 Carrera Unified Formulation

ABSTRACT

This work investigates the effect of voids within the matrix of composite materials. Effects on local stress and plastic strain values are evaluated by conducting a micromechanical analysis. The microscale Representative Volume Element (RVE) is modeled through refined 1D elements based on the Carrera Unified Formulation (CUF). Using 1D models for the RVE leads to a significant reduction in computational costs compared to standard 3D elements. Fibers are modeled as orthotropic, and the matrix has an elastoplastic behavior. Random distributions of voids are considered, and statistical analyses are carried out. Furthermore, the influence of the depth of the RVE is investigated. The results show significant mean and peak stress values increases as the void volume fraction grows. Also, the use of deeper RVE leads to higher stress values.

1. Introduction

Nowadays, fiber-reinforced composites are widely used in various engineering applications. Their advantages stem from the high specific strength and stiffness. However, the multiscale nature of composites requires the development of accurate models for analyzing their mechanical behavior (Aboudi et al., 2012) and achieving a level of accuracy comparable to that of isotropic materials. Another potentially critical aspect to consider is the generation of defects during manufacturing, e.g., dispersed air gaps – voids – in the matrix or the fiber misalignment. Such defects can alter the microstructure of composites, affect elastic properties, and trigger failure onset (Hinton et al., 2004). He et al. (2020) quantified voids within the composite while other works focused on countermeasures during manufacturing (Potter et al., 2008; Saenz-Castillo et al., 2019; Zhang et al., 2022). Moreover, several experimental works studied how the mechanical performance of fiber-reinforced polymers decays due to defects (Blok et al., 2018; Hsu, 1988; Justo et al., 2018; Stone and Clarke, 1975). Voids are most often considered among all defects due to their impact on various properties (Mehdikhani et al., 2019). The presence and shape of voids are critical in evaluating the homogenized properties of porous materials, as noted in Masmoudi et al. (2017) and Khdir et al. (2014). Additionally, voids can significantly modify the dimensions and configuration of the stress field within the material (Touliatou and Wheel, 2019).

The numerical modeling of defects aims to understand better the performance degradation of composites (Talreja, 2015). Numerical methods to estimate material properties usually involve analysis of a Representative Volume Element (RVE) (Sun and Vaidya, 1996). The RVE is considered the smallest representative volume and corresponds to a periodic fiber packing sequence (Li and Sitnikova, 2019; Gitman et al., 2007; Gitman, 2006). Micromechanics is used to evaluate the behavior of multiphase materials (Aboudi et al., 2012; Aboudi, 2004; Nemat-Nasser and Hori, 1999), and various approaches are available for obtaining homogenized properties, and local stress and strain fields (Aboudi et al., 2001). Among the others, the method of cells has proven to be very versatile and reliable (Aboudi, 1981) and was later extended (Aboudi, 2004, 1989; Paley and Aboudi, 1992). The Generalised Method of Cells (GMC) was used by Dai et al. (2022) to simulate the effect of residual thermal stress and weak interphases on micro-cracking and later progressive failure of B₄C-TiB₂ composites. In some recent works, the High-Fidelity Generalised Method of Cells (HFGMC) replaced the GMC as a new generalized method (Aboudi, 2004; Bednarczyk et al., 2010; Pineda, 2012; Pineda et al., 2013). Recent investigations (Huang, 2023b,a) examined the effect of reinforcement-induced stress concentration on homogenized stress in the matrix by incorporating a stress concentration factor (SCF).

The Finite Element Method (FEM) is another approach for micromechanics. In the work of [Dong and Huo \(2016\)](#), FEM was used to model voids and dry patches via a two-scale RVE model with periodic boundary conditions to evaluate elastic constants and micro stress of 3D braided composites. [Huang and Gong \(2018\)](#) discussed the influence of voids in fiber tows and woven composites. They used multiscale FEM and found that the reduction of elastic properties in woven composites is less sensitive to the voids in the matrix than those in fiber tows. [Jiang et al. \(2019\)](#) showed that voids have little influence on the longitudinal stress-strain response, while a more pronounced decrease of in-plane and out-of-plane shear strength with increasing voids content is obtained. In [Pineda et al. \(2022\)](#), the prediction of the difference in strength between a baseline model of a woven composite containing 0.4% of voids and a representative model with ten times increase in void content was obtained using the NASA Multiscale Analysis Tool (NASMAT). A ~10%–11% variation between the two models in the ultimate stress was found. The effect of interfiber and circular voids on the strength of composite under transverse tension and compression was discussed in [Ashouri Vajari et al. \(2014\)](#), while [Zhang et al. \(2021\)](#) investigated the irregular stress and damage evolution contours that occur due to the random arrangement of the fibers and the voids in the matrix. In the work of [Carrera et al. \(2020\)](#), the effect of matrix voids on homogenized properties was studied. Moreover, dehomogenization allowed for obtaining local stress fields using both random and clustered distributions of voids. [Nagaraj et al. \(2021\)](#) introduced the material nonlinearity by involving an elastoplastic matrix behavior and studied how voids affect von Mises stress (VM) and the equivalent plastic strain (PEEQ) of composites.

To improve accuracy, 3D FEM is used for RVE; however, such a strategy may lead to unaffordable computational costs in many cases, e.g., multiscale and nonlinear analyses. An alternative approach to tackling such a problem was proposed by [Carrera et al. \(2014\)](#), [Kaleel et al. \(2017, 2018b\)](#) and based on the use of 1D higher-order structural theories obtained via the Carrera Unified Formulation (CUF). The present article adopts such a framework to reduce computational costs while maintaining 3D accuracy in stress and strain. Following this approach, shape functions act along the RVE axis, and the expansion functions enhance the cross-section kinematics. Past works proved that 1D CUF could be used to tackle various problems, including progressive failure analysis ([Pagani et al., 2022](#)) and composite stress analysis.

This work aims to extend the findings from [Carrera et al. \(2020\)](#), including the effect of matrix nonlinearity, as previously done by [Nagaraj et al. \(2021\)](#), where a single random distribution of voids is used for each strain applied. The present paper involves micromechanical dehomogenization, followed by a statistical analysis performed on multiple void distributions. The purpose is to collect statistical parameters and identify critical load conditions for the RVE, leading to stress peaks. Furthermore, the present work investigates the impact of the RVE thickness on the micromechanical nonlinear response. This paper is organized as follows: Section 2 presents the CUF approach; Section 3 describes the micromechanics model; Section 4 provides a brief overview of the statistical analysis and corresponding parameters; in Section 5 numerical results are shown and discussed; and in Section 6 conclusions are drawn.

2. CUF and finite element formulation

Considering the reference frame shown in [Fig. 1](#), the three displacement components are

$$\mathbf{u}(x, y, z) = \{u_x, u_y, u_z\}^T \quad (1)$$

CUF is employed to generate structural theories and related equations. In the 1D case, the displacement field becomes

$$\mathbf{u}(x, y, z) = F_\tau(x, z) \mathbf{u}_\tau(y), \quad \tau = 1, 2, \dots, M \quad (2)$$

Fig. 1. Reference frame.

F_τ is the expansion function and \mathbf{u}_τ is the vector of generalized displacements. Moreover, M is the number of expansion terms. The expansion exploits Lagrange polynomials in this work, resulting in a Component Wise (CW) approach. A comprehensive explanation of Lagrange polynomials for CUF can be found in [Carrera and Petrolo \(2012\)](#). The current work utilizes 9-node bi-quadratic expansion elements (L9) to discretize the unknown displacements over the cross-section, as shown in [Fig. 2](#). The iso-parametric formulation is used to model arbitrarily shaped geometries. The L9 displacement field is given by

$$\begin{aligned} u_x &= F_1 u_{x_1} + F_2 u_{x_2} + F_3 u_{x_3} + \dots + F_9 u_{x_9} \\ u_y &= F_1 u_{y_1} + F_2 u_{y_2} + F_3 u_{y_3} + \dots + F_9 u_{y_9} \\ u_z &= F_1 u_{z_1} + F_2 u_{z_2} + F_3 u_{z_3} + \dots + F_9 u_{z_9} \end{aligned} \quad (3)$$

u_{x_1}, \dots, u_{z_9} are the displacement variables of the problem, and they represent the translational displacement components of each point of the L9 element.

The beam is discretized using the classical finite element approach along y using standard shape functions, i.e.,

$$\mathbf{u}(x, y, z) = F_\tau(x, z) N_i(y) \mathbf{u}_{\tau i}, \quad \tau = 1, 2, \dots, M, \quad i = 1, 2, \dots, p + 1 \quad (4)$$

N_i is the shape function of order p , and $\mathbf{u}_{\tau i}$ is the vector of nodal displacements. This paper used CUF to obtain 1D structural models, with standard shape functions acting along one direction and expansion functions over the cross-section. The three displacement components are obtained as a combination of generalized displacement variables, such variables are the nodal degrees of freedom of the problem. If, for instance, an expansion with five terms is used, the number of nodal degrees of freedom is fifteen. As mentioned in the book of [Washizu \(1968\)](#), 1D or 2D models with infinite expansions provide 3D solutions. A convergence analysis over the expansion terms can be carried out to select the proper order. Also, the role of each term over the solution can be studied via the axiomatic/asymptotic approach ([Carrera and Petrolo, 2010](#)). In recent years, CUF has been applied to many classes of composite structures, different loading conditions, and dynamic and nonlinear regimes ([Carrera et al., 2021](#)). The stress and strain components are

$$\begin{aligned} \boldsymbol{\sigma} &= \{\sigma_{xx} \ \sigma_{yy} \ \sigma_{zz} \ \sigma_{xy} \ \sigma_{xz} \ \sigma_{yz}\}^T \\ \boldsymbol{\varepsilon} &= \{\varepsilon_{xx} \ \varepsilon_{yy} \ \varepsilon_{zz} \ \varepsilon_{xy} \ \varepsilon_{xz} \ \varepsilon_{yz}\}^T \end{aligned} \quad (5)$$

The linear strain-displacement relation is used,

$$\boldsymbol{\varepsilon} = \mathbf{D} \mathbf{u} \quad (6)$$

\mathbf{D} is the linear differential operator, i.e.,

$$\mathbf{D} = \mathbf{D}_\Omega + \mathbf{D}_y$$

$$\mathbf{D}_\Omega = \begin{bmatrix} \frac{\partial}{\partial x} & 0 & 0 \\ 0 & 0 & 0 \\ 0 & 0 & \frac{\partial}{\partial z} \\ 0 & \frac{\partial}{\partial x} & 0 \\ \frac{\partial}{\partial z} & 0 & \frac{\partial}{\partial x} \\ 0 & \frac{\partial}{\partial z} & 0 \end{bmatrix} \quad \mathbf{D}_y = \begin{bmatrix} 0 & 0 & 0 \\ 0 & \frac{\partial}{\partial y} & 0 \\ 0 & 0 & 0 \\ \frac{\partial}{\partial y} & 0 & 0 \\ 0 & 0 & 0 \\ 0 & 0 & \frac{\partial}{\partial y} \end{bmatrix} \quad (7)$$

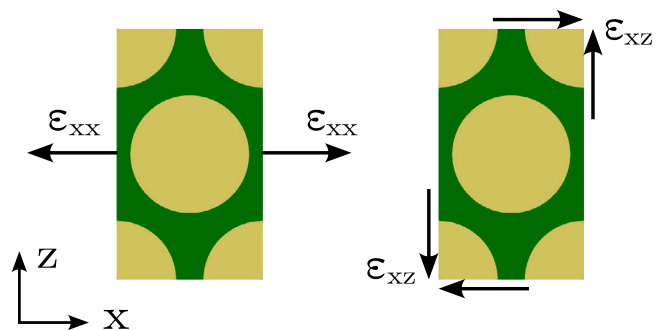

Fig. 7. Axial (left) and shear (right) strains applied to the hex-packed RVE.

The constitutive law is, then, employed,

$$\sigma = C^{ep} \epsilon \tag{8}$$

C^{ep} is the elastoplastic tangent matrix. This work considers material nonlinearities due to von Mises plasticity, and a Newton–Raphson scheme is used to solve the iterative process. Using the principle of virtual work over strain energy and the work of external forces,

$$\delta L_{int} = \delta L_{ext} \tag{9}$$

Defining V as the volume of the body, the strain energy becomes

$$\delta L_{int} = \delta u_{sj} k_{\tau sij} u_{\tau i} \tag{10}$$

$k_{\tau sij}$ is the Fundamental Nucleus (FN),

$$k_{\tau sij} = \int_V \mathbf{D}_{sj}^T C^{ep} \mathbf{D}_{\tau j} dV \tag{11}$$

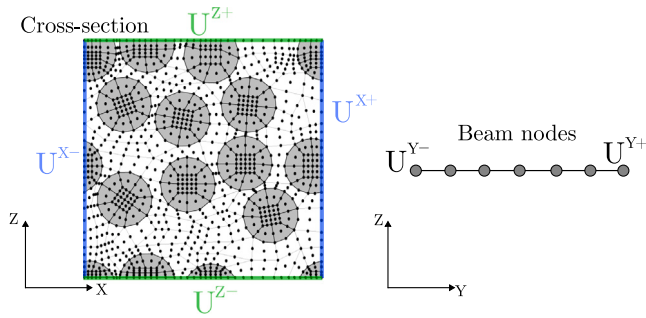

Fig. 15. Application of PBC on the random RVE on both the cross-section and the nodes in the y -direction.

FN is a 3×3 matrix composed by

$$\mathbf{k}_{\tau s i j} = \begin{bmatrix} k_{\tau s i j}^{xx} & k_{\tau s i j}^{xy} & k_{\tau s i j}^{xz} \\ k_{\tau s i j}^{yx} & k_{\tau s i j}^{yy} & k_{\tau s i j}^{yz} \\ k_{\tau s i j}^{zx} & k_{\tau s i j}^{zy} & k_{\tau s i j}^{zz} \end{bmatrix} \quad (12)$$

Similarly, the external force work can be obtained as follows:

$$\delta L_{\text{ext}} = \delta \mathbf{u}_{s j} \mathbf{p}_{s j} \quad (13)$$

$\mathbf{p}_{s j}$ is the external load vector. By iterating indices τ, s, i, j , the global stiffness matrix and global load vector are built. For the sake of brevity, the explicit expression of FN are not reported here, but can be found in Carrera et al. (2014).

3. Micromechanics framework

The reference frame adopted to describe the micromechanical framework is shown in Fig. 3. This work involves different types of representative volume elements, the beam model is used along x_1 , while L9 defines the displacement fiend over the x_2 - x_3 plane. Periodic boundary conditions (PBC) are employed (Xia et al., 2003) as follows:

$$u_i^{j+}(x, y, z) - u_i^{j-}(x, y, z) = \bar{\epsilon}_{ik} \Delta x_k^j \quad (14)$$

$$\Delta x_k^j = x_k^{j+} - x_k^{j-}$$

$j+$ and $j-$ indicate the positive and negative x_k -directions. $\bar{\epsilon}_{ik}$ is the applied macroscopic strain. The homogenized strain ($\bar{\epsilon}_{ij}$) and stress ($\bar{\sigma}_{ij}$) can be evaluated by volume averaging the microscopic strain (ϵ_{ij}) and stress (σ_{ij}) (Sun and Vaidya, 1996),

$$\bar{\epsilon}_{ij} = \frac{1}{V} \int_V \epsilon_{ij} dV \quad (15)$$

$$\bar{\sigma}_{ij} = \frac{1}{V} \int_V \sigma_{ij} dV \quad (16)$$

By introducing the homogenized material matrix $\bar{\mathbf{C}}_{ijkl}$, the constitutive relation can be expressed as follows:

$$\bar{\sigma}_{ij} = \bar{\mathbf{C}}_{ijkl} \bar{\epsilon}_{kl} \quad (17)$$

More details concerning the CUF micromechanics framework can be found in Kaleel et al. (2017).

Voids are modeled by randomly selecting a set of Gauss points within the matrix domain and assigning them low elastic moduli, as previously done in Carrera et al. (2020) and Nagaraj et al. (2021). The computation of the FE matrices employs the Gauss-Legendre quadrature, and the void sites' Gauss points concur to the integrals with modified elastic moduli. The random selection of matrix Gauss points as void sites is carried out to reach a given void volume fraction is reached. This process generates voids with a domain size equal to the volume associated with the selected Gauss point, not the entire element, and distinct sets of Gauss point combinations can provide the same

total void volume fraction. In the computation of the FE matrices, Gauss points that are void sites are considered with modified elastic properties. Fig. 4 presents an illustrative case of different Gauss point selections with a void volume fraction of 5%.

4. Statistical analysis

The novelty proposed in this article involves the extension of the effect of voids on composites that also exhibit a plastic behavior. For each void volume fraction, 50 defect distributions were randomly generated. The number of distributions was chosen as a reasonable compromise between the computational cost of non-linear elastoplastic analysis and the need for sufficient results to perform statistical analysis (Carrera et al., 2020). The aim of this Section is the introduction of statistical parameters used in this paper to investigate the effect of random void distributions on the mechanical response of the RVE. Absolute maximum and minimum of each mechanical quantity for each distribution of results were considered. Furthermore, the mean value and standard deviation (s) were considered,

$$s = \sqrt{\frac{1}{50-1} \sum_{i=1}^{50} |x_i - \bar{x}|^2} \quad (18)$$

x_i is a given mechanical quantity and \bar{x} is the mean value of each distribution. Also, the analysis considered the first, second and third quartiles. As well-known, the second quartile q_2 is the median; the first quartile q_1 is the median of the bottom half and the third quartile q_3 is the median of the top half (Langford, 2006). For the sake of clarity, a graphic representation of statistical parameters was used via boxplots in which quartiles, the notch extremes and the outliers can be observed. The notch extremes represent interval endpoints and they are computed as follows:

$$q_L = q_2 - 1.57 \frac{q_3 - q_1}{\sqrt{50}} \quad (19)$$

$$q_U = q_2 + 1.57 \frac{q_3 - q_1}{\sqrt{50}} \quad (20)$$

q_L is the lower endpoint, and q_U the upper one. Values exceeding the endpoints are the outliers,

$$q < q_L \quad \& \quad q > q_U \quad (21)$$

5. Numerical results

Numerical results considered two RVE architectures, hex-packed and randomly distributed fibers, and the influence of various parameters, such as the void volume fraction and the depth of the RVE. Void volume fractions from 1 to 5% were considered. As a matter of clarity, implementing a fiber-dispersed RVE does not contrast with the conceptualization of periodicity. Real composite microstructures are rarely structured; consequently, classical periodic unit cells (PUC) may not provide precisely the microstructural parameters (Li et al., 2018). In addition, microstructure conditions, such as the dimensions, geometry, spatial distribution, and material properties, strongly influence the interactions between the constituents and thus play a decisive role in the performance of these composites at a multiscale level (Li et al., 2018; Park et al., 2019). Therefore, a random packaging of fibers results in more attractive detection of the local response of composites. In addition, the material nonlinearity was considered for the matrix using the J2 flow theory as detailed in Carrera et al. (2019). The flow theory, referred to as the von Mises plasticity model, is based on the hypothesis that an isotropic material yields when the J2 stress deviator reaches the critical value. The following equation states an isotropic hardening case

$$f = q(\sigma) - \sigma_y(\bar{\epsilon}_p) \quad (22)$$

Fig. 16. Boxplots of maximum σ_{xx} over the fiber (a) and in matrix (b) of random RVE when ϵ_{xx} is applied.

Fig. 23. Effect of voids on normalized macroscopic response for the random RVE.

where f is the von Mises locus, σ_y is the yield stress, $\bar{\epsilon}_p$ is the isotropic hardening parameter and $q(\sigma)$ is the von Mises stress, composed by

$$q(\sigma) = \sqrt{3J_2} = \sqrt{\frac{1}{2} \left[(\sigma_{xx} - \sigma_{yy})^2 + (\sigma_{yy} - \sigma_{zz})^2 + (\sigma_{zz} - \sigma_{xx})^2 + 6(\sigma_{xy}^2 + \sigma_{xz}^2 + \sigma_{yz}^2) \right]} \quad (23)$$

where J_2 is the second invariant of the deviatoric stress. In the present framework, a rate-independent isotropic hardening is employed. It is included in the formulation by defining the yield stress as a function of the accumulated plastic strain, as shown in Eq. (22). This corresponds to a uniform expansion of the initial yield locus. The strain hardening approach is also utilized in the current framework to address the isotropic hardening behavior. The framework accommodates data points that approximate the arbitrarily nonlinear hardening curve. A linear interpolation is employed between data points to enable the direct use of the experimental hardening curve within the simulation. The constitutive model implemented within the CUF framework is based on (Neto et al., 2008).

5.1. Statistical analysis on hex-packed RVE

The aim of this section is the statistical analysis of local stress components through dehomogenization on a hex-packed RVE with 60% of fiber volume fraction. The mechanical properties of fibers and matrix are listed in Table 1, and the nonlinear behavior of the matrix is described using a plasticity curve, as illustrated in Fig. 5. The cross-section has 920 L9 elements, whereas 2 B4 elements were used along the y -direction, as shown in Fig. 6. The number of L9 and B4 elements was chosen according to the convergence analysis carried out in Carrera et al. (2020). Axial and shear strains equal to 0.005 were applied, as shown in Fig. 7. Fig. 8 shows the void distributions adopted.

Fig. 24. Boxplots of maximum σ_{xx} in the fiber of random RVE with variable thickness when ϵ_{xx} (a) and ϵ_{xz} (b) are applied.

Fig. 25. Boxplots of maximum σ_{xz} in the fiber of the random RVE with variable thickness when ϵ_{xx} (a) and ϵ_{xz} (b) are applied.

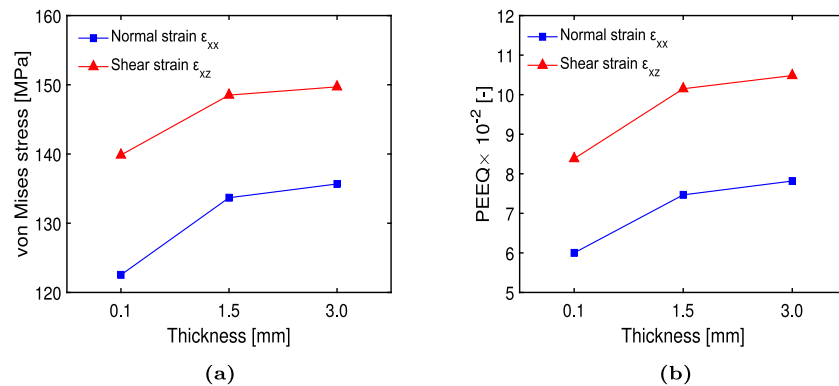

Fig. 26. Mean VM (a) and PEEQ (b) in the random RVE for various thickness values.

Table 1

Elastic mechanical properties of constituent materials - elastic and shear moduli in GPa.

Fiber	E_{11}	E_{22}	E_{33}	G_{12}	G_{13}	G_{23}	ν_{12}	ν_{13}	ν_{23}
Fiber	276.00	16.00	16.00	5.00	5.00	5.00	0.28	0.28	0.31
Matrix	E	ν							
	3.50	0.35							

The statistical analysis uses the parameters defined in Section 4 for each void distribution. Considering the axial strain as the load case, Table 2 presents the statistical parameters for maximum stress components for different void volume fractions Fig. 9 shows boxplots concerning the von Mises stress (VM), equivalent plastic strain (PEEQ), and maximum σ_{xx} over the matrix. Table 3 presents statistical parameters concerning stress and strain components over the matrix, whereas Fig. 10 shows the distributions of σ_{xx} and von Mises stress

over the cross-section with 5% of void volume fraction. Shear strain is then considered, and boxplots related to the maximum normal stress over the fiber and the matrix are shown in Figs. 11 and 12. Table 4 contains the statistical parameters concerning VM and PEEQ over the matrix for each void volume fraction. Furthermore, Fig. 13 compares the final distribution of local σ_{xz} over the cross-section for increasing void percentages. The results show that:

Table 2

Fig. 28. Plasticity curves for the 8552 matrix (Chamis et al., 2013) and for the 6376C (O'Higgins, 2007).

- Almost all stress and strain components increase as the void volume fraction grows. The impact of the void volume fraction is higher on the matrix than the fiber.
- The shear load case leads to a more severe increment of von Mises stress and equivalent plastic strain with increasing voids compared to the axial case.

- The presence of voids can alter the stress distributions significantly, with variations in mean values of stress components larger than 10%.

5.2. Statistical analysis on RVE with randomly distributed fibers

The second RVE architecture, based on the work of Pineda et al. (2013), has a random distribution of fibers and a volume fraction of 47%, with properties provided in Table 1 and the elastoplastic behavior of the matrix is detailed in Fig. 5. Two B4 elements along the y -direction and 277 L9 over the cross-section were used as previously done in Nagaraj et al. (2021). The magnitude of applied strains is 0.02. In addition, voids were dispersed within the matrix, as shown in Fig. 14 for two void volume fractions, and the application of PBC on the RVE is discernible in Fig. 15.

Figs. 16–18 show the boxplots of axial and shear transverse stresses. Table 5 presents mean values of normal stresses, VM, and PEEQ. Table 6 shows the variation of the mean value as compared to the minimum and maximum, e.g., σ_{xx} mean value when ϵ_{xx} is applied is 18.4% higher than the minimum value and 14.7% lower than the maximum. Table 7 presents the maximum values of shear stresses. Fig. 19 compares the distribution of PEEQ over the section for various loading conditions and 3% of voids, and Fig. 20 shows the probability density function (Haynes, 2013) of VM. Finally, homogenization is performed to obtain the macroscopic behavior of the RVE, and Fig. 21 illustrates the macroscopic stress–strain curve for the RVE loaded in the x -direction with increasing void volume fractions, also exhibiting a comparison between the linear and nonlinear response of the RVE. In Fig. 22, the homogenized stress–strain curves are presented for the random RVE that comprises 5% of void under (i) axial strain ϵ_{xx} ; (ii) shear strain ϵ_{xz} ; (iii) shear strain ϵ_{yz} . Furthermore, assuming the macroscopic stress determined at 1% of voids as the reference, Fig. 23 illustrates the influence that voids have on normalized stress for the RVE loaded with shear strains ϵ_{xz} and ϵ_{yz} .

The results suggest that:

- As in the previous Section, an increase in void fraction leads to higher stresses.
- The range of stress values at a given void fraction is around 30%.
- Ranging from 1 to 5% of voids, the VM mean value increases by some 5%–10%.
- The presence of voids has a relevant effect also on the macroscopic response of the RVE. Specifically, higher void fractions lead to a decrease in the macroscopic stress.

Fig. 29. Nonlinear homogenized stress–strain response for the pristine square-packed RVE and with void content from 1 to 5% and comparison with reference benchmark (Chamis et al., 2013) of IM7-8552 material system.

Fig. 30. Nonlinear homogenized stress–strain response for the pristine square-packed RVE and with void content from 1 to 5% and comparison with reference benchmark (McCarthy et al., 2010) of HTA-6376C material system.

5.3. Influence of the RVE thickness on stress and plastic strain distributions

This section investigates the influence of the RVE thickness along the fiber direction on the micromechanical response. As the defects are randomly located within the matrix (Mehdikhani et al., 2019), their distribution through the thickness of the RVE may induce significant variations in the peaks of the local stress and strain. The void volume fraction is 4% for all cases, and the thickness varies from 0.1 to 3 mm; all other properties are as in Section 5.2. Figs. 24 and 25 show boxplots for σ_{xx} and σ_{xz} , whereas, Fig. 26 compares mean von Mises stress and PEEQ when the thickness varies from 0.1 to 3.0 mm. The results show that:

- Higher thickness values lead to higher σ_{xx} and σ_{xz} , and VM.
- The variation of VM is in the range 5%–10% if considering 0.1 and 3 mm thickness values. The same variation is very low if the thickness changes from 1.5 to 3 mm.

5.4. Influence of voids on the homogenized response

The current section investigates voids’ influence on composites’ macroscopic stress–strain response. The selected architecture is a square-packed RVE under a shear strain ϵ_{xy} . The discretization consists of 216 L9 elements for the cross-section, while 2 B4 elements act along the fiber direction, as shown in Fig. 27. The accuracy of CUF findings compared to the experimental references has been assessed in Kaleel et al. (2018a), where no voids were considered. This work compares the results of the current micromechanical model to some experimental benchmarks with a pristine RVE. After that, the investigation focuses on the macroscopic response with void content ranging from 1 to 5%. The current assessment involves two different material systems, namely (i) IM7-8552 with a 60% of fiber volume fraction (Chamis et al., 2013), (ii) HTA-6376C with a 62% of fiber volume fraction (O’Higgins, 2007; McCarthy et al., 2010). The material properties of the constituents are listed in Table 8, whereas Fig. 28 presents the plasticity curves for the

Table 8

Elastic mechanical properties of constituent materials for the IM7-8552 and the HTA-6376C - elastic and shear moduli in GPa.

Fiber	E_{11}	E_{22}	E_{33}	G_{12}	G_{13}	G_{23}	ν_{12}	ν_{13}	ν_{23}
IM7 (Chamis et al., 2013)	272.50	15.50	15.50	29.00	29.00	7.00	0.20	0.20	0.30
HTA (O'Higgins, 2007)	223.00	23.00	23.00	32.00	32.00	32.00	0.28	0.28	0.28
Matrix	E	ν							
8552 (Chamis et al., 2013)	4.10	0.29							
6376C (O'Higgins, 2007)	3.70	0.20							

matrix. Fig. 29 illustrates the homogenized stress–strain response of the IM7-8552 RVE. The effect of voids on the homogenized response of HTA-6376C is shown in Fig. 30.

The results suggest that:

- Regarding both material systems, the CUF framework shows a good agreement of the homogenized stress–strain curves with experimental benchmarks.
- The presence of voids induces a significant decrease in the homogenized stress.

6. Conclusions

This work has investigated the influence of void volume fraction and RVE thickness on the micromechanical response of composites. A micromechanical framework has been used based on the Carrera Unified Formulation (CUF) and the Component Wise (CW) approach. Three different RVE architectures have been considered: a hex-packed RVE, an RVE with randomly distributed fibers, and a square-packed RVE. Normal and shear strains have been used as loading conditions, and void volume fractions from 1 to 5% and thickness values from 0.1 to 3 mm have been considered. Statistical analyses have been carried out by considering random distributions of voids. The numerical results have shown that:

- Increments of void fractions and thickness lead to higher stress values.
- The choice of the RVE architecture does not affect the maximum stresses significantly.
- The analyses showed the same results when the second RVE was taken into consideration.
- For the considered ranges of void volume fractions, the variation of mean stress values is about 5%–10%.
- For a given void volume fraction, different distributions of voids can lead to differences between maximum stress values of about 30%.
- A slight but considerable difference arises between the macroscopic linear and nonlinear responses. A micromechanical framework involving progressive failures would make nonlinearities more pronounced.
- A significant increase in stress has been observed by changing the RVE thickness from 0.1 to 3 mm.
- Void content has a significant effect on the homogenized stress–strain response of composite, compared to pristine architectures.

Future investigations will incorporate the effect of voids on a multiscale framework, where the constitutive response at a material point interacts with a lower scale through explicit heterogeneous definitions via homogenization, also including the crack nucleation and propagation at the microscale level. Furthermore, the explicit modeling of voids for more detailed localized stress distributions will be considered, and the CUF framework for micromechanical analysis of textile composites will be investigated. Another extension will focus on the thermomechanical analysis and the effects of voids on thermal properties. The effect of voids on the failure onset and its propagation is also under investigation.
