Abstract *Through a physical layer simulation study we highlight that the coherent accumulation of nonlinear interference becomes non-negligible for optical networks operating within high symbol rate transmission scenarios. This initiates a discussion on how to accurately plan and model optical networks, starting from the physical layer.*

Introduction

The current and future requirements from optical line system (OLS) operators, cloud service providers and end users are producing a progressive yearly increase in demand for higher transmission rates and larger optical network capacities and throughput^{[1]-[3]}. Correspondingly, optical networks are shifting to a format that enables a greater degree of flexibility with respect to wavelength assignment, transmission standards and symbol rates, representing a shift towards a disaggregated structure^{[4]-[6]}. A fully disaggregated network approach requires all OLS components to be considered independently^[7], as they may be controlled by different network providers and operators. In this scenario the lightpath (LP) history may not be known, presenting a challenge when attempting to model the physical layer: the nonlinear interference (NLI) produced during propagation is coherent^{[8],[9]}, meaning that the NLI accumulation depends upon the configurations of all previously crossed fiber spans. This problem is further compounded by the presence of alien wavelengths, which are signals originating from third-party equipment that must be properly managed during network planning, complicating path assignment and, in turn, the LP history^[10]. NLI accumulation is often computed using a fully incoherent model, such as the extended family of Gaussian noise (GN) models^{[11],[12]}, which have proven to be accurate and conservative for current operational symbol rates, at the least for full C-band occupation^[13]. As symbol rates increase, so too does the coherent contribution to the total NLI accumulation^[9], reducing the accuracy of a fully incoherent model and negatively impacting the ability of OLS controllers to measure quality of transmission (QoT) degradation, set oper-

ational margins and adapt to changing network demands. To ensure optimal prediction of QoT degradation within modern optical networks it is therefore important to determine the magnitude of the coherent contribution to the overall generalized signal-to-noise-ratio (GSNR) degradation, in order to achieve maximum operational capacities, satisfy future end user requirements and preserve a conservative margin. Within this paper we present the results of an extensive simulation campaign using an internally-developed, MATLAB[®]-based software framework^[14], which is used to assess the ability for an optical network to be fully disaggregated starting from the physical layer. In this framework, we analyze the coherent contribution to the overall QoT degradation. Consequently, we discuss the impact of this contribution in the case of future network planning, in particular for optical networks that utilize high symbol rate transmission.

NLI Generation in a Disaggregated OLS

The QoT degradation in optical networks that utilize coherent technology is usually quantified using the GSNR^[15]. The GSNR takes into account the contributions of both the amplified spontaneous emission (ASE) produced by optical amplifiers and the NLI that is produced due to nonlinear propagation through the optical fiber. Considering a cascade of N optical domains, the total GSNR at the termination of the final domain is given by

$$\text{GSNR} = \left(\sum_{i=1}^N \text{GSNR}_i^{-1} \right)^{-1}, \quad (1)$$

where i is the index of the fiber span and GSNR_i is the GSNR of each optical domain. The NLI generation depends upon the transmission stan-

standards, symbol rates, spacing and insertion powers of all active channels. The ASE noise may be evaluated by characterizing the optical amplifiers within the OLS and is fully separable from the NLI; consequently we focus only upon the generation and accumulation of NLI within this work. The NLI may be separated into its two constituent contributions: cross-phase modulation (XPM) and self-phase modulation (SPM). Due to walk-off, the XPM may be considered local and incoherent^{[8],[16]} for a wide range of use cases. In contrast, SPM is a coherent and non-local effect, being the primary hindrance to a fully disaggregated physical layer model. Fortunately, it is possible to quantify the maximum SPM value after a given number of spans^[9], providing an upper limit to the SPM accumulation.

It has previously been shown that the SPM and XPM are separable^{[8],[12],[17]} for all realistic use cases^{[8],[16]}, meaning that the total amount of NLI power, P_{NLI} , generated for a single channel under test (CuT) may be calculated as a sum of the individual channel contributions

$$P_{\text{NLI}} = P_{\text{NLI},0} + \sum_{k \neq 0} P_{\text{NLI},k}, \quad (2)$$

where k is the channel index and $P_{\text{NLI},k}$ is the total amount of NLI power for the k th channel. In Eq. 2, the first and second terms enclose the entirety of the SPM and XPM effects, respectively. Assuming spatial separability allows the total NLI power to also be summed on a span-by-span basis, yielding the total nonlinear SNR power, SNR_{NL}

$$\text{SNR}_{\text{NL}} = \left(\sum_{i=1,k}^N \text{SNR}_{\text{NL},i,k} \right)^{-1}, \quad (3)$$

where $\text{SNR}_{\text{NL},i,k}$ are the i th span and k th channel contributions to the total SNR_{NL} . An accurate recovery of this total via a superposition of all individual $\text{SNR}_{\text{NL},i,k}$ contributions enables the total SPM contribution to be analyzed on a pump-by-pump and span-by-span basis.

Simulation Campaign

To evaluate the contributions to the total NLI in a wide range of realistic use cases we conducted a simulation campaign over a wide set of OLS configurations and signal parameters, comparing, for each, two distinct simulation scenarios; which we label as the *full-spectrum* and *superimposed* cases, with a sketch of the overall sim-

Fig. 1: A sketch of the simulation set-up.

ulation flow shown in Fig. 1. The full-spectrum scenario consists of the propagation of a multi-channel, wavelength-division multiplexed (WDM) signal, representing the target system under investigation. The superimposed case performs multiple separate pump-and-probe (P&P) simulations that, in turn, consider the propagation of the channel under test (the probe) and another channel within the WDM grid (the pump). By creating a superposition of each of these individual P&P simulations, the result may be compared to the full-spectrum using Eq. 2, allowing the individual NLI and SPM contributions to be investigated.

Results & Analysis

The simulation campaign encompasses a variety of baud rates, WDM grid spacings and dispersions; within this work we highlight two specific configurations; a widespread use case ($R_s = 32.0$ GBaud, $\Delta f = 37.5$ GHz) and a realistic high symbol rate transmission scenario ($R_s = 64.0$ GBaud, $\Delta f = 75.0$ GHz), both with dispersion values of $D = 16.7$ ps/(nm-km), equal to that of a standard single-mode fiber (SMF). We launch all scenarios with polarization multiplexed-quadrature phase shift keying (PM-QPSK) modulation applied to the CuT, and for two pump predistortion cases; zero predistortion, representing transmission through a standalone OLS, and Gaussian modulated signals, representing an OLS that is a subsystem of a larger network with significant dispersion having been accumulated along the path of the LP. Firstly, we present the SNR_{NL} accumulations of the full-spectrum simulation and the corresponding superposition in Fig. 2, for both predistortion cases. Additionally we include, for reference, the result of an analytical derivation of the XPM contribution to the total NLI, as described in^[8]. We remark that, for both predistortion cases, the superposition is able to recover the result of the full-spectrum case and serves as an accurate and conservative prediction in all configuration scenarios. Next, the SNR_{NL} span-by-span increments, $\Delta \text{SNR}_{\text{NL}}$, of

Fig. 2: The SNR_{NL} accumulations for: (a) a widespread use case, and (b) a realistic high symbol rate transmission scenario. A full-spectrum simulation is compared to a superposition of all constituent pump-and-probe simulations, for both predistortion cases.

these scenarios are presented in Fig. 3, showing the increments of the superposition, the SPM contribution of the CuT and the aforementioned analytical XPM contribution, for both predistortion cases. It is visible within these plots that the XPM accumulation contains a transient that quickly vanishes after the first few spans of transmission, before settling to a constantly increasing value, representing fully incoherent accumulation. Conversely, the SPM continues to accumulate coherently, with the contribution to the overall SNR degradation continuing to increase even after a large number of fiber spans have been crossed. For the $R_s = 32.0$ GBaud, $\Delta f = 37.5$ and $D = 16.7$ ps/(nm·km) case, the SPM contribution remains small with respect to the total XPM contribution, even at the termination of the final fiber span. On the other hand, in the $R_s = 64.0$ GBaud, $\Delta f = 75.0$ and $D = 16.7$ ps/(nm·km) case, the SPM contribution becomes dominant after approximately 5 spans of transmission, even accounting for the majority of the NLI contribution at the final fiber span. Additionally, we highlight that the SPM contribution progressively increases for higher symbol rates, meaning that this issue will be compounded further as transmission rates increase in future generations of coherent systems. As a result, we stress that, for state-of-the-art optical networks such as those consisting primarily of SMF-type fiber and transmitting signals with a symbol rate of *at least* $R_s = 64.0$ GBaud, a fully incoherent model is insufficient to accurately model

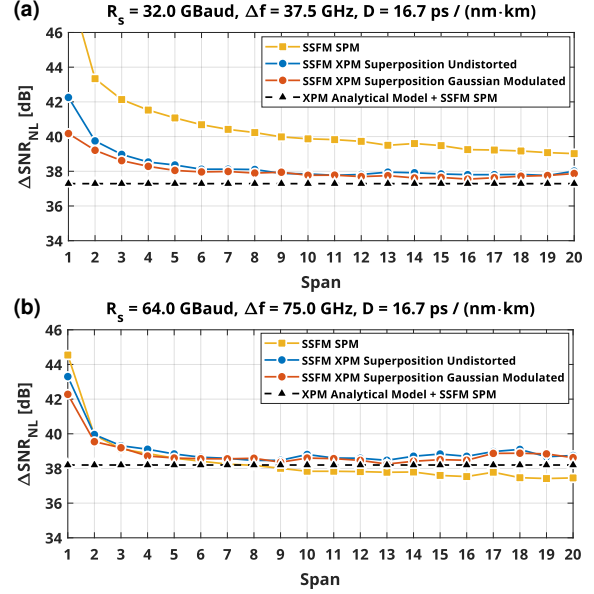

Fig. 3: The SNR_{NL} span-by-span increments, ΔSNR_{NL} , for: (a) a widespread use case and (b) a realistic high symbol rate transmission scenario. A full-spectrum simulation is compared to a superposition of all constituent pump-and-probe simulations, for both predistortion cases.

the NLI accumulation. To tackle this issue, it is necessary to consider a model of the total NLI power that properly considers the coherent behaviour of the SPM. We wish to emphasize that a model which considers the total NLI contribution on a channel-by-channel basis satisfies this requirement, permitting an accurate and conservative recovery of the SNR_{NL} and an easier handling of the possibility of alien wavelengths from a network planning point of view.

Conclusions

Within this work we show that, for coherent optical systems operating in both widespread and high symbol rate transmission scenarios, the total NLI generation for an OLS under full spectral load may be recovered by considering a superposition of all corresponding pump-and-probe contributions. We subsequently show that the contribution of coherent effects to the total NLI becomes dominant for high symbol rate scenarios, such as for $R_s = 64.0$ GBaud and above, highlighting that it is necessary to use a coherent NLI model when calculating the GSNR in optical networks that utilize high symbol rate transmission.
