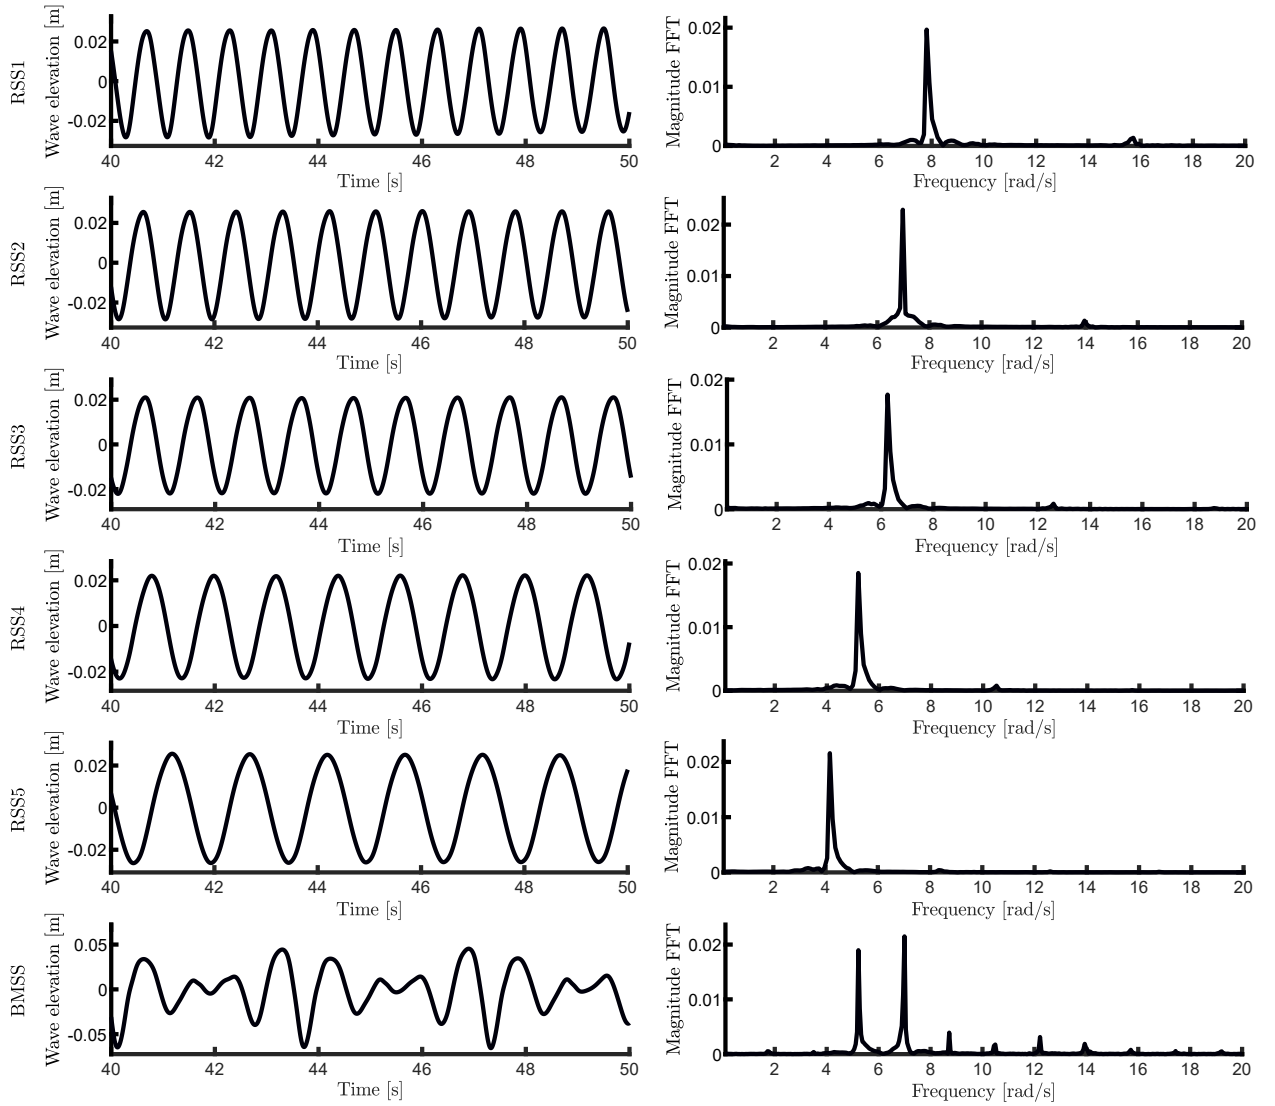

Figure 13: Test 1: Experimental free-surface elevation as measured by WP 1, both in time (left), and frequency (right), for RSS1 to RSS5 and BMSS.

476 happening within the wave tank which, though capable of providing a great wave absorption effort, inevitably generates
 477 small wall reflections in different directions. To illustrate this, Figure 17 presents the normalised error (NSE) w.r.t.
 478 WP 15 (consistently with the correlation in Figure 16), computed as $e_{WP_i} = |\eta_{WP_i} - \eta_{WP_{15}}| / \max |\eta_{WP_{15}}|$ for
 479 $i \in \{4, 5, 6, 7, 8, 16, 17, 18\}$ (all in row-alignment with WP 15), for the first 40 [s] of wave generation corresponding
 480 with ISS1-1. One can immediately notice that errors are always low, with maximum values (for this particular time-
 481 snippet) of approximately 5%. We further note that the choice of ‘ordering’ for the y-axis of Figure 17 is not arbitrary,
 482 but has a one-to-one correspondence with the wave probe placement in Figure 2. This particular ordering helps in
 483 illustrating tank reflections: While during the very first seconds all measurements are virtually identical, the error
 484 between different wave probes (w.r.t. WP 15) increases with time, and with a marked difference in space. In particular,
 485 it can be appreciated how wave reflections are coming from a specific direction in the tank for this case (ostensibly
 486 from the side corresponding with WP 8), so that the error clearly propagates in time according to the positioning of
 487 the probe (*i.e.* reflections take slightly longer to arrive to wave probes which are further away from WP 8).

Figure 14: Test 1: Experimental free-surface elevation as measured by WP 1, both in time (left), and frequency (right), for ISS1-1 to ISS3-1 and WNSS1.

Figure 15: Realisations 1 to 3 for RSS2 (top) and RSS4 (bottom).

488 4.2. Test 2: Wave excitation

489 Following Test 1, as described in Section 4.1, we proceed to measure the so-called wave excitation force/torque
 490 acting on the different WEC array configurations, for each specific free-surface elevation generated within the wave
 491 tank, and every single layout tested. To achieve this, the devices involved in each layout are essentially blocked (each
 492 associated PTO motor shaft is locked - see *e.g.* [21]), and hence the force f_B exerted by each particular wave can be
 493 measured directly via the load cell attached to point **B** (see Section 2.2 and Figure 3), and transformed to torque w.r.t.
 494 point **A**, *i.e.* τ_A , via equation (1).

Figure 16: Free-surface elevation measurement for WP 15 to WP 18 (top), and corresponding normalised cross-correlation w.r.t. WP 15 (bottom).

Figure 17: Set of wave probes in row-alignment, centered w.r.t. D1, D2, D3 and D4, and their corresponding normalised error against WP 15.

495 To briefly illustrate the nature of the measurements obtained within this test, Figure 18 shows wave excitation torque
 496 (computed about each corresponding reference point **A** in Figure 3) for L4 (layout composed of D1, D2 and D3) and
 497 L5 (layout composed of D1, D3 and D5), when the generated wave corresponds with RSS4. It can be appreciated how,
 498 while the excitation is relatively similar for all devices in L4, this changes when considering L5, given the positioning
 499 of D5 within the wave tank.

500 To further illustrate Test 2, Figure 19 shows wave excitation torque τ_A for D1 in different layout configurations (L0,
 501 L1 and L4), when the generated wave within the basin corresponds to RSS4. Note that, as described in detail within
 502 Section 2.4, L0 represents the ‘undisturbed’ (baseline) device, *i.e.* only D1 is present in the layout configuration. L1
 503 and L4 incorporate one (D2) and two (D2 and D3) WECs within the basin, in an adjacent configuration w.r.t. D1, hence
 504 naturally introducing interactions between devices.

Figure 18: Wave excitation torque for L4 and L5, when RSS4 is generated within the wave basin.

Figure 19: Wave excitation torque for D1 in different layout configurations (L0, L1 and L4), when RSS4 is generated within the wave basin.

4.3. Test 3: Uncontrolled device motion

505 Test 3, introduced within this section, completes the information gathered within Tests 1 and 2, by providing
 506 motion variables for each device within SWELL, in every single layout tested, and each generated wave within the
 507 basin. In particular, as described within Section 2.2, two main motion variables can be measured directly, using the
 508 instrumentation available in each device: Linear (PTO) position z_{PTO} (either via the incorporated sensor within the
 509 corresponding driver or the laser position sensor placed on top of the motor - see Section 2.2), and floater (linear)
 510 acceleration \ddot{z}_E (measured via the accelerometer placed on top of each floater). We note that, throughout the activities
 511 pertaining this particular test, the PTO reference force is set to zero, *i.e.* $u_{PTO}^{ref} = 0$ in Figure 6, effectively guaranteeing
 512 ‘free’ (uncontrolled) motion of the WEC system according to each generated input wave.
 513

514 To have a powerful dataset, useful for a large modelling/validation activities, we aim to provide a complete
 515 description of the system motion (*i.e.* displacement, velocity and acceleration) about the reference point **A** (see
 516 Figure 3), for each layout considered. As discussed previously within Section 2.2, while θ_A and $\dot{\theta}_A$ can be reconstructed
 517 straightforwardly following equation (1), $\ddot{\theta}_A$ effectively requires estimation. To do this with the available measures, we

518 employ standard methodologies from the field of sensor fusion, and we leverage a Kalman Filtering (KF) technique to
 519 provide estimates when needed.

Figure 20: Motion for L4 and L5, when RSS4 is generated within the wave basin.

520 To illustrate the data collected via Test 3, Figure 20 shows angular positions θ_A for every device in L4 and L5,
 521 when RSS4 is generated within the wave basin. Note that this figure is, in fact, a ‘companion’ of Figure 18, in the
 522 sense that the former represents the motion of the WEC prototypes when the latter (torque) is applied to each array
 523 configuration. It is interesting to see that, for this specific wave (RSS4), the devices in L4 (which are in a row-like
 524 formation) move in a synchronised fashion, *i.e.* they share virtually the same amplitude and phase in motion. This
 525 is, clearly, not necessarily the case for the remainder of the waves tested within this campaign, since the motion (and
 526 intensity of the interaction between devices in the array) intrinsically depend on the wave characteristics. For instance,
 527 Figure 21 shows θ_A for the same configuration, *i.e.* L4, when ISS1-1 is generated within the wave tank. Note that,
 528 while D1 and D3 (which are located at the ‘end-points’ of the layout) behave almost identically, D2 (sitting in between
 529 D1 and D3) presents a very different motion, due to the effect of the interaction between devices. Finally, to further
 530 complete the results illustrated within this section, Figure 22 presents θ_A for D1 in different layout configurations (L0,
 531 L1 and L4), when the generated wave within the basin corresponds to RSS4. Note that, as in the case of Figures 20
 532 and 18, Figure 22 represents the ‘companion’ of Figure 19, being wave excitation torque/device motion pairs.

Figure 21: Motion for L4, when ISS1-1 is generated within the wave basin.

Figure 22: Motion for D1 in different layouts (L0, L1 and L4), when RSS4 is generated within the wave basin.

Table 5

Passive and reactive control parameters for each sea state considered within Test 4.

SS	Passive (P)		Reactive (PI)	
	ϕ^P [Nms/rad]	ϕ^{PI} [Nms/rad]	ψ^{PI} [Nm/rad]	
ISS1	9.57	2.74	-32.31	
ISS2	16.74	4.14	-24.73	
ISS3	2.81	2.79	-2.59	

4.4. Test 4: Controlled device motion

While Test 3, as described in Section 4.3, provides information on the motion associated with each WEC layout, the test is performed without the presence of an energy-maximising PTO control force/torque in the system, *i.e.* with $u_{PTO}^{ref} = 0$ in Figure 6. As it is well-established within the literature, and discussed within Section 1, WEC systems require tailored control technology to enhance energy extraction in operating conditions, so as to minimise the associated LCoE. When optimally designed, these control systems tend to exaggerate device motion (see [50]), potentially triggering nonlinear effects which are not present/dominant when in uncontrolled conditions.

As such, validated models, capable of representing WEC systems under the action of energy-maximising control (see the lower block in Figure 6), are effectively fundamental for accurate and reliable performance assessment of both single and array configurations. With this in mind, Test 4 incorporates in SWELL information of a subset of the WEC layouts and sea states considered within this campaign (see Table 4), under diverse control conditions. In particular, two well-known and widely-adopted control architectures are considered, often referred to, in the literature, as *passive* (proportional - P), and *reactive* (proportional-integral - PI) controllers, *i.e.*

$$\begin{aligned}
 (P) : \quad \tau_{PTO}^{ref} &= \phi^P \dot{\theta}_A, \\
 (PI) : \quad \tau_{PTO}^{ref} &= \phi^{PI} \dot{\theta}_A + \psi^{PI} \theta_A,
 \end{aligned} \tag{2}$$

where the set of parameters $\Phi = \{\phi^P, \phi^{PI}, \psi^{PI}\} \subset \mathbb{R}$ is computed in terms of the so-called impedance-matching (also referred to complex-conjugate - see *e.g.* [17, 72]) condition for WEC systems, using the frequency-response map of L0 (*i.e.* a single device - D1) as benchmark. The specific values for the set of parameters Φ , which are given explicitly for completeness within Table 5, naturally depend on the generated wave condition (see the discussion provided in *e.g.* [72]), and are equally considered for all the devices and layouts tested, for consistency of the dataset, hence allowing a direct comparison between different array configurations. Note that τ_{PTO}^{ref} can be mapped to a corresponding force u_{PTO}^{ref} by simply employing the relations presented in equation (1).

To illustrate the results obtained within this test, Figure 23 presents motion θ_A for L0, in uncontrolled (solid), passively- (dashed), and reactively-controlled (dotted) conditions, for ISS1-1. As it can be appreciated, both passive and reactive cases clearly present different closed-loop dynamics, with the latter generating both larger control torque requirements, and effective device motion, in line with the discussion provided within the first paragraph of this section

Figure 23: Controlled behaviour for L0 when ISS1-1 is generated within the basin.

551 (see also Section 1). Note that, clearly, the reactive controller requires negative instantaneous power flow, injecting
 552 energy into the WEC system at specific time instants to maximise the total absorbed power [17]. To further emphasise
 553 the fact that devices under controlled conditions can present larger motions than those in uncontrolled scenarios, Figure
 554 24 illustrates a time-snippet of uncontrolled and reactively-controlled angular displacement θ_A for L4, when ISS1-1 is
 555 generated within the wave basin. Notice that all three devices involved (D1, D2 and D3) present larger displacement
 556 values in the reactive control case, consistent with the presented discussion.

Figure 24: Controlled behaviour for L4 when ISS1-1 is generated within the basin.

4.5. Synergy between tests

Tests 1 to 4 have been all designed with a pre-defined synergy, so as to facilitate a dataset to the WEC community able to provide enough information to perform a large number of data-based modelling/validation tasks for array configurations. The main synergies between these tests can be appreciated in the schematic presented within Figure 25, and are detailed in the paragraphs below.

Figure 25: Schematic diagram indicating synergy between different tests.

Tests 1 and 2 provide information for data-based modelling/validation of free-surface-elevation-to-wave-excitation dynamics (path indicated with dark-blue in Figure 25). For instance, exploiting the data provided by the wave probes placed in the central position of each device (as collected in Test 1), and the corresponding wave excitation force/torque (recovered from Test 2), one can directly characterise/validate the free-surface-to-excitation dynamics of each device and layout considered. In particular, the set of white noise sea states (WNSS1, WNSS2 and WNSS3) is particularly useful for this task, being able to provide information for such a mapping in a large operational bandwidth. By way of example, Figure 26 presents an empirical frequency-domain characterisation of the free-surface-elevation-to-wave-excitation-torque dynamics associated with L0 (*i.e.* D1), in terms of the so-called empirical transfer function estimate (ETFE - see *e.g.* [21, 68]). This map has been computed using the free-surface elevation measured at the central position of D1 as input set, for all three white noise sea states (as in Test 1), and their associated measured wave excitation torque (as in Test 2).

Following an analogous procedure, Tests 2 and 3 can be used to characterise/validate the excitation-to-motion dynamics (path indicated with light-blue in Figure 25). This is illustrated in Figure 27, which presents the corresponding ETFE for L0, computed using the set of excitation torques for WNSS1 to WNSS3 (as measured in Test 2), and their corresponding uncontrolled motion (as per Test 3). Finally, note that, using Tests 1 and 3, one can also characterise/validate the behaviour of the tested WEC array layouts from the free-surface elevation to the corresponding device motion (path indicated with green in Figure 25).

The methodology discussed in the paragraphs immediately above can be also performed in energy-maximising control conditions, by exploiting the information provided within Test 4. In particular, combining Tests 1 and 2, with the outputs generated in Test 4, the dataset contains information to model/validate the dynamics of WEC array numerical models in controlled conditions, for different layout configurations, being this fundamental for reliable performance assessment of WEC farm technology. Finally, with suitable combinations of the information gathered in Tests 1, 2, 3 and 4 (as schematically indicated within Figure 25), one can also validate models for device interaction, and proximal and distal wave fields. In particular, the large number of wave probes available throughout the experiments (see Figure 2) allows for a detailed numerical description of the interaction between devices and resulting wave field, for all the layout configurations tested within this campaign.

Figure 26: Free-surface-elevation-to-wave-excitation-torque ETFE for L0, computed using WNSS1, WNSS2 and WNSS3. The black line indicates the average over the three I/O experiments.

Figure 27: Wave-excitation-to-angular-velocity ETFE for L0, computed using WNSS1, WNSS2 and WNSS3. The black line indicates the average over the three I/O experiments.

588 **5. Dataset specification**

589 This section is devoted to provide a description of the dataset included within this paper, *i.e.* SWELL, composed
 590 of the data collected in the tests described in Section 4. The directory structure, associated with SWELL, can be
 591 appreciated in Figure 28. In particular, two main folders can be found within the structure, namely *Tests* and
 592 *Linear motors*. The former contains the core of the dataset, including data from Tests 1 to 4 (as described in

Figure 28: Directory structure for SWELL.

593 Section 4), for every WEC array layout involved. The latter, instead, is composed of the data characterising each
 594 PTO linear motor, in line with the discussion provided in Section 2.5.

595 SWELL is fully composed of MATLAB-compatible files, in the native format ‘.mat’. This is done with the aim of
 596 maximising the impact of the dataset, providing files ready to be processed and analysed promptly. The totality of the
 597 data is stored in a standard matrix format (with dimensions as clarified in the following paragraphs), hence avoiding
 598 any potential compatibility issues between diverse MATLAB software versions/releases. We further note that ‘.mat’
 599 files can be opened straightforwardly using *e.g.* PYTHON or OCTAVE, being hence also compatible with a wide set of
 600 analysis tools outside MATLAB.

601 We begin with a description of the main part of the directory, *i.e.* Tests, which contains 9 folders, each
 602 corresponding with one of the 9 layouts tested (*i.e.* from L0 to L8). Inside each of these folders, 19 files with extension
 603 ‘.mat’ can be found, each linked with a single operating condition, *i.e.* sea state and realisation (if applicable). For
 604 instance, ‘01_RSS1_1.mat’ refers to results for RSS1 realisation 1 (note that a single realisation of RSS1 is effectively
 605 considered within the campaign - see Table 3), while *e.g.* ‘16_ISS3_2.mat’ refers to ISS3, realisation 2.

606 Referring to the content related to these latter 9 folders, within each of these ‘.mat’ files, as listed in Figure 28, a
 607 number of variables can be found, associated with the results obtained from Tests 1 to 4, for each layout considered.
 608 The complete set of variables can be appreciated in Table 6, including associated test, name in file, description, units,

609 and effective variable dimensions, where $\{N_t, N_d\} \subset \mathbb{N}$ refer to the length of the time vector and number of devices
 610 present in the layout, respectively. Note that, the variables related to Tests 1 to 3 are effectively present in the totality
 611 of the ‘.mat’ files included within the dataset, while those related to Tests 4 and 5 are exclusive to layouts L0 to L5
 612 (see also Table 4).

613 The time vector, as specified within Table 6, is common to all tests and variables, *i.e.* all variables have been
 614 synchronised and interpolated w.r.t. a single reference time vector, for each ‘.mat’ file within the main folder Tests.
 615 This has been possible by exploiting a trigger output signal available within the wavemaker system of Aalborg
 616 University, which provides a digital flag at the precise moment wave generation starts/ends. Apart from synchronisation,
 617 we have filtered the signals accordingly, to avoid noise pollution within the dataset. In particular, to achieve such an
 618 objective, a zero-phase (forward-backward) Chebyshev filter (see *e.g.* [66]) has been applied to all variables involved
 619 in Table 6, with a filter order 4 and a (sufficiently large) cut-off frequency of 50 [rad/s].

620 Finally, and related to the PTO characterisation discussed within Section 2.5, the folder `Linear motors` contains
 621 information regarding each linear (PTO) motor, for D1 to D5. In particular, two ‘.mat’ files can be found within each
 622 device folder, namely `I/O_tests.mat` and `Friction_tests.mat`. As detailed within Table 7, the former file contains
 623 I/O information for each single motor, where the reference force (input) is a chirp signal with different amplitudes (see
 624 Figure 7). In contrast, the latter features the friction tests described in Section 2.5 (and illustrated in Figure 8), including
 625 all motion variables required to characterise these effects numerically (see Table 8).

626 6. Conclusions

627 We provide, in this paper, a detailed account of an experimental campaign designed with the sole objective of
 628 providing an open-access dataset for arrays of wave energy conversion systems, termed SWELL, hence facilitating
 629 a crucial resource for model validation and data-based modelling. The campaign, executed within the wave basin
 630 facilities available at Aalborg University, is composed of 4 essential tests with a pre-designed synergy, aimed at
 631 maximising the value of the information available within SWELL for the WEC development community. In particular,
 632 key variables, such as free-surface elevation at different points within the basin (Test 1), wave excitation force (Test 2),
 633 uncontrolled motion (Test 3), and behaviour under energy-maximising (passive and reactive) control conditions (Test
 634 4), are effectively included as part of the dataset, for each of the sea states, devices, and layouts considered. Furthermore,
 635 a characterisation of each PTO system is also presented, by means of I/O and friction tests. This is, to the best of our
 636 knowledge, the largest open-access dataset characterising arrays of WEC systems available in the literature, including a
 637 wide variety of WEC layouts, realistic PTO effects (including energy-maximising control), tested in different scenarios
 638 following a consistent protocol, designed to suit the needs associated with a vast number of modelling tasks. SWELL
 639 provides, hence, an essential resource for reliability assessment of diverse numerical modelling approaches, supporting
 640 efficient decision making, and contributing to the pathway towards effective commercialisation of ocean wave energy.

641 ACKNOWLEDGMENT

642 The authors are grateful with Dr. M. Folley, from Queen’s University Belfast, for his valuable input during the
 643 execution of the experimental campaign. The support of Dr. S. Wood, which has been fundamental for setup of the
 644 data acquisition system, is also appreciated by the authors. This project has received funding from the European Union’s
 645 Horizon 2020 research and innovation programme under the Marie Skłodowska-Curie grant agreements No 101024372
 646 and 101034297, and support from the framework COST Action 17105 - WECANet. The support of the Facultad
 647 de Ingeniería, Universidad Nacional de La Plata (UNLP), CONICET, and Agencia I+D+i from Argentina, is also
 648 acknowledged.

Table 6

Variables for Tests 1 to 4, contained within the dataset.

	Name	Description	Units	Dim.
All tests	<i>time</i>	Time vector (common to all variables)	s	$1 \times N_t$
Test 1	<i>waveElevation_UD</i>	Wave elevation in all probe locations (1 to 19)	m	$19 \times N_t$
Test 2	<i>waveElevation_WE</i>	Wave elevation in probes 1 to 14	m	$14 \times N_t$
	<i>excitationForce_WE</i>	Wave excitation force (w.r.t. point B)	N	$N_d \times N_t$
	<i>excitationTorque_WE</i>	Wave excitation torque (w.r.t. point A)	Nm	$N_d \times N_t$
Test 3	<i>waveElevation_UM</i>	Wave elevation in probes 1 to 14	m	$14 \times N_t$
	<i>motorPos_UM</i>	Position of linear motor (as measured by motor driver)	m	$N_d \times N_t$
	<i>laserPos_UM</i>	Position of linear motor (as measured by laser sensor)	m	$N_d \times N_t$
	<i>motorVel_UM</i>	Velocity of linear motor (as estimated by motor driver)	m/s	$N_d \times N_t$
	<i>accelerometerAcc_UM</i>	Acceleration w.r.t. point E (as measured by accelerometer)	m/s ²	$N_d \times N_t$
	<i>angularPos_UM</i>	Angular position w.r.t. point A	rad	$N_d \times N_t$
	<i>angularVel_UM</i>	Angular velocity w.r.t. point A (output of KF)	rad/s	$N_d \times N_t$
	<i>angularAcc_UM</i>	Angular acceleration w.r.t. point A	rad/s ²	$N_d \times N_t$
Test 4	<i>waveElevation_CM_P</i>	Wave elevation in probes 1 to 14 under P control	m	$14 \times N_t$
	<i>motorPos_UM_P</i>	Position of linear motor (as measured by motor driver) under P control	m	$N_d \times N_t$
	<i>laserPos_UM_P</i>	Position of linear motor (as measured by laser sensor) under P control	m	$N_d \times N_t$
	<i>motorVel_UM_P</i>	Velocity of linear motor (as estimated by motor driver) under P control	m/s	$N_d \times N_t$
	<i>accelerometerAcc_UM_P</i>	Acceleration w.r.t. point E (as measured by accelerometer) under P control	m/s ²	$N_d \times N_t$
	<i>angularPos_UM_P</i>	Angular position w.r.t. point A under P control	rad	$N_d \times N_t$
	<i>angularVel_UM_P</i>	Angular velocity w.r.t. point A (output of KF) under P control	rad/s	$N_d \times N_t$
	<i>angularAcc_UM_P</i>	Angular acceleration w.r.t. point A under P control	rad/s ²	$N_d \times N_t$
	<i>controlForce_UM_P</i>	Requested control force (reference to motor driver) w.r.t. point B under P control	N	$N_d \times N_t$
	<i>controlTorque_UM_P</i>	Requested control torque (reference to motor driver) w.r.t. point A under P control	Nm	$N_d \times N_t$
	<i>waveElevation_CM_PI</i>	Wave elevation in probes 1 to 14 under PI control	m	$14 \times N_t$
	<i>motorPos_UM_PI</i>	Position of linear motor (as measured by motor driver) under PI control	m	$N_d \times N_t$
	<i>laserPos_UM_PI</i>	Position of linear motor (as measured by laser sensor) under PI control	m	$N_d \times N_t$
	<i>motorVel_UM_PI</i>	Velocity of linear motor (as estimated by motor driver) under PI control	m/s	$N_d \times N_t$
	<i>accelerometerAcc_UM_PI</i>	Acceleration w.r.t. point E (as measured by accelerometer) under PI control	m/s ²	$N_d \times N_t$
	<i>angularPos_UM_PI</i>	Angular position w.r.t. point A under PI control	rad	$N_d \times N_t$
	<i>angularVel_UM_PI</i>	Angular velocity w.r.t. point A (output of KF) under PI control	rad/s	$N_d \times N_t$
	<i>angularAcc_UM_PI</i>	Angular acceleration w.r.t. point A under PI control	rad/s ²	$N_d \times N_t$
<i>controlForce_UM_PI</i>	Requested control force (reference to motor driver) w.r.t. point B under PI control	N	$N_d \times N_t$	
<i>controlTorque_UM_PI</i>	Requested control torque (reference to motor driver) w.r.t. point A under PI control	Nm	$N_d \times N_t$
